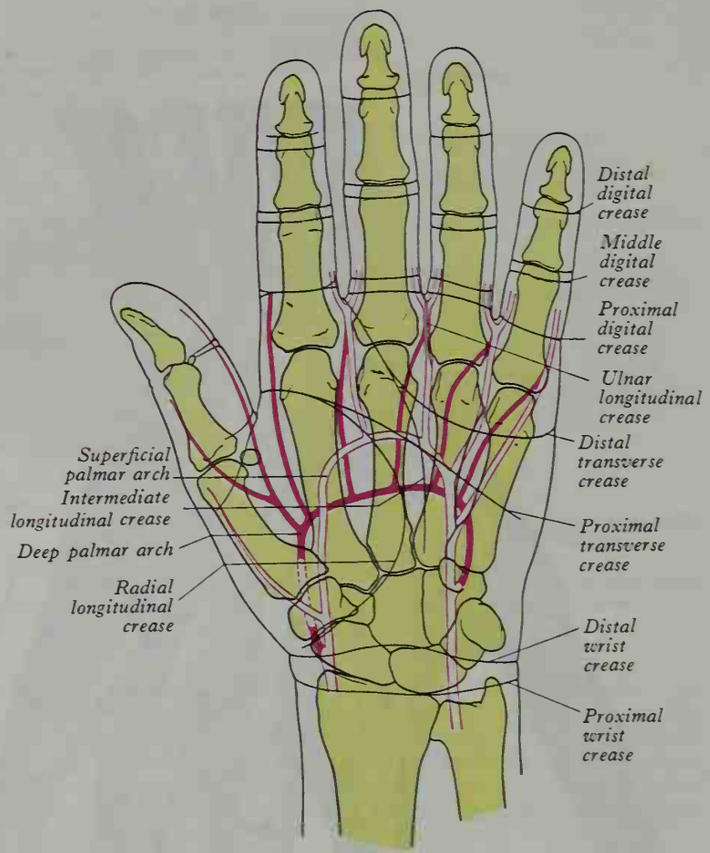
The anterior interosseous artery (**6**.77, 80) descends on the anterior surface of the interosseous membrane, accompanied by the anterior interosseous branch of the median nerve, and is

6.80 The arteries of the posterior surface of the right forearm and hand.

6.81 The superficial palmar arch and its branches. A part of the abductor pollicis brevis has been excised to expose the superficial palmar branch of the radial artery.



overlapped by the contiguous margins of the flexor digitorum profundus and flexor pollicis longus; it gives off *muscular* branches, and the *nutrient* arteries of the radius and ulna. As it lies on the interosseous membrane, the artery gives off branches which pierce the interosseous membrane and pass to the deep extensor muscles in the forearm. At the upper border of the pronator quadratus it pierces the interosseous membrane and reaches the back of the forearm, where it anastomoses with the posterior interosseous artery and descends on the back of the wrist in the compartment of the extensor retinaculum containing the tendons of extensor digitorum and extensor indicis to join the dorsal carpal arch. Before the artery pierces the interosseous membrane, a branch descends behind pronator quadratus to join the anterior carpal arch. The *median artery*, a long, slender branch, starts from the beginning of the anterior interosseous artery; it accompanies and supplies the median nerve. It often arises from the common interosseous artery. Sometimes it is much enlarged and runs with the nerve into the palm of the hand (p. 192), where it may join the superficial palmar arch or end as one or two of the palmar digital arteries.

The posterior interosseous artery (**6**.77, 80), usually much smaller than the anterior, passes backwards between the oblique cord and the upper border of the interosseous membrane. It appears on the back of the forearm between supinator and abductor pollicis longus, and descends between the superficial and deep layers of muscles, to which it distributes branches. As it lies upon abductor pollicis longus, it is accompanied by the deep branch of the radial nerve. At the lower part of the forearm it becomes very small and anastomoses with the termination of the anterior interosseous artery, and with the dorsal carpal arch. It gives off, near its origin, the *interosseous recurrent artery*, which ascends to the interval between the lateral epicondyle and olecranon, on or through the fibres of the supinator, but deep to anconeus, and anastomoses with the middle collateral branch of the arteria profunda brachii, and with the posterior ulnar recurrent and the ulnar collateral arteries.

The muscular branches of the ulnar artery are distributed to the muscles in the ulnar region of the forearm.

The palmar carpal branch (**6**.77) is a small vessel which crosses the front of the carpus behind the tendons of flexor digitorum profundus; it anastomoses with the palmar carpal branch of the radial artery to form the palmar carpal arch (p. 704).

The dorsal carpal branch (**6**.80) arises immediately above the pisiform bone, and winds backwards deep to the tendon of

6.82 A diagram to show the relation of the skin flexure lines and palmar arterial arches to the bones of the left hand.

flexor carpi ulnaris; it passes laterally across the dorsal surface of the carpus under the extensor tendons, anastomoses with the dorsal carpal branch of the radial artery, thus completing the dorsal carpal arch (p. 705). Near to its origin it gives off a small branch which runs along the ulnar side of the fifth metacarpal bone, and supplies the ulnar side of the dorsal surface of the little finger.

The deep palmar branch (**6**.77, 81), often double, passes between the abductor and flexor digiti minimi, and through or deep to the origin of the opponens digiti minimi; it anastomoses with the radial artery, thus completing the deep palmar arch; it is accompanied by the deep branch of the ulnar nerve.

The Superficial Palmar Arch (**6**.81, 82)

This is formed mainly by the ulnar artery, which enters the hand with the ulnar nerve in front of the flexor retinaculum, and lateral to the pisiform bone. It then passes medial to the hook of the hamate and crosses the palm, forming the superficial palmar arch, which is convex towards the fingers, and is at the level of a line drawn across the hand from the distal border of the root of the extended thumb. In about one-third of subjects the arch is formed by the ulnar artery alone; in a further third it is completed by the superficial palmar branch of the radial artery. More rarely it is completed by the arteria radialis indicis, a branch of the arteria princeps pollicis or the median artery. (For variations *see* Coleman and Anson 1961.) It is covered by the palmaris brevis and the palmar aponeurosis, and lies on the flexor digiti minimi, the branches of the median nerve, which it supplies, the flexor tendons and the lumbricals.

Branches:

Three common palmar digital arteries (**6**.81) arise from the convexity of the superficial palmar arch and proceed distally on the second, third and fourth lumbricals. Each is joined by the corresponding palmar metacarpal artery from the deep palmar arch, and then divides into a pair of *proper palmar digital arteries*, which run along the contiguous sides of the index, middle, ring and little fingers, dorsal to the corresponding digital nerves; they anastomose freely in the subcutaneous tissue of the finger tips and by smaller branches near the interphalangeal joints. Each gives off two dorsal branches, which anastomose with the dorsal digital arteries, and supply the soft parts on the back of the middle and distal phalanges, including the matrix of the finger nail. The *palmar digital artery* for the medial side of the little finger springs from the arch under palmaris brevis. The palmar digital arteries supply nutrient branches to the phalanges and to the metacarpophalangeal and interphalangeal joints. The palmar digital arteries are the main supply to the digits, the dorsal digital arteries (p. 705) being very small.

A free anastomosis takes place between the radial and ulnar arteries, (*a*) on the front and back of the wrist through the palmar and dorsal carpal arches, and (*b*) in the hand through the superficial and deep palmar arches, and their digital and metacarpal branches.

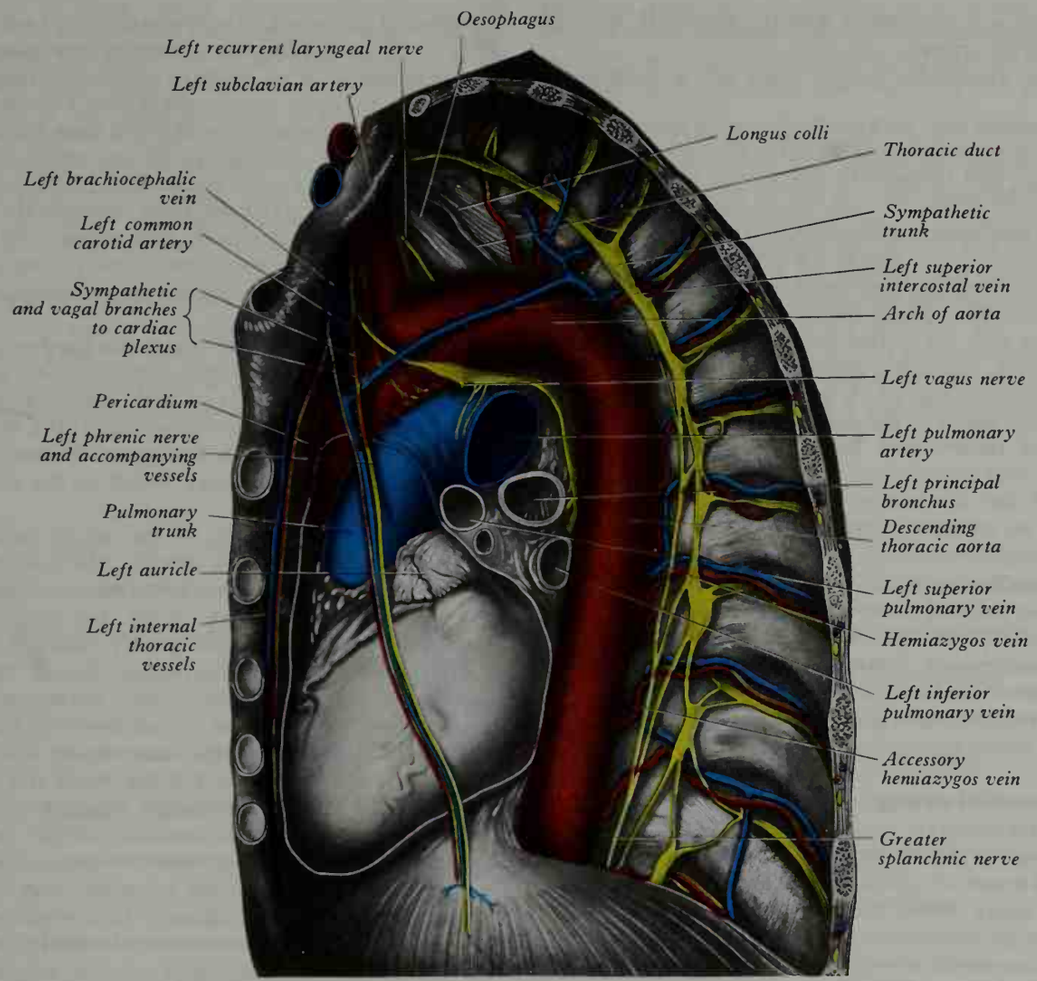
Applied Anatomy. In wounds of the palmar arches it may prove useless to ligature one of the arteries of the forearm alone, and simultaneous ligature of both radial and ulnar arteries above the wrist is often unsuccessful, because of of the anastomotic carpal networks. Therefore, upon the failure of local pressure to arrest haemorrhage in the hand it may be expedient, if the ends of the bleeding vessels cannot readily be exposed and tied, to compress, or even ligate, the brachial artery.

THE ARTERIES OF THE TRUNK

The Thoracic Aorta

The thoracic aorta (**6**.83, **8**.88) is that part of the *descending aorta* which is confined to the posterior mediastinum. It begins at the lower border of the fourth thoracic vertebra, where it is continuous with the aortic arch, and ends in front of the lower border of the twelfth thoracic vertebra at the aortic opening in the diaphragm. At its origin it is situated on the left of the vertebral column; as it descends it approaches the median plane, and at its termination lies in front of the column.

Relations. It is in relation, *anteriorly*, from above downwards, with the root of the left lung, the pericardium, separating it from the left atrium, the oesophagus and diaphragm; *posteriorly*, with the vertebral column and the hemiazygos veins; on the *right side*, with the azygos vein and thoracic duct and, in the lower part of its course, with the right pleura and lung; on the *left side*, with the left pleura and lung. The oesophagus, with its accompanying plexus of nerves, lies on the *right side* of the aorta above; but in the lower part of the thorax it is placed in front of the vessel, and, close to the diaphragm, is placed anteriorly and to its left side.



Surface Anatomy. The vessel can be represented by a band 2·5 cm broad extending from the sternal end of the second left costal cartilage to a point in the median plane about 2 cm above the transpyloric plane (p. 1319).

Branches:

The thoracic aorta gives off *visceral branches* to the pericardium, lungs, bronchi, and oesophagus, and *parietal branches* to the walls of the thoracic cavity.

The pericardial branches consist of a few small vessels which are distributed to the posterior surface of the pericardium.

The bronchial arteries vary in number, size and origin. There is as a rule one *right bronchial artery*, which arises from the third posterior intercostal artery, or from the upper left bronchial artery. It runs on the posterior surface of the right bronchus, dividing and subdividing along the bronchial tubes, supplying them, the areolar tissue of the lung and the bronchopulmonary

6.83 The left aspect of the mediastinum. The left lung and pleura have been removed, and an extensive opening has been made into the pericardial sac to expose the heart.

lymph nodes; it also sends branches to the pericardium and the oesophagus. The *left bronchial arteries*, usually two in number, arise from the thoracic aorta, the upper opposite the fifth thoracic vertebra and the lower just below the left bronchus. They run on the posterior surface of the left bronchus and have a distribution similar to that of the right bronchial artery. (See also p. 1024.)

Cauldwell *et al.* (1948) found the above arrangement in 40 per cent of 150 cadavers. The next most frequent arrangements (at about 20 per cent each) were two left and two right bronchial arteries, or one on each side, all as direct branches of the descending thoracic aorta arising near the levels of the third and fourth intercostal arteries. In about 10 per cent of instances there were *one* left and *two* right bronchial arteries. Other, more complex variations consisted chiefly of more numerous vessels arising directly from the descending aorta. Very rarely one or other of the bronchial arteries may arise from the aortic arch.

The oesophageal arteries, four or five in number, arise from the front of the aorta, and pass obliquely downwards to the oesophagus; on this they form a *vascular chain*, which anastomoses above with the oesophageal branches of the inferior thyroid arteries, and below with ascending branches from the left phrenic and left gastric arteries. (It is often forgotten that the aortic oesophageal arteries are persisting ventral splanchnic arteries to the foregut, in addition to the subdiaphragmatic coeliac, superior and inferior mesenteric arteries).

The mediastinal branches are numerous small vessels which supply the lymph nodes and the areolar tissue in the posterior mediastinum.

The phrenic branches are small, and arise from the lower part of the thoracic aorta; they are distributed to the posterior part of the upper surface of the diaphragm, and anastomose with the musculophrenic and pericardiacophrenic arteries.

The Posterior Intercostal Arteries

There are usually nine pairs of posterior intercostal arteries derived from the thoracic aorta. They arise from the back of the vessel, and are distributed to the lower nine intercostal spaces, the first and second spaces being supplied by the superior intercostal artery (p. 699). The *right* posterior intercostal arteries are longer than the left, on account of the position of the aorta on the left side of the vertebral column; they cross the bodies of the vertebrae behind the oesophagus, thoracic duct and azygos vein, and are covered by the right lung and pleura. The *left* posterior intercostal arteries run backwards on the sides of the vertebrae and are in contact with the left lung and pleura; the upper two vessels are crossed by the left superior intercostal vein, the lower vessels by the hemiazygos and accessory hemiazygos veins. The further course of the posterior intercostal arteries is practically the same on both sides. Opposite the heads of the ribs the sympathetic trunk passes downwards in front of them, and the splanchnic nerves also descend in front of the lower arteries.

Each artery (**6**.83) crosses its intercostal space obliquely towards the angle of the rib above, and thence is continued forward in the costal groove. It is placed at first between the pleura and the internal (posterior) intercostal membrane, as far as the angle of the rib; from this onward it runs between the internal intercostal and the intercostalis intimus (p. 547), and anastomoses in front with the anterior intercostal branch of the internal thoracic or musculophrenic artery. Each artery is accompanied by a vein and a nerve, the former above and the latter below the artery, except in the upper spaces where the nerve is at first above the artery. The third posterior intercostal artery anastomoses with the superior intercostal artery, and may form the chief supply of the second intercostal space. The lower two posterior intercostal arteries are continued anteriorly from the intercostal spaces into

the abdominal wall and anastomose with the subcostal, superior epigastric and lumbar arteries.

Each posterior intercostal artery gives off a number of branches.

The dorsal branch runs backwards through a space which is bounded above and below by the necks of the ribs, medially by the body of a vertebra and laterally by a superior costotransverse ligament. It gives off a *spinal branch* which enters the vertebral canal through the intervertebral foramen, and is distributed to the vertebrae, spinal cord (*see* p. 896 and 7.54) and its membranes, anastomosing with the spinal arteries above and below and with the opposite artery. The dorsal branch then courses over the transverse process with the dorsal ramus of the corresponding thoracic spinal nerve, supplying offshoots to the muscles of the back, and a cutaneous twig which accompanies the cutaneous branch of the dorsal ramus of the nerve.

The collateral intercostal branch leaves the posterior intercostal artery near the angle of the rib, and descends to the upper border of the rib below, along which it courses to anastomose with an anterior intercostal branch of the internal thoracic or musculophrenic artery.

Muscular branches are given to the intercostal and pectoral muscles and to the serratus anterior; they anastomose with the superior and lateral thoracic branches of the axillary artery.

The lateral cutaneous branches accompany the lateral cutaneous branches of the thoracic nerves.

Mammary branches are given off by the vessels in the second, third and fourth spaces; they increase considerably in size during lactation.

The right bronchial artery may arise from the right third posterior intercostal artery (p. 109).

Applied Anatomy. In puncturing the thorax the needle should not be introduced nearer the posterior median line than the angle of the rib, for the artery crosses the space medial to this point. In the lateral portion of the chest, where the puncture is usually made, the main intercostal artery lies at the upper part of the intercostal space, and therefore the puncture should be made just above the rib forming the lower boundary of the space.

The subcostal arteries, the last pair of branches from the thoracic aorta, are in series with the posterior intercostal arteries, but are named *subcostal* because they are situated below the twelfth rib and are, of course, not 'intercostal'. Each artery runs laterally over the body of the twelfth thoracic vertebra, and behind the splanchnic nerves, the ganglionated trunk of the sympathetic, the pleura and diaphragm. The right artery also passes behind the thoracic duct and the azygos vein, and the left behind the accessory hemiazygos vein. Each subcostal artery then enters the abdomen under the lateral arcuate ligament, and courses with the twelfth thoracic nerve along the lower border of the twelfth rib, anterior to quadratus lumborum and posterior to the kidney. The right artery runs behind the ascending, and the left behind the descending, colon. Each then pierces the aponeurosis of origin of the transversus abdominis, and, passing forward between this muscle and the obliquus internus, anastomoses with the superior epigastric, lower posterior intercostal and lumbar arteries. Each subcostal artery gives off a dorsal branch, which is distributed like the dorsal branch of a posterior intercostal artery.

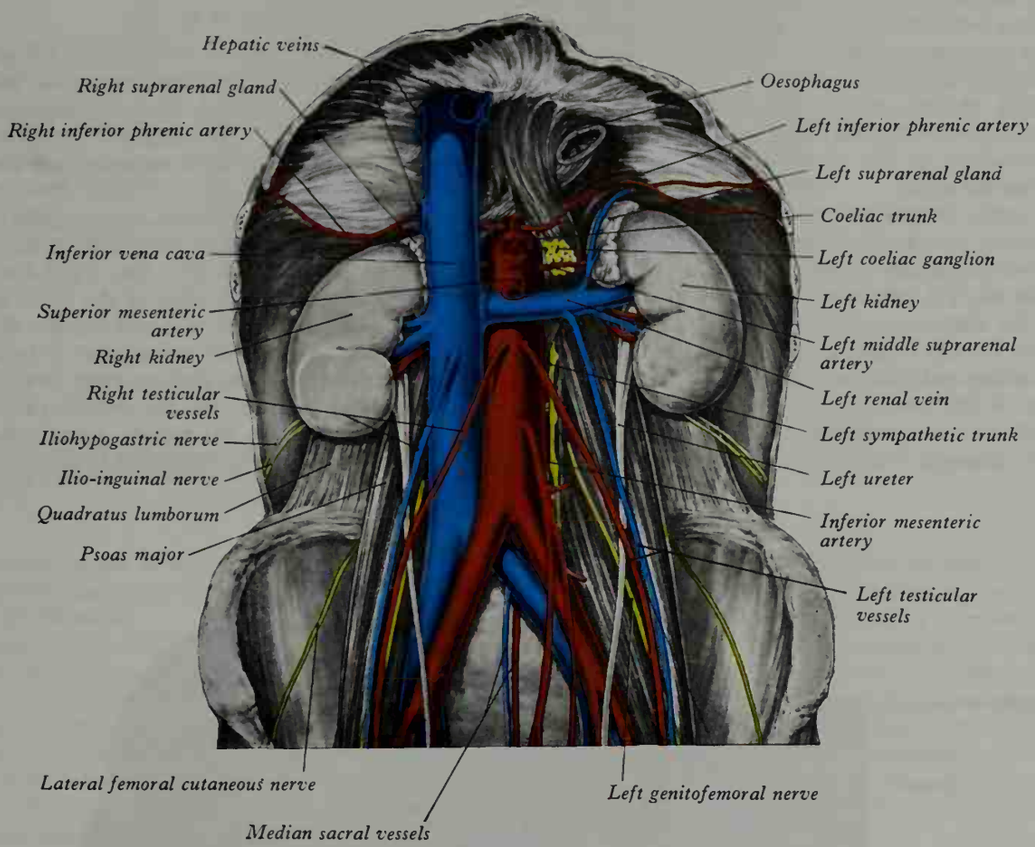
A small *aberrant artery* sometimes branches from the right side of the thoracic aorta near the origin of the right bronchial. It passes upwards and to the right behind the trachea and the oesophagus, and may anastomose with the right superior intercostal artery. It represents the remains of the right dorsal aorta (p. 187), and occasionally is enlarged to form the first part of the right subclavian artery (p. 693).

Variations. The lumen of the aorta is occasionally found to be partly or completely obliterated, either above (preductual or infantile type), or opposite to or just beyond (postductual or adult type), the site of entry of the ductus arteriosus. The condition is congenital and is known as *coarctation* of the aorta. The ductus arteriosus may remain patent after birth, but rarely plays any compensatory role, for in most cases the systemic blood pressure is much higher than that in the pulmonary circulation.

In the preductual type the length of the coarctation is very variable and may involve the origin of the left subclavian and even of the brachiocephalic artery, thereby providing little scope for the development of an effective collateral circulation to regions supplied by the aorta distal to the lesion. Therefore many cases of this type are incompatible with more than a few months of life. Furthermore, the surgical problems posed are considerable. Sometimes, however, the coarctation in the preductual type is restricted to that part of the aorta between the brachiocephalic and left subclavian arteries. In this instance the blood and pulse pressures in the left arm are considerably lower than those in the right, and a collateral circulation may develop through branches of the brachiocephalic artery.

The postductual type of coarctation has been attributed to an abnormal extension of ductual tissue into the aortic wall, giving rise to a simultaneous stenosis of both vessels as it contracts after birth. This form of coarctation is compatible with many years of normal life, and leads to the establishment of an extensive collateral circulation to carry blood to the aorta immediately below the stenosis.

The extreme vascularity of the whole thoracic wall is an important feature, for many arteries which arise indirectly from the aorta, above its obliterated portion, anastomose with vessels connected with the aorta below the obliteration and the connecting channels become greatly enlarged. In the anterior thoracic wall the thoracoacromial, lateral thoracic and the subscapular arteries from the axillary, the suprascapular from the subclavian and the first and second posterior intercostal arteries from the costocervical trunk anastomose with the third, and lower, posterior intercostal arteries, while the internal thoracic artery and its terminal branches anastomose with the lower posterior intercostal arteries and the inferior epigastric arteries. The posterior intercostal arteries are always especially involved. Enlargement of their dorsal branches may eventually cause notching of the inferior margins of the ribs with which they are in contact. The X-ray shadow of the enlarged left subclavian artery is increased. The enlargement of the scapular vessels and anastomoses may lead to pulsation in the interscapular region ('pulsating scapula').



The Abdominal Aorta

The abdominal aorta (**6**.84, 92) begins in the median plane at the aortic hiatus of the diaphragm, in front of the lower border of the last thoracic vertebral body and it descends in front of the vertebral column, ending at the level of the body of the fourth lumbar vertebra, a little to the left of the midline, by dividing into the two common iliac arteries. It diminishes rapidly in size, because such large branches arise from it. Recent measurements of casts of the abdominal aorta in 100 individuals, ranging from 16 to 70 years, showed an increase with age. In males the superior and inferior extremities measured 9·8 to 14·1 mm and 8·1 to 14·6 mm; in females the luminal diameters were 9·7 to 15·7 mm and 9·1 to 14·6 mm (Aleksandrowicz *et al.* 1974). These values contrast with those derived from radiological observations of 61 adults (17–41 years) contributed by Leithner *et al.* (1975), who recorded diameters of 26 mm and 19 mm (averages) for the extremities of the abdominal aorta. These latter workers also attributed a mean value of 37° to the angle of aortic bifurcation. These dimensional observations are of interest in connexion with current attempts to assess a suspected hydrodynamic ('haemodynamic') factor in the genesis of atherosclerosis in the abdominal aorta (*see* Newman *et al.* 1971; Lallemand and Newman 1973). Theoretically it can be shown that the pressure pulse wave in arteries is reflected at any junction at certain values of the combined arterial *luminal* areas of the branch or branches to that of the parent vessel; this relation is the *area ratio* of the junction. At an equal bifurcation, such as the aortic, with an area ratio of 1:15, reflexion of the pressure pulse wave is near to zero, and the vessels are said to be 'matched'. Oscillations and possibly turbulence set up by 'mis-matching' (at other ratios), perhaps also influenced by asymmetry of the bifurcation, may be causal in intimal damage and hence predispose to aortic atheroma. The luminal and other dimensions of the bifurcation may, therefore, assume a special significance, as

may the changes in these values which occur during life. Measurement of the aortico-iliac junction in humans, dogs and domestic fowls (free from vascular disease) has shown that the area ratio is usually close to the theoretical value for 'matching', and that the ratio is independent of age in the dog and fowl (Gosling *et al.* 1971). However, in mankind the aortic bifurcation appears to be 'matched' only in early infancy; it is 1·11 ±0·02 at birth, becoming progressively lower with advancing age and reaching a value of about 0·7 in the 5th decade, at which theory predicts a 'mismatch' producing a reflection of the pulse pressure wave at about one-third of its oscillatory amplitude. These studies are continuing, and their implications make the latest report on the geometry of the aortic bifurcation (Shah *et al.* 1978) of particular interest. This embodied the most extensive dimensional data so far recorded, including not only diamters but also angles of deviation, iliac lengths and curvatures, and data for the proximal parts of its testicular (or ovarian) branches, and is crossed by the horizontal part of the duodenum. In its lowest part the aorta is covered by the posterior parietal peritoneum and is crossed by the parietal attachment of the mesentery and its contents.

Posteriorly the abdominal aorta descends in front of the upper four lumbar vertebrae, the intervening intervertebral discs and corresponding part of the anterior longitudinal ligament. The lumbar arteries, which arise from its dorsal aspect, and the third and fourth (and sometimes the second) left lumbar veins, which cross behind it to reach the inferior vena cava, separate the aorta from the ligament. The vessel may overlap the anterior border of the left psoas major to a slight extent.

On the *right* the aorta is related above to the cisterna chyli and the thoracic duct, the azygos vein, and the right crus of the diaphragm, which overlaps it and separates it from the inferior

6.84 The abdominal aorta and its branches in the male.

dorsal angulation of these vessels as they enter the pelvic cavity. Unfortunately, the diameters were measured externally by calipers and in a relatively small series of cadavers at autopsy. These data cannot, therefore, be compared with those cited above, of which these recent workers appear to have been unaware. It is to be hoped that these interesting observations will be carried further, with improved techniques and greater cohesion between the different groups involved.

Relations. The abdominal aorta is at first related *anteriorly* to the coeliac trunk and its branches, the coeliac plexus of nerves and the omental bursa, which intervene between it and the papillary process of the liver and the lesser omentum. Immediately below this level the superior mesenteric artery leaves the aorta and crosses anteriorly to the left renal vein. The body of the pancreas, with the splenic vein applied to its posterior aspect, extends obliquely to the left and slightly upwards across the abdominal aorta, but is separated from it by the superior mesenteric artery and left renal vein. Below the pancreas, the aorta is related to the vena cava and the right coeliac ganglion. Below the level of the second lumbar vertebra it is in contact with the inferior vena cava.

On the *left*, it is related above to the left crus of the diaphragm and the left coeliac ganglion. Opposite the second lumbar vertebra, it is related to the duodenojejunal flexure and the sympathetic trunk, which continues downwards along the left side of the vessel. The ascending part of the duodenum and the inferior mesenteric vessels constitute additional relations.

Surface Anatomy. The vessel can be represented by a band about 2 cm wide extending from a point in the median plane 2·5 cm above the transpyloric plane to the point where it divides about 1 cm below and to the left of the umbilicus. When the abdominal wall is relaxed the lowest portion of the aorta may be felt pulsating just above this point. The pulsations can even be seen in thin people when recumbent.

The branches of the abdominal aorta (**6**.84) may be divided into four sets: ventral, lateral, dorsal and terminal. The ventral and lateral branches are distributed to viscera, while the dorsal

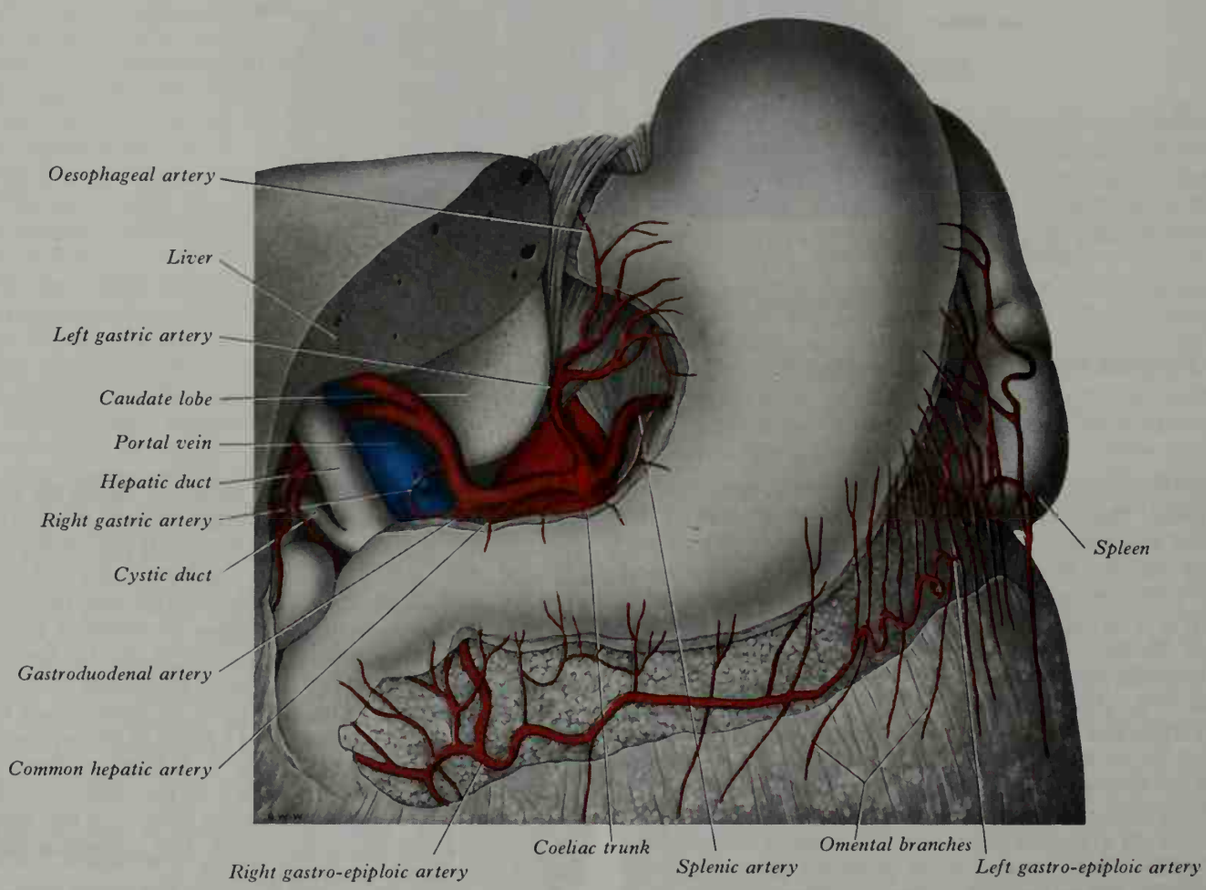
branches supply the body wall. The terminal branches supply the pelvis and lower limbs.

Ventral	*Lateral*
Coeliac.	Inferior phrenic.
Superior mesenteric.	Middle suprarenal.
Inferior mesenteric.	Renal.
	Testicular or Ovarian
Dorsal	*Terminal*
Lumbar.	Common iliac.
Median sacral.	

(For a detailed account of the upper abdominal vasculature consult Michels 1956.)

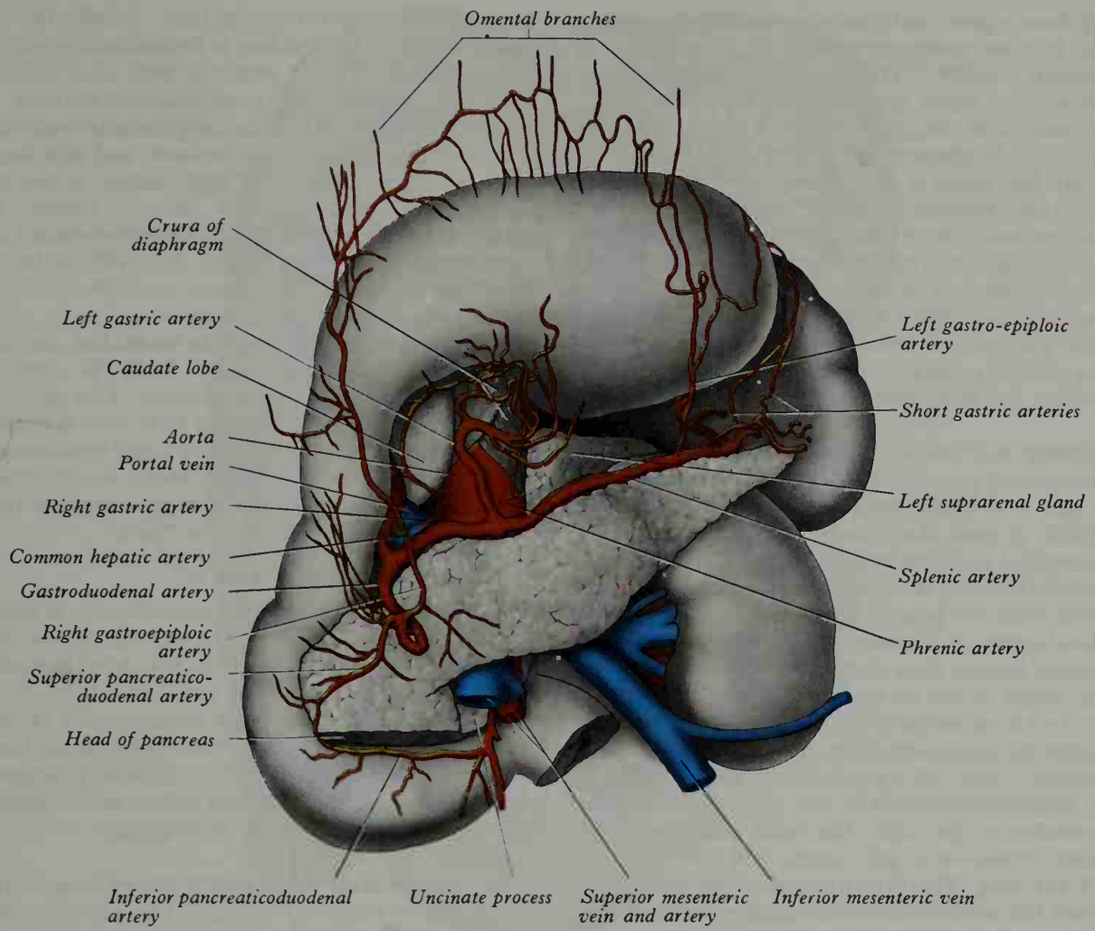
The Coeliac Trunk

The coeliac trunk (**6**.85, 86) is a wide branch, about 1·25 cm long, from the front of the aorta, just below the aortic hiatus of the diaphragm; it passes nearly horizontally forwards and slightly to the right above the pancreas and the splenic vein, and divides into three: (1) *left gastric*; (2) *hepatic*; (3) *splenic*. It may give off one or both of the inferior phrenic arteries; the superior mesenteric artery may arise in common with the coeliac trunk from the aorta, or the usual branches of the coeliac trunk may branch independently from the aorta.



Relations. The coeliac trunk is behind the omental bursa (lesser sac of the peritoneum), and is surrounded by the coeliac plexus of nerves, which sends extensions along the three divisions of the artery. On its *right side* it is related to the right coeliac ganglion, the right crus of the diaphragm, and the caudate process of the liver; on its *left* are the left coeliac ganglion, the left crus of the diaphragm, and cardiac end of the stomach. *Below*, it is related to the upper border of the pancreas and the splenic vein. The suspensory muscle of the duodenum (p. 1344) may split to encircle the artery, although it usually lies on its left.

1. The Left Gastric Artery (**6**.85)



This, the smallest branch of the coeliac trunk, passes upwards and to the left, behind the omental bursa, to the cardiac end of the stomach. In its course, the left gastric artery lies close to the left inferior phrenic artery and medial to or in front of the left suprarenal gland. At or near the cardiac end of the stomach it gives off two or three *oesophageal branches*, which ascend through the oesophageal opening of the diaphragm and anastomose with the aortic oesophageal arteries; others supply the cardiac part of the stomach and anastomose with branches of the splenic artery. The artery then turns forwards and downwards in the left gastro-pancreatic fold, and runs (frequently as two branches) along the lesser curvature of the stomach to the pylorus, between the layers of the lesser omentum; it gives branches to both surfaces of the stomach and anastomoses with the right gastric artery. An *accessory left gastric artery* may arise from the left branch of the hepatic artery and traverse the lesser omentum to gain the lesser curvature of the stomach.

2. The Hepatic Artery (**6**.85, 86)

This is intermediate in size between the left gastric and splenic branches; in *later* fetal and early postnatal life it is the largest branch of the coeliac trunk. It is accompanied by the hepatic plexus of nerves and is first directed forwards and to the right, to the upper surface of the superior part of the duodenum, passing below the medial end of the epiploic foramen (**6**.85). It then crosses in front of the portal vein, and ascends, between the layers of the lesser omentum and in front of the epiploic foramen, to the porta hepatis, where it divides into right and left branches to supply the corresponding lobes of the liver, accompanying the ramifications of the portal vein and hepatic ducts. In the lesser omentum the hepatic artery lies in front of the portal vein and on the left of the bile duct, and its right branch crosses behind (occasionally in front of) the common hepatic duct (**6**.87). For purposes of description, the hepatic artery is subdivided into (*a*) the *common hepatic artery*, extending from the coeliac trunk to the

6.85 The coeliac trunk and its branches. Part of the liver and all the lesser omentum have been removed, as well as the posterior wall of the omental bursa and part of the anterior layer of the greater omentum.

6.86 The coeliac trunk and its branches exposed by turning the stomach upwards and removing the peritoneum on the posterior abdominal wall.

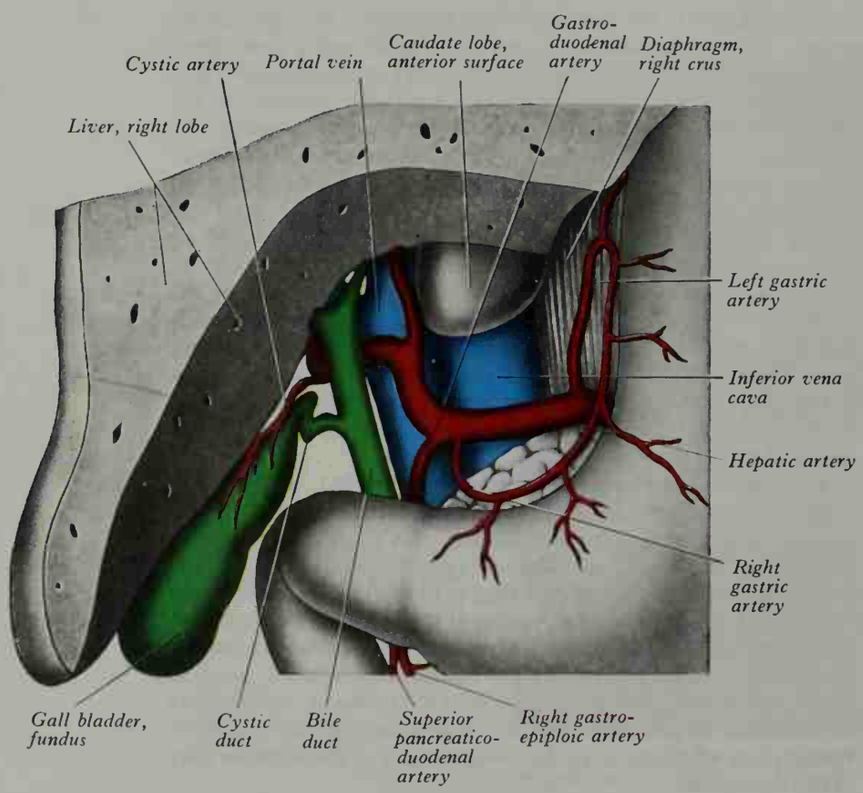
origin of the gastroduodenal artery, and (*b*) the *hepatic artery proper*, extending from that point to the bifurcation of the artery into its right and left branches.

In embryonic and *early* fetal life, the hepatic artery arises from the left gastric (in 67 per cent of 56 individuals, according to Godlewski *et al.* 1975). This arrangement rarely persists, but the hepatic artery may arise from the superior mesenteric; alternatively the right or left hepatic branches may be derived from other vessels, the former from the superior mesenteric, the latter from the left gastric artery. For these and other variations consult Quain (1865, 1899), and Woodburne (1962); see also p. 715 and p. 1383.

The hepatic artery gives off the right gastric, the gastroduodenal and the cystic arteries, branches to the bile duct from the right hepatic artery, and sometimes the supraduodenal artery (*vide infra*).

The right gastric artery (**6**.85) arises above the superior part of the duodenum, usually before, but sometimes beyond the gastroduodenal artery. It descends in the lesser omentum to the pyloric end of the stomach, and passes from right to left along the lesser curvature, supplying the upper parts of the anterior and posterior surfaces of the stomach, and ends by anastomosing with the left gastric artery. It may give off the supraduodenal artery (*vide infra*).

The gastroduodenal artery (**6**.85, 86), which arises behind, or sometimes above, the superior part of the duodenum, is a short but large branch. It descends between the superior part of the duodenum and the neck of the pancreas, lying immediately to the right of the line along which the peritoneum is reflected from the posterior surface of the first half-inch (1·25 cm) of the duodenum (**6**.85). The artery usually lies to the left of the bile duct, but sometimes is in front of it. At the lower border of the superior part of the duodenum it divides into the *right gastro-epiploic* and *superior pancreaticoduodenal* arteries. Prior to this division it supplies small branches to the pyloric end of the stomach and to the pancreas, small retroduodenal branches to the back of the superior part of the duodenum, and sometimes the supraduodenal artery (*vide infra*). The first branch of the common hepatic artery is more frequently the gastroduodenal artery than the right gastric artery. The gastroduodenal artery may occasionally come from the superior mesenteric, the coeliac trunk, or an aberrant right hepatic artery (p. 715). The most invariable feature of the gastroduodenal artery is its intermediate position between the pancreas and duodenum, a point of surgical importance in view of the common involvement of this artery in duodenal ulceration (Bradley 1973).



The *supraduodenal artery*, which may be double, is an inconstant vessel. It arises from either the gastroduodenal, the hepatic artery (common hepatic, hepatic artery proper, or the right or left branches of the latter), or the right gastric artery. It supplies the superior aspect and upper parts of the anterior and posterior surfaces of the proximal half or more of the superior part of the duodenum, though in many cases the proximal part of the duodenum is invaded by branches from the right gastric artery (see also p. 1344).

The right gastro-epiploic artery (**6**.85, 86), which is the larger terminal branch of the gastroduodenal, skirts the right margin of the omental bursa and then runs to the left along the greater curvature of the stomach, between the layers of the greater omentum. It ends by anastomosing with the left gastro-epiploic branch of the splenic artery. Except at the pylorus, where it is in contact with the stomach, it lies about a finger's breadth from the greater curvature. This vessel has numerous branches, some of which ascend to supply both surfaces of the stomach, while others descend into the greater omentum (omental or epiploic branches). It also gives off branches to the lower surface of the superior part of the duodenum.

The superior pancreaticoduodenal arteries (**6**.86), are usually two in number. The *anterior* descends on the front of the groove between the duodenum and the head of the pancreas. It

supplies both of these organs, and anastomoses with the anterior division of the inferior pancreaticoduodenal branch of the superior mesenteric artery. The *posterior superior pancreaticoduodenal artery*, which generally arises independently from the gastroduodenal at the upper border of the superior part of the duodenum, runs downwards and to the right in front of the portal vein and the bile duct. It then passes downwards on the back of the head of the pancreas, supplying branches to the gland and to the duodenum, and crosses behind the bile duct, just before that structure pierces the duodenal wall. It ends by anastomosing with the posterior division of the inferior pancreaticoduodenal artery. (The pancreaticoduodenal arteries form vascular arcades of very variable disposition before their final branches of distribution—*see* Michels 1962.) The superior artery supplies several branches to the lower part of the common bile duct (*see* p. 1383).

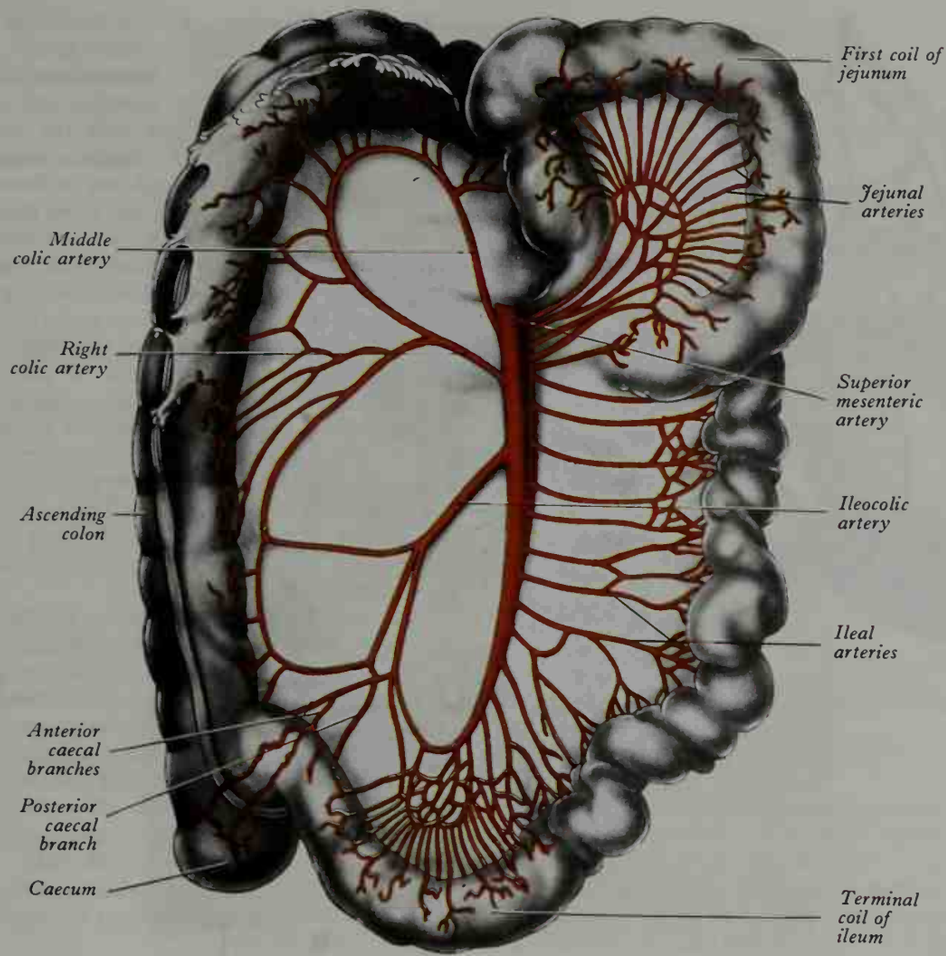
The cystic artery (**6**.87) usually comes from the right branch of the hepatic artery, and passes behind the common hepatic and cystic ducts to gain the upper surface of the neck of the gall bladder, on which it runs downwards and forwards before dividing into *superficial* and *deep* branches. The former ramifies on the lower, and the latter on the upper surface. occasionally the cystic artery arises from the hepatic artery itself (or rarely from the gastroduodenal artery) and crosses in front of, or behind, the bile duct or common hepatic duct to reach the gall bladder. Such variations in the *origin* of the cystic artery are of considerable surgical interest. In a large series of 800 specimens Anson (1963) observed the following incidences: from the right hepatic—63·9 per cent, the hepatic trunk—26·9 per cent, the left hepatic—5·5 per cent, the gastroduodenal—2·6 per cent, the superior pancreaticoduodenal—0·3 per cent, the right gastric—0·1 per cent, the coeliac trunk—0·3 per cent, and the superior mesenteric—0·8 per cent. The direct origins from the hepatic artery varied from the latter's start to its bifurcation into right and left hepatic branches. An *accessory cystic artery* may arise from the common hepatic artery or from one of its branches. The cystic artery supplies branches to the hepatic ducts and to the upper part of the common bile duct (*see* p. 1383). A comparative study of the *distribution* of the cystic artery in a variety of reptilian, avian and mammalian species included 74 injected and cleared human gall bladders (Gordon 1967). Briefly, the cystic artery of man reached the gall bladder at its neck and in no specimen was it at any point in contact with the cystic duct. Coursing over the neck, one or two pairs of vessels encircled the neck, anastomosing posteriorly. Division into its two principal longitudinal branches occurred at any point along the neck, and each then gave off 4–8 pairs of lateral branches at right angles to the parent vessels, anastomoses completing 4–8 vascular circles. The principal vessels bifurcated and formed a diamond-shaped anastomosis at the junction of body and fundus, the centre of the diamond being traversed by a fine anastomotic network. The overall arterial pattern was classified as *bipinnate*.

6.87 The relations of the hepatic artery, bile duct and portal vein exposed by removal of the lesser omentum and the peritoneum on the posterior abdominal wall.

The terminal, intrahepatic branches display a pattern of branching which, in its major detail (p. 1376), is relatively constant from individual to individual. This ramification justifies a **segmental** description of the liver, and it is the result, as in other organs, of the mode of growth and branching of an original epithelial blastema, its pattern being accompanied by arterial rami (and innervation). Arterial hepatic segmentation is noted on p. 1379. Consult also Woodburne (1962).

3. The Splenic Artery (**6**.85, 86)

This, the largest branch of the coeliac trunk, is remarkable for its tortuosity. Surrounded by the splenic plexus of nerves, and accompanied by the splenic vein, which lies behind the pancreas, it passes horizontally to the left, behind the stomach and the omental bursa, and along the upper border of the pancreas; it crosses in front of the left suprarenal gland and the upper part of the left kidney, and enters the lienorenal ligament. On arriving near the spleen it divides into five or more *segmental* branches which enter the hilum of the spleen (*see* p. 778).



Branches:

The pancreatic branches (**6**.86) are numerous small vessels supplying the neck, body and tail of the pancreas; they are derived from the splenic artery as it runs along the upper border of the pancreas. A *dorsal branch*, which may arise from the superior mesenteric, middle colic, hepatic or, more rarely, the coeliac artery, descends behind the pancreas and divides into right and left vessels. The former, usually two in number, run between the neck and uncinate process of the gland and form *a prepancreatic arterial arch* with a branch from the anterior superior pancreaticoduodenal: the latter runs to the left along the inferior border of the gland to reach the tail. It anastomoses with the branches (*arteria pancreatica magna* and *arteria caudae pancreatis*) of the splenic artery which supply the left of the body and tail of the pancreas.

Short gastric arteries (**6**.86), five to seven in number, arise from the end of the splenic artery and its terminal divisions or from the left gastro-epiploic artery. They pass between the layers of the gastrosplenic ligament, and are distributed to the fundus of the stomach, anastomosing with branches of the left gastric and left gastro-epiploic arteries.

The posterior gastric artery, derived from any part of the splenic artery, but most commonly from its intermediate section, has been described by many authorities (e.g. Quain 1844), but recent texts have omitted mention of this vessel as pointed out by Susuki *et al.* (1978), who have surveyed reports on this vessel. In their own observations 38 (62·3 per cent) of 61 adult cadavers displayed this vessel; incidences from 14 other reports (appearing from 1904 to 1968) varied from 12·7 to 77 per cent, with an average of about 58 per cent in a total of 870 cadavers (three studies cited percentages only). The authors quoted describe the vessel as ascending behind the peritoneum of the omental bursa towards the fundus and reaching the posterior gastric wall through the gastrophrenic fold of peritoneum. In their series it was usually about 2 mm in diameter, and hence of considerable significance in surgical manoeuvres in this region.

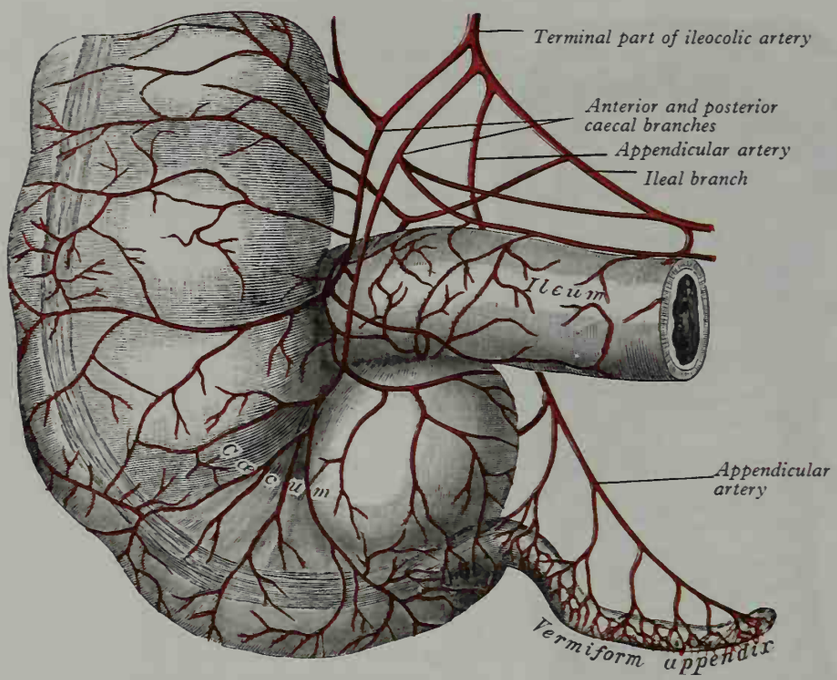
The left gastro-epiploic artery (**6**.85, 86), the largest of the branches of the splenic artery, arises near the hilum of the spleen and runs obliquely downwards, forwards and to the right. It sends several branches through the gastrosplenic ligament to be distributed to about the upper third of the greater curvature, and these are appreciably longer than the gastric branches of the right gastro-epiploic artery and may be 8 to 10 cm long. Its terminal

6.88 The superior mesenteric artery and its branches. The first coil of the jejunum and the terminal coil of the ileum have been spread out to show the arrangement of their arteries.

part gives off a large omental branch which runs downwards and to the right in the greater omentum, and itself curves forwards at a higher level to join the right gastro-epiploic. The looped course of the terminal part of the left gastro-epiploic leaves a portion of the greater curvature devoid of branches in its upper part. In the operation of partial gastrectomy the greater omentum is divided below the right gastro-epiploic artery, cutting all its omental branches. The greater omentum survives because its supply from the large omental branch of the left gastro-epiploic artery has not been damaged (Horton 1952).

The arteries that supply the greater omentum are the epiploic (omental) branches of the right and left gastro-epiploic arteries. The right, middle and left colic arteries do not give branches to the greater omentum, and it is to be noted that the transverse mesocolon, though adherent to the greater omentum, is separable from it (*see* p. 1330).

The terminal splenic branches enter the hilum of the spleen between the two layers of the lienorenal ligament. Their distribution within the spleen is described with the anatomy of that organ (p. 778).



Variations of the hepatic artery. Variations in the arrangement of the hepatic artery and its branches are common and of surgical importance. They include the following. (1) The common hepatic artery may arise from the superior mesenteric artery or, less commonly, directly from the aorta. In these cases it usually passes to the right behind the portal vein to enter the lesser omentum. (2) An accessory left hepatic artery arises most frequently from the left gastric artery and passes to the right in the lesser omentum to the porta hepatis. (3) An accessory right hepatic artery arises most commonly from the superior mesenteric artery and generally runs behind the portal vein and bile duct in the lesser omentum to gain the porta hepatis.

The accessory left and right hepatic arteries may arise from vessels other than the superior mesenteric artery, e.g. the gastroduodenal or the aorta. They may exist in conjunction with 'normal' branches of the hepatic artery and constitute additional sources of blood supply to the liver; on the other hand they may *replace* the normal branches and constitute the sole supply to the appropriate parts of the liver and they are then called *'aberrant replacing arteries'*.

Collateral circulation after ligature of the hepatic artery. Obstruction of the hepatic artery may lead to necrosis of the liver. The effects on the liver depend on the site of the block. Occlusion of the common hepatic artery, proximal to the origin of the right gastric artery, will allow a collateral circulation to the liver through the left and right gastric, left and right gastro-epiploic, pancreaticoduodenal and gastroduodenal arteries, and hepatic necrosis is unlikely to occur. If, however, the obstruction of the hepatic artery proper is beyond the origin of the gastroduodenal artery, the only collateral circulation is by means of the small inferior phrenic arteries (p. 719).

The Superior Mesenteric Artery

The superior mesenteric artery (**6**.88) supplies the whole of the small intestine except the superior part of the duodenum; it also supplies the caecum, the ascending colon and most of the transverse colon. It diverges from the front of the aorta about 1 cm below the coeliac trunk, and is crossed anteriorly at its origin by the splenic vein and the body of the pancreas. It is separated from the front of the aorta by the left renal vein. It next passes downwards and forwards, anterior to the uncinate process of the pancreas and the horizontal part of the duodenum, and descends

6.89 The arteries of the caecum and vermiform appendix.

between the layers of the mesentery near its root until it reaches the right iliac fossa. Here, considerably diminished in size, it anastomoses with one of its own branches, the ileocolic artery. As it descends it crosses in front of the inferior vena cava, the right ureter and psoas major, and forms an arch, its convexity forwards, downwards and to the left. It is accompanied by the superior mesenteric vein, on its right, and is surrounded by the superior mesenteric plexus of nerves. Occasionally a fibrous strand passes to the umbilicus from the terminal part of the superior mesenteric artery, or from one of its lower ileal branches; it is a remnant of the embryonic artery which runs along the vitelline or yolk duct to the yolk sac.

Branches:

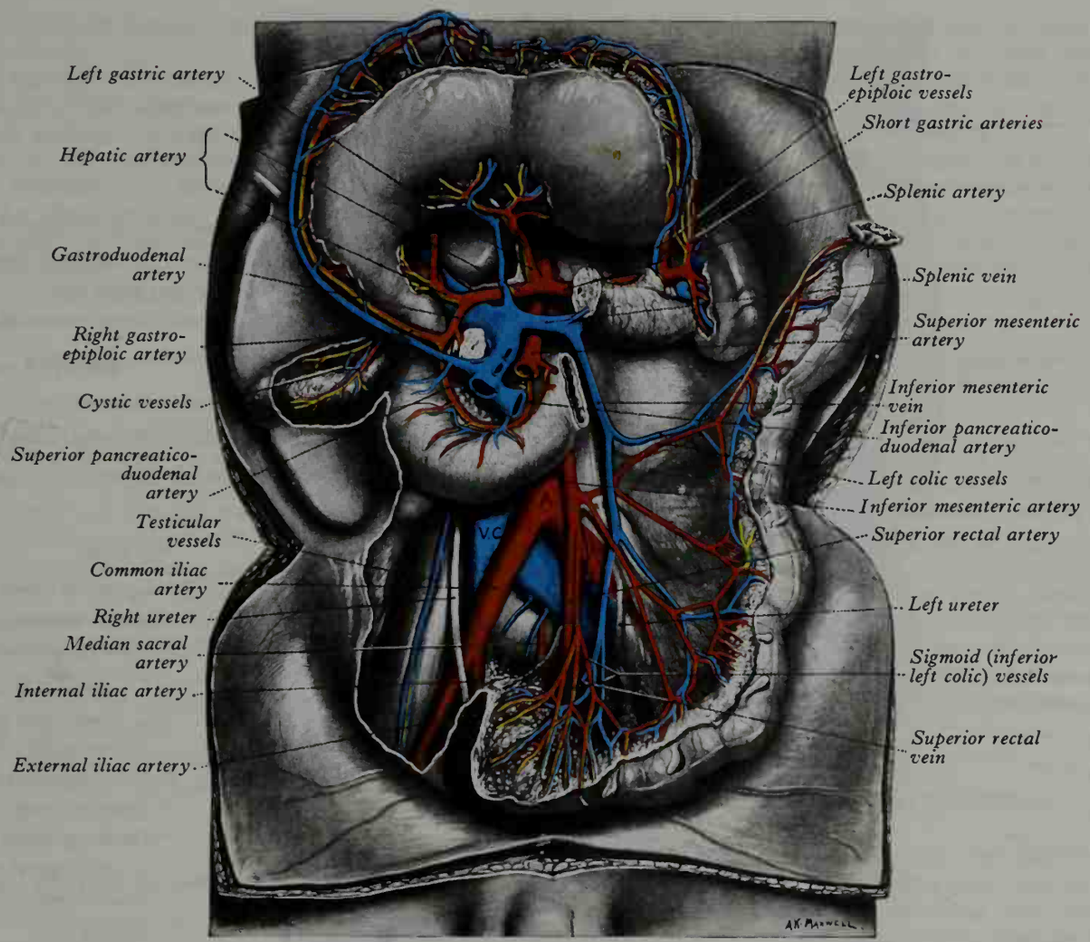
The inferior pancreaticoduodenal artery (**6**.86) leaves the superior mesenteric artery or its first jejunal branch, level with the upper border of the horizontal part of the duodenum. Usually it divides at once into anterior and posterior branches. The *anterior* goes to the right in front of the head of the pancreas and then ascends to anastomose with the anterior superior pancreaticoduodenal artery. The *posterior* passes upwards to the right behind the head of the pancreas, which it sometimes pierces, to anastomose with the posterior superior pancreaticoduodenal artery. Both branches supply the head of the pancreas, including its uncinate process, and adjoining parts of the duodenum.

The jejunal and ileal branches (**6**.88) arise from the left side of the superior mesenteric artery, usually twelve to fifteen in number, and are distributed to the jejunum and ileum, except for the terminal part of the latter, which is supplied by the ileocolic artery. They run nearly parallel with one another between the layers of the mesentery, each vessel dividing into two, which unite with adjacent branches to form a series of arches (**6**.88). The branches from the arches unite to form a second series of arches, and the process may be repeated three or four times. In the short, upper part of the mesentery only one set of arches exists, but as the mesentery increases in depth, second, third, fourth, and even fifth series are present. From the terminal arches numerous small straight vessels supply the intestine. These terminals are distributed, roughly alternately, to opposite surfaces of the gut, and it has been claimed that neighbouring vessels do not anastomose with one another (Cokkinis 1930). As a rule the jejunal arteries are longer and less numerous than the ileal arteries. From both groups small branches are given off to the lymph nodes and other structures between the layers of the mesentery. It should be noted that the changes in mode of distribution from jejunal to ileal levels is gradual. (*See* **8**.120 C, D.)

The ileocolic artery (**6**.88) is the lowest of the branches from the right of the superior mesenteric artery. It passes downwards and to the right behind the peritoneum, towards the right iliac fossa, where it divides into superior and inferior branches; the *superior* branch anastomoses with the right colic artery, the *inferior* with the end of the superior mesenteric artery. In its course, the ileocolic artery crosses in front of the right ureter, testicular (or ovarian) vessels and psoas major.

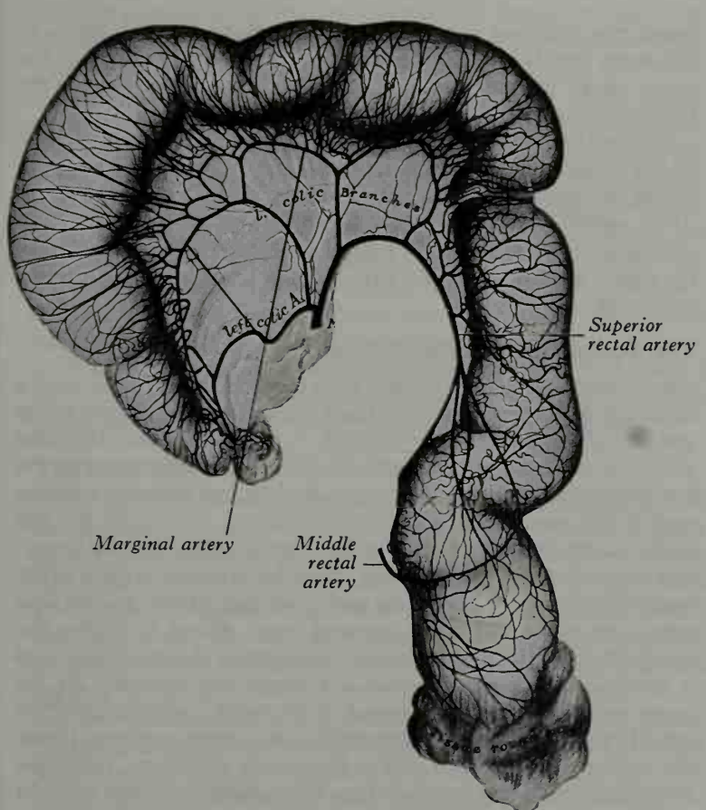
The inferior branch of the ileocolic runs towards the upper border of the ileocolic junction and supplies the following branches (**6**.89): (a) *ascending* (*colic*) which passes upwards on the ascending colon; (*b*) *anterior* and *posterior caecal*, distributed to the front and back of the caecum; (*c*) an *appendicular artery*, which descends behind the termination of the ileum and enters the mesoappendix; after giving off a recurrent branch, which anastomoses with a branch from the posterior caecal artery, it runs at first close to and later in the free margin of the mesoappendix, but its terminal part is in actual contact with the appendicular wall; (*d*) *ileal*, which runs upwards and to the left on the lower part of the ileum, supplying this part of the small intestine, and ends by anastomosing with the termination of the superior mesenteric artery.

The right colic artery (**6**.88) arises from near the middle of the concavity of the superior mesenteric, or from a stem common to it and the ileocolic artery. It passes to the right behind the peritoneum, and in front of the right testicular (or ovarian) artery and vein, the right ureter, and psoas major, towards the ascending colon. Sometimes the vessel lies at a higher level, and crosses the descending part of the duodenum and the lower end of the right kidney. At the colon it divides into a descending branch, which anastomoses with the ileocolic artery, and an ascending branch, which anastomoses with the middle colic. These branches form arches, from the convexity of which vessels are distributed to the ascending colon, supplying about its upper two-thirds and the right colic flexure.



The middle colic artery (**6**.88) departs from the superior mesenteric artery just below the pancreas and, passing downwards and forwards in the transverse mesocolon, divides into a right and a left branch; the former anastomoses with the right colic artery, the latter with the left colic artery, a branch of the inferior mesenteric artery. The arches thus formed are 3 or 4 cm from the transverse colon, to which they distribute branches.

Occasionally the superior mesenteric artery may give orlgin to the common hepatic artery, the gastroduodenal artery, or an accessory right hepatic artery. It may also provide accessory pancreatic or splenic arteries. The superior mesenteric artery has been observed to arise from a common coeliaco-mesenteric trunk (Mangoushi 1975).

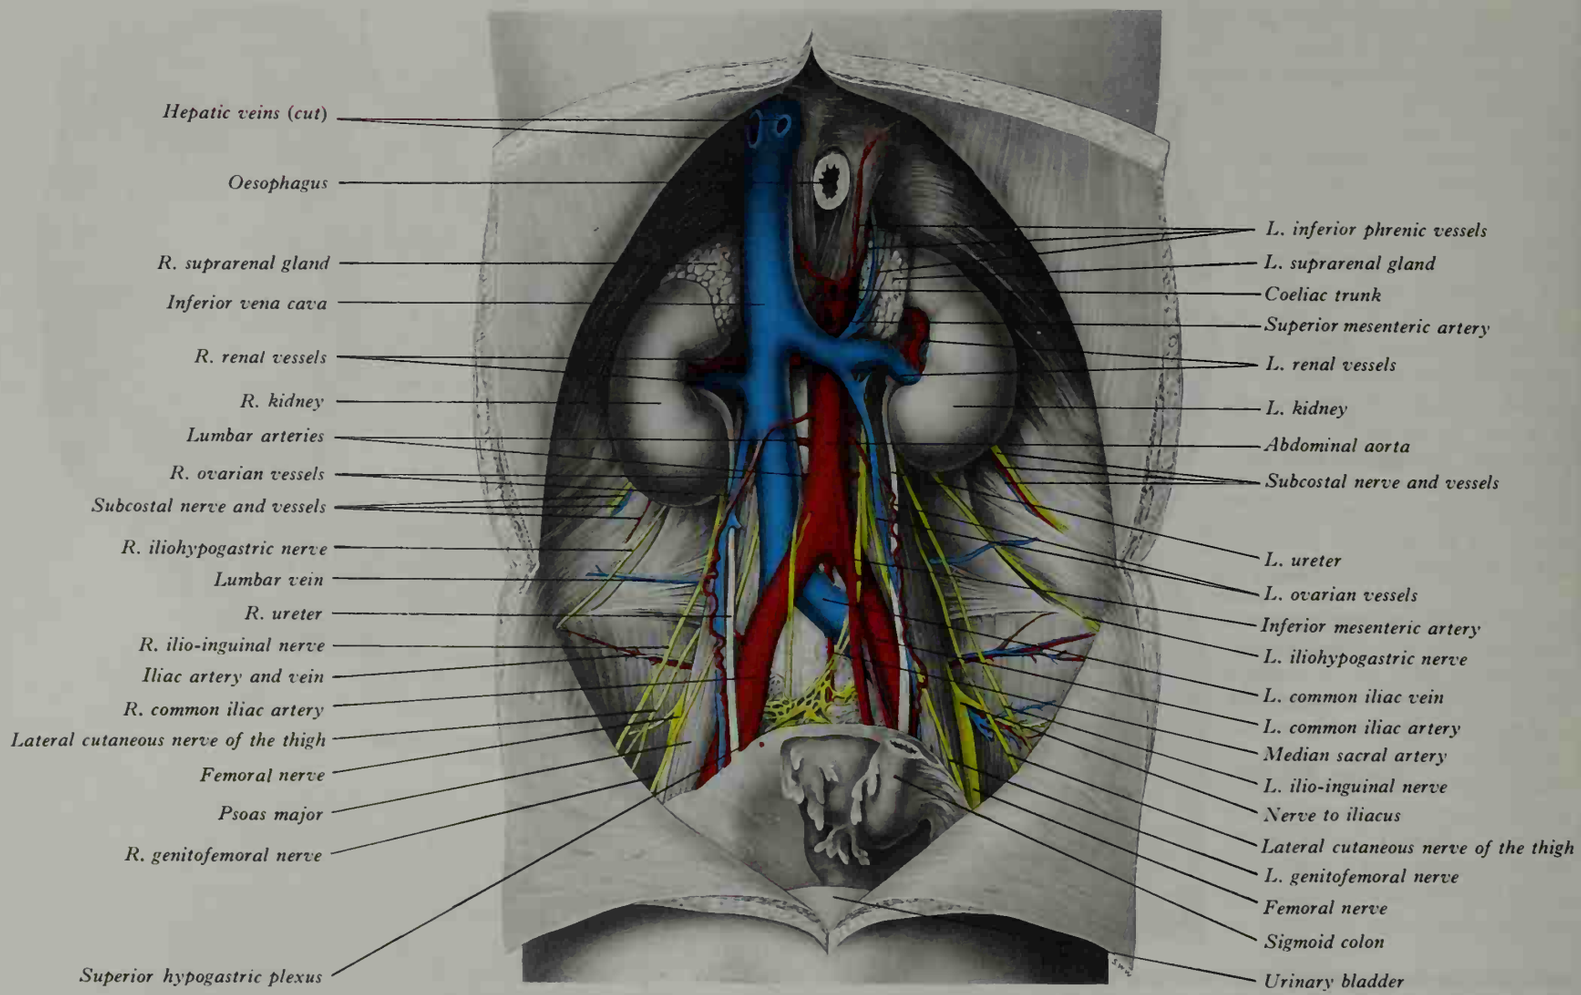


The Inferior Mesenteric Artery

The inferior mesenteric artery (**6**.90) supplies the left third of the transverse colon, the whole of the descending colon, the sigmoid colon and the rectum. It is smaller than the superior mesenteric artery, and arises 3 or 4 cm above the aorta's division into the common iliac arteries, just above the lower border of the horizontal part of the duodenum. It descends behind the peritoneum, at first in front of the aorta, and then on its left. It crosses the left common iliac artery medial to the left ureter, and is continued in the sigmoid mesocolon into the lesser pelvis as the *superior rectal artery*. In the lower part of its course, the inferior mesenteric vein lies on its lateral side. The inferior mesenteric artery gives off left colic, sigmoid and superior rectal branches.

The left colic artery (**6**.90) runs upwards and to the left behind the peritoneum and in front of the psoas major, and, after a short but variable course, divides into an ascending and a descending branch. The trunk or the branches of the artery cross in front of the left ureter and left testicular (or ovarian) vessels. The ascending branch passes in front of the left kidney into the transverse mesocolon, where it anastomoses with the middle colic artery; the descending branch anastomoses with the highest sigmoid artery. From the arches formed by these anastomoses, branches are distributed to the left half of the transverse colon,

6.90 The inferior mesenteric vessels and their branches (male subject). *Note*.—The stomach has been turned upwards and the whole of the jejunum and ileum, the caecum, ascending colon and transverse colon have been removed, together with part of the pancreas.



6.91 The sigmoid colon and rectum, showing the distribution of the branches of the inferior mesenteric artery and their anastomoses. (From a preparation by Hamilton Drummond.)

and to the descending colon. The territories of supply of the middle and left colic arteries show some reciprocal variation; the left branch of the middle colic may take over supply of the splenic flexure (in 19 of 100 cadavers according to investigations by Sierociński 1975).

The sigmoid (inferior left colic) arteries (**6**.90, 91), two or three in number, run obliquely down to the left behind the peritoneum in front of the left psoas major, ureter, and testicular or ovarian vessels. Their branches supply the lower part of the descending and the sigmoid colon, anastomosing above with the left colic artery, below with the superior rectal. The anastomoses between the branches of the left colic and sigmoid arteries form what is sometimes a continuous 'marginal artery' near the colon. The continuity of the marginal artery (of Drummond 1914) is, in fact, rarely interrupted, even in the vicinity of the sigmoido-rectal junction. Anastomosis at this level is sometimes effected by tenuous vessels which may be overlooked in dissection; injection experiments have demonstrated filling of the superior rectal vessels after high aortic injection, and the most recent series of dissections (100 individuals), by Sierociński (1976), indicated a constant anastomosis between the last sigmoid and the superior rectal arteries. Sudeck (1907) introduced the concept of uncertainty in this anastomosis, suggesting it as a '*critical point*' in colico-rectal surgery, and many authorities have repeated this view. (*See* Hollinshead, 1971, for a review of the literature.)

The superior rectal artery (**6**.90, 91), the continuation of the inferior mesenteric, descends into the pelvis in the sigmoid mesocolon, crossing the left common iliac vessels. It divides, opposite the third sacral vertebra, into two branches; these descend one on each side of the rectum; about halfway down they break up into several small branches. These pierce the muscular coat of the rectum and run straight down between the muscular and mucous coats, to the level of the sphincter ani internus; here,

6.92 A dissection to show the relations of structures on the posterior abdominal wall (female subject).

by anastomoses with one another, they form loops around the lower end of the rectum, and communicate with the middle rectal artery, a branch of the internal iliac artery, and with the inferior rectal, which arises from the internal pudendal (*see* p. 721).

The Middle Suprarenal Arteries

These two small vessels arise, one from each side of the aorta, level with the superior mesenteric artery. Each passes laterally and slightly upwards over the crus of the diaphragm to the suprarenal gland, where it anastomoses with suprarenal branches of the phrenic and renal arteries. The right artery passes behind the inferior vena cava and is close to the coeliac ganglion. The left is related to the coeliac ganglion, splenic artery and upper border of the pancreas.

The Renal Arteries (**6**.84, 92)

These two large trunks branch from the sides of the aorta immediately below the superior mesenteric, and both cross the corresponding crus of the diaphragm, nearly at right angles to the aorta. The *right* is longer, on account of the position of the aorta; it passes behind the inferior vena cava, right renal vein, head of the pancreas, and descending part of the duodenum. The *left* is a little higher; it lies behind the left renal vein, the body of the pancreas and splenic vein, and may be crossed anteriorly by the inferior mesenteric vein. Just before the hilum of the kidney, each artery divides into four or five branches; most of these lie between the renal vein and the pelvis of the ureter, the vein in front and the pelvis behind; but one or more are usually behind the pelvis. Each renal artery gives off some small *inferior suprarenal branches* (p. 191), and supplies the ureter and surrounding cellular tissue and muscles. The distribution of the renal arteries in the kidneys is described on p. 1397.

Surface Anatomy. The renal arteries can be represented by broad lines running laterally for 4 cm from the lateral margins of the aorta just below the transpyloric plane. In the case of the artery of the left side the line should incline upwards across the transpyloric plane.

One or two *accessory renal arteries* frequently occur, especially on the left side: usually from the aorta, they may come off above or below the main artery, the former being slightly more frequent. They usually enter the upper or lower part of the kidney; an accessory artery to the lower pole of the kidney crosses in front of the ureter and, on the right side, usually in front of the inferior vena cava.

The Testicular Arteries (**6**.84, 92)

These two long, slender vessels arise from the front of the aorta a little below the renal arteries. Each passes obliquely downwards and laterally behind the peritoneum, on the psoas major; the right artery is in front of the inferior vena cava and behind the horizontal part of the duodenum, right colic and ileocolic arteries, root of the mesentery, and terminal part of the ileum; the left artery passes behind the inferior mesenteric vein, left colic artery, and lower part of the descending colon. Each passes in front of the genitofemoral nerve, the ureter and lower part of the external iliac artery to reach the deep inguinal ring, where it enters the spermatic cord. With the other constituents of the spermatic cord it traverses the inguinal canal and enters the scrotum. At the upper end of the posterior aspect of the testis it divides into two branches which pass on to the medial and lateral surfaces, pierce the tunica albuginea and end in the tunica vasculosa. From the latter terminal branches pass into the substance of the testis at various points over the free surface. Some pass into the mediastinum testis and loop back again before reaching their distribution (Harrison and Barclay 1948). In the abdomen the testicular artery supplies the fat around the kidney, the ureter and

iliac lymph nodes; in the inguinal canal it gives one or two twigs to the cremaster muscle.

Sometimes the right testicular artery passes behind the inferior vena cava. Both arteries represent persistent lateral splanchnic branches of the aorta (p. 191), which enter the mesonephros and cross ventral to the supracardinal vein but dorsal to the subcardinal. Normally the lateral splanchnic artery, which persists as the right testicular artery, passes caudal to the particular suprasubcardinal anastomosis which persists in the formation of the inferior vena cava. When it passes cranial to this anastomosis the right testicular artery is behind the inferior vena cava in the adult.

The Ovarian Arteries

In the female these correspond to the testicular arteries but enter the pelvis to supply the ovaries (**6**.95). The details of the first part of each artery are the same as those of the testicular, but on arriving at the brim of the lesser pelvis the artery crosses the external iliac artery and vein, and enters the pelvic cavity. It then runs medially in the suspensory ligament of the ovary and gains the broad ligament of the uterus, below the uterine tube. At the level of the ovary it passes backwards in the mesovarium and breaks up into branches to the ovary. Small branches are given to the ureter and uterine tube, and one passes to the side of the uterus to unite with the uterine artery. Others run on the round ligament of the uterus, through the inguinal canal, to the skin of the labium majus and the inguinal region.

Early in intrauterine life, when the testes or ovaries flank the vertebral column below the kidneys, the testicular and ovarian arteries are short; but with the descent of the gonads into the pelvis, the arteries gradually lengthen.

The (Inferior) Phrenic Arteries (**6**.84, 92)

These are two small vessels which supply the diaphragm. They may arise separately from the front of the aorta, immediately above the coeliac trunk, or by a common stem, either from the aorta or the coeliac trunk; sometimes one is derived from the aorta, the other from one of the renal arteries. From its origin the artery runs upwards and laterally in front of the crus of the diaphragm and close to the medial border of the suprarenal gland. The left passes behind the oesophagus, and runs forwards on the left side of the oesophageal opening. The right phrenic artery passes behind the inferior vena cava, along the right side of the opening for this vein. Near the posterior border of the central tendon of the diaphragm each vessel divides into a medial and lateral branch. The medial curves forwards, and anastomoses with its fellow of the opposite side in front of the central tendon, and with the musculophrenic and pericardiacophrenic arteries. The lateral branch passes towards the side of the thorax, and anastomoses with the lower posterior intercostal arteries and with the musculophrenic artery. The lateral branch of the right artery gives off a few twigs to the inferior vena cava; the left artery sends some branches to the oesophagus. Each vessel gives off two or three small *superior suprarenal branches* to the suprarenal gland of its own side. The liver (*see* p. 715), Collateral Circulation) and the spleen also receive a few twigs from the phrenic arteries.

The Lumbar Arteries (**6**.92)

These are in series with the posterior intercostal arteries. Usually four in number on each side, they arise from the back of the aorta, opposite the bodies of the upper four lumbar vertebrae. A fifth pair, smaller in size, occasionally arise from the median sacral artery; but the lumbar branches of the iliolumbar arteries usually take their place. The lumbar arteries run laterally and backwards on the bodies of the lumbar vertebrae, behind the sympathetic trunks, to the intervals between adjacent transverse processes, and then continue into the abdominal wall. The right arteries pass deep to the inferior vena cava, and the upper two on the right, the first only on the left, run deep to the corresponding crus of the diaphragm. The arteries of both sides pass under the tendinous arches providing attachment for psoas major, and travel on behind this muscle and the lumbar plexus. They then cross quadratus lumborum, the upper three arteries running behind, the last usually in front of that muscle. At the lateral border of quadratus lumborum they pierce the posterior aponeurosis of transversus abdominis, and pass forwards between this and internal oblique. They anastomose with one another and with the lower posterior intercostal, subcostal, iliolumbar, deep circumflex iliac and inferior epigastric arteries.

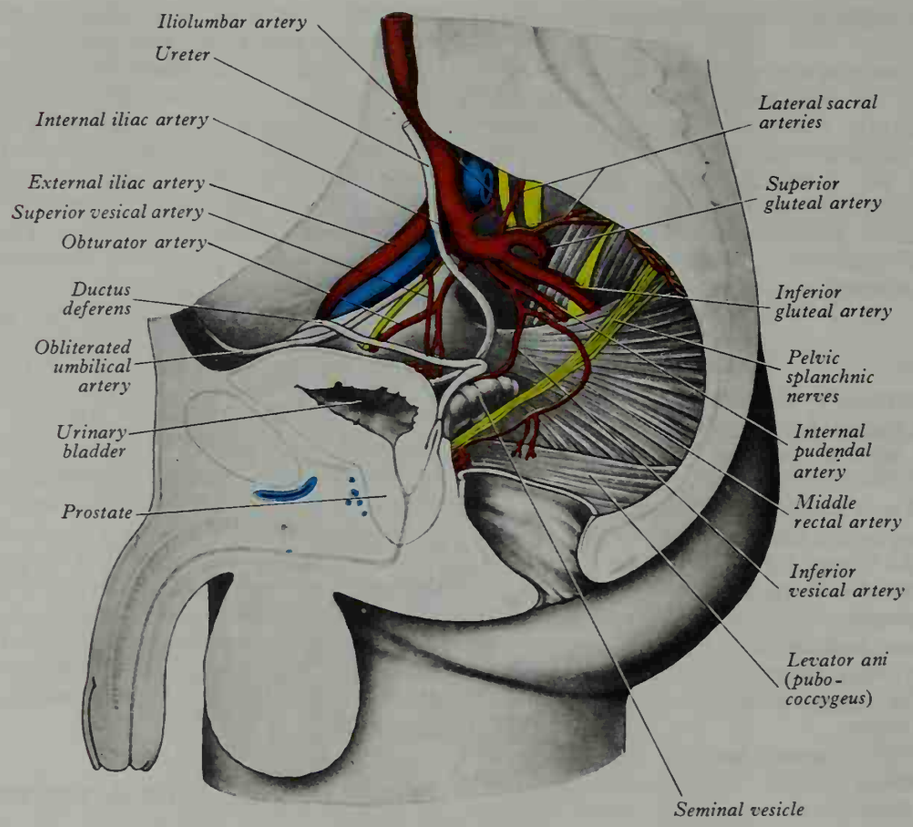
Branches. Each lumbar artery gives off a *dorsal ramus* which passes backwards between adjacent transverse processes to the muscle and skin of the back. The posterior ramus also furnishes a *spinal branch*, which enters the vertebral canal to supply its contents and adjacent vertebra, anastomosing with the arteries above and below it, and with the artery of the opposite side. The spinal branch of the first lumbar artery gives off branches to the lower part of the spinal cord. Branches of the lumbar arteries and their dorsal rami also supply the neighbouring muscles.

The Median Sacral Artery (**6**.84, 92)

This is a small branch from the back of the aorta a little above its bifurcation. It descends in the midline in front of the fourth and fifth lumbar vertebrae, the sacrum and coccyx, and ends in the coccygeal body. At the level of the fifth lumbar vertebra it is crossed by the left common iliac vein, and it frequently gives off on each side a small lumbar artery (*arteria lumbalis ima*). Minute branches pass from it to the posterior surface of the rectum. On the last lumbar vertebra it anastomoses with the lumbar branch of the iliolumbar artery; in front of the sacrum it anastomoses with the lateral sacral arteries, and sends offsets into the pelvic sacral foramina.

The Common Iliac Arteries

The abdominal aorta divides, on the left side of the body of the fourth lumbar vertebra, into the right and left common iliac arteries (**6**.84, 92). These diverge as they descend to divide opposite the intervertebral disc between the last lumbar vertebra and sacrum into two branches, the *external* and *internal iliac arteries*; the former supplies the greater part of the lower limb, the latter, the viscera and walls of the pelvis, perineum and gluteal region. The bifurcation is anterior to the sacroiliac joint.



The Right Common Iliac Artery (**6**.84, 92)

This is about 5 cm long and passes obliquely across the body of the last lumbar vertebra. *In front*, it is crossed by sympathetic fibres passing to the superior hypogastric plexus, and, at its point of division, by the ureter; throughout its course it is covered with the parietal peritoneum, by which it is separated from the coils of the small intestine. *Behind*, it is separated from the bodies of the fourth and fifth lumbar vertebrae and the intervening intervertebral disc by the sympathetic trunk, the terminal parts of the two common iliac veins and the commencement of the inferior vena cava. The obturator nerve, the lumbosacral trunk and the iliolumbar artery are situated more deeply and traverse the fatty tissue which occupies the interval between the last lumbar vertebra and the psoas major. *Laterally* it is in relation above with the inferior vena cava and the right common iliac vein, below, with the psoas major. *Medially* its upper part is related to the left common iliac vein.

The Left Common Iliac Artery (**6**.84, 92)

This is about 4 cm long, and is in relation, *in front*, with the peritoneum, ileum, sympathetic fibres passing to the superior hypogastric plexus, and the superior rectal artery, and is crossed at its bifurcation by the ureter. *Behind*, are the sympathetic trunk and bodies of the fourth and fifth lumbar vertebrae, and intervening intervertebral disc. The obturator nerve, lumbosacral trunk and iliolumbar artery are placed more deeply. The left common iliac vein lies partly *medial* to, and partly *behind*, the artery; *laterally* the artery is close to the psoas major.

Surface Anatomy. The vessel corresponds on each side to the upper third of a broad line from the bifurcation of the aorta (p. 710) to the point midway between the anterior superior iliac spine and the pubic symphysis. The *external iliac artery* corresponds to the lower two-thirds of this line, which should be slightly convex laterally.

6.93 The arteries of the male pelvis. Right side. The internal iliac vein and its tributaries have been removed; the rectum has been divided just above the anal canal and its upper part has been taken away.

Branches. In addition to the terminal branches each common iliac artery gives small branches to the peritoneum, psoas major, ureter, and surrounding areolar tissue; occasionally the iliolumbar and accessory renal arteries are branches.

The Internal Iliac Arteries

Each internal iliac artery (**6**.93), about 4 cm long, arises at the bifurcation of the common iliac artery, level with the lumbosacral intervertebral disc and in front of the sacroiliac joint; it descends to the upper margin of the greater sciatic foramen, where it divides into an *anterior trunk*, which continues in the line of the parent vessel towards the spine of the ischium, and a *posterior trunk*, which passes backwards towards the foramen. (*See* Braithwaite 1952.)

In front are the ureter and, in the female, the ovary and the fimbriated end of the uterine tube; *behind*, is the internal iliac vein, the lumbosacral nerve trunk and sacroiliac joint; *laterally*, near its origin, is the external iliac vein, between it and psoas major; lower down, is the obturator nerve; and *medially* it is next to the parietal peritoneum, separating it from the terminal part of the ileum on the right and the sigmoid colon on the left, and to some of the tributaries of the internal iliac vein.

In the fetus, the internal iliac artery is twice as large as the external iliac, and is the direct continuation of the common iliac. It ascends on the back of the anterior wall of the abdomen to the umbilicus, converging on its fellow. Having passed through the umbilical opening, the two arteries, now termed *umbilical*, enter the umbilical cord, where they are coiled round the umbilical vein, and ultimately ramify in the placenta.

At birth, when the placental circulation ceases, only the pelvic portion of the artery remains patent, as the internal iliac artery and the first part of the superior vesical artery of the adult; the remainder of the vessel becomes a fibrous cord, termed the *medial umbilical ligament*, raising the peritoneal *medial umbilical fold*, which extends from the pelvis to the umbilicus. In the male, the patent part of the umbilical artery usually gives off the artery to the ductus deferens.

BRANCHES FROM THE ANTERIOR TRUNK OF THE INTERNAL ILIAC ARTERY

The superior vesical artery (**6**.93) supplies numerous branches to the upper part of the bladder (Braithwaite 1951). From one of these the *artery to the ductus deferens* occasionally starts and accompanies the ductus to the testis, where it anastomoses with the testicular artery. Other branches supply the ureter. The first part of the superior vesical artery is the proximal, patent section of the fetal umbilical artery (*vide supra*).

The inferior vesical artery (**6**.93) frequently arises in common with the middle rectal artery, and is distributed to the fundus of the bladder, prostate, seminal vesicles and lower part of the ureter. The prostatic branches communicate with corresponding vessels of the opposite side. The inferior vesical artery may sometimes provide the artery to the ductus deferens.

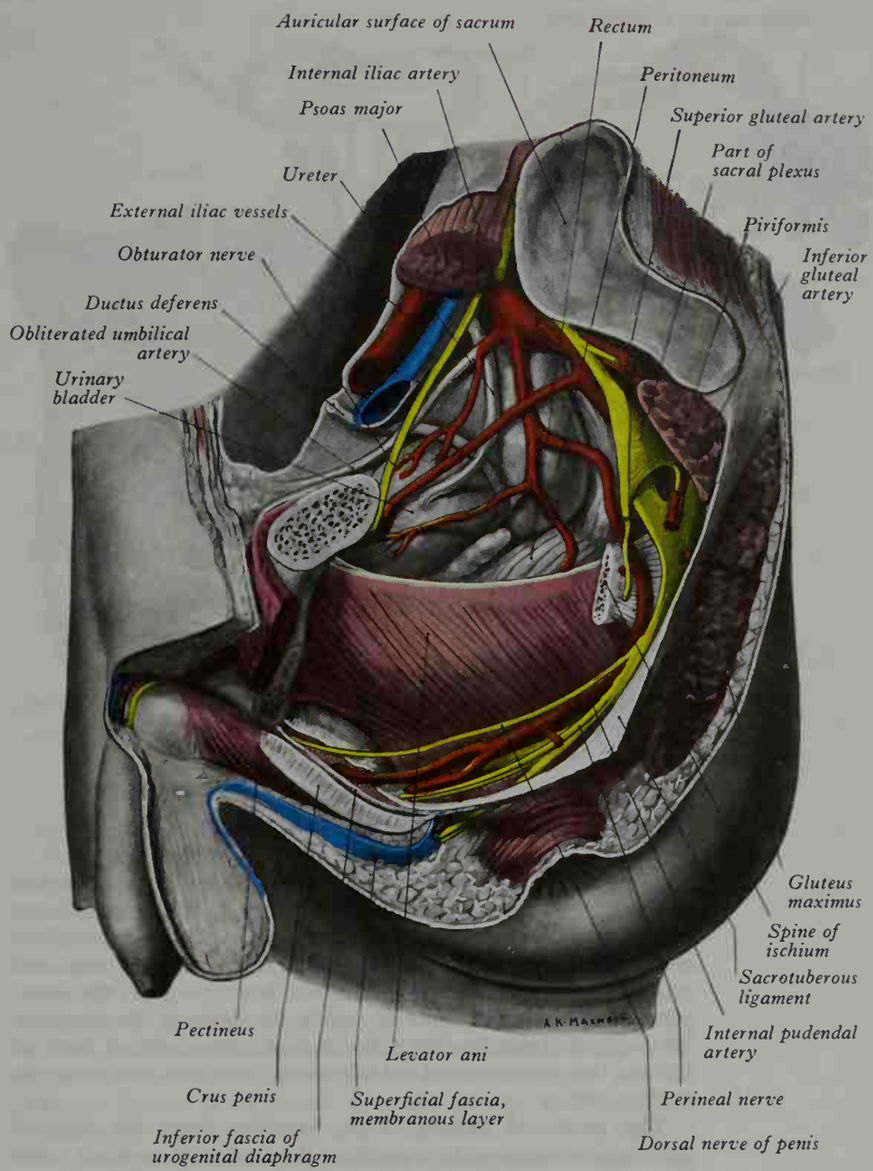
The middle rectal artery (**6**.91, 93) usually arises with the preceding vessel. It vascularizes the muscular tissue of the lower rectum, anastomosing with the superior and inferior rectal arteries. It supplies the seminal vesicles and prostate by branches which join those of the inferior vesical artery.

The uterine artery (**6**.95) runs medially on the levator ani towards the cervix uteri; about 2 cm from this it crosses above and in front of the ureter—to which it supplies a small branch—and above the lateral vaginal fornix. Reaching the side of the uterus, it ascends along it tortuously in the broad ligament to the junction of uterine tube and uterus. It then runs laterally towards the hilum of the ovary, and ends by joining with the ovarian artery. It supplies the cervix uteri and branches descend on the vagina; the latter anastomose with branches of the vaginal arteries forming two median longitudinal vessels, the *azygos arteries of the vagina*; one descends in front of, the other behind, the vagina. It supplies numerous branches to the body of the uterus, and from its termination, twigs reach the uterine tube and round ligament of

the uterus. The terminal branches in the uterine muscle are exceedingly tortuous (helicine arteries).

The vaginal artery, frequently double or triple, usually corresponds to the inferior vesical in the male; it descends upon the vagina, supplying its mucous membrane, and sends branches to the bulb of the vestibule, the fundus of the bladder and the adjacent part of the rectum. It assists in forming the azygos arteries of the vagina (*vide supra*).

The obturator artery (**6**.93) passes forwards and downwards on the lateral wall of the pelvis, to the upper part of the obturator foramen, and, leaving the pelvic cavity through the obturator canal, divides into an anterior and a posterior branch. In the pelvic cavity this vessel is related laterally to the obturator fascia, separating it from the obturator internus; medially, it is crossed by the ureter and ductus deferens, which separate it from the parietal peritoneum; in the nullipara the ovary is a medial relation. The obturator nerve is above and the obturator vein below.



Branches. Inside the pelvis, the obturator artery provides (*a*) *iliac branches* to the iliac fossa; these supply the bone and iliacus, and anastomose with the iliolumbar artery; (*b*) a *vesical branch* which runs medially to the bladder, and may replace the inferior vesical branch of the internal iliac; and (*c*) a *pubic branch* just before the obturator leaves the pelvic cavity; this branch ascends the pubis and anastomoses with the opposite vessel, and the pubic branch of the inferior epigastric.

Outside the pelvis, the obturator artery divides, at the upper margin of the obturator foramen, into an anterior and posterior branch, which encircle the foramen between the obturator externus and obturator membrane.

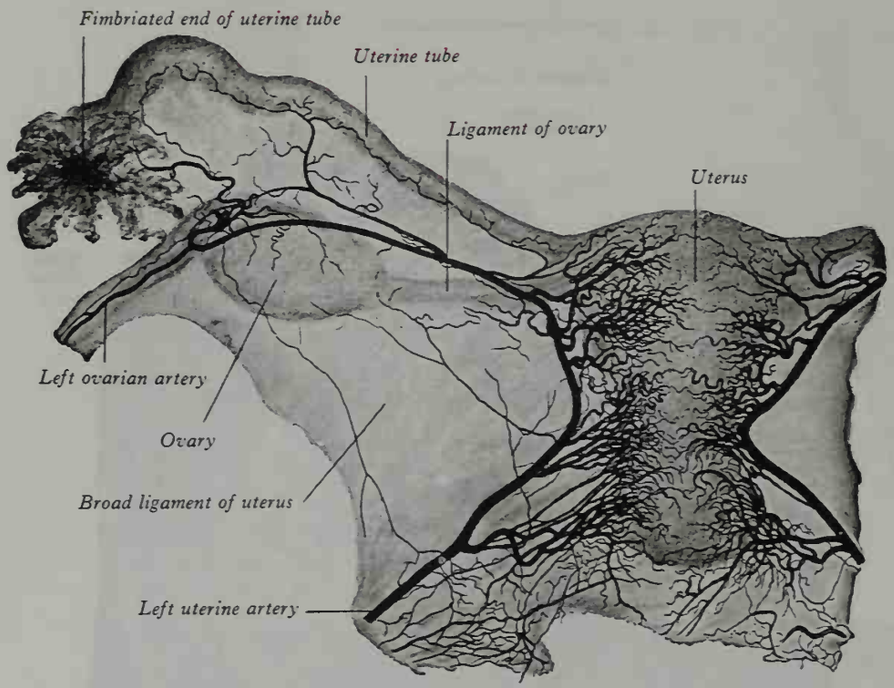
The *anterior branch* runs forwards on the outer surface of the obturator membrane and then curves downwards along the anterior margin of the foramen. It supplies branches to the obturator externus, pectineus, adductors and gracilis, and anastomoses with the posterior branch and with the medial circumflex femoral artery.

The *posterior branch* follows the posterior margin of the foramen and turns forwards on the ramus of the ischium where it anastomoses with the anterior branch. It supplies the muscles attached to the ischial tuberosity and anastomoses with the inferior gluteal artery. It also has an *acetabular branch* which enters the hip joint through the acetabular notch, ramifies in the fat of the acetabular fossa, and sends a twig along the ligament of the head of the femur.

Variations. In 20 to 30 per cent of people, the obturator artery is replaced by an enlarged pubic branch of the inferior epigastric (p. 723); this descends almost vertically to the upper part of the obturator foramen. Such an *abnormal obturator artery* is usually in contact with the external iliac vein, and lateral to the femoral ring; in such cases it would not be endangered in the operation for strangulated femoral hernia. Occasionally, however, it curves along the free margin of the lacunar part of the inguinal ligament, and may partly encircle the neck of a hernial sac; moreover, it may be inadvertently incised at operation. Rarely, the artery passes across the femoral ring and may be pushed either medially or laterally by a femoral hernia. According to Pick *et al.* (1942), who reported on 640 dissections of the obturator artery, the vessel is most commonly a branch of the internal iliac (24 per cent), or from this artery's anterior (21 per cent) or posterior (3 per cent) divisions. They put the incidence of epigastric origin at 27 per cent (*vide supra*); apart from the superior gluteal (11 per cent) and the inferior gluteal artery (9 per cent); rare origins include the external iliac, internal pudendal, and iliolumbar arteries.

6.94 Structures of the male pelvic contents from the left side. Most of the left innominate bone has been removed together with the obturator internus. The sciatic nerve has been cut away close to its origin from the sacral plexus. All the vessels and nerves exposed are those of the *left* side. Note superior vesical, obturator, inferior vesical and middle rectal arteries which are, for technical reasons, without leader lines or tabbing labels.

The Internal Pudendal Artery (**6**.93, 94, 96, 97)



This, the smaller of the two terminal branches of the anterior trunk of the internal iliac, supplies the external genitalia. Though its course is the same, it is smaller in the female and its distribution somewhat different.

In the male the artery runs downwards and laterally to the lower part of the rim of the greater sciatic foramen, leaves the pelvic cavity between piriformis and coccygeus, and enters the gluteal region. Here it curves round the back of the ischial spine to enter the perineum through the lesser sciatic foramen, and thence traverses the pudendal canal, in the lateral wall of the ischiorectal fossa, medial to the obturator internus and about 4 cm above the lower limit of the tuberosity. Gradually approaching the margin of the ischial ramus, it proceeds forwards above, or deep to, the inferior fascia of the urogenital diaphragm, skirts the medial margin of the inferior pubic ramus, and ends a little behind the inferior pubic ligament by dividing into the *deep and dorsal arteries of the penis*. It may descend through the inferior fascia of the diaphragm before its bifurcation. (It is perhaps worthy of note that the part of the internal pudendal artery distal to its perineal branch has sometimes been known as the *artery of the penis*, an appropriate description in view of its distribution—*vide infra*.)

Relations. Within the pelvis the internal pudendal artery crosses anterior to piriformis, the sacral plexus, and the inferior gluteal artery. Crossing the ischial spine it is covered by gluteus maximus, lying between the pudendal nerve medially and the nerve to obturator internus lateral to it. In the perineum, as noted, it clings to the lateral wall of the ischiorectal fossa. Here, in the pudendal canal (p. 562), it travels at first with two companion veins and the pudendal nerve; beyond this, the latter's terminal branches flank the artery, the dorsal nerve of the penis above, the perineal nerve below.

Branches (**6**.96, 97):

Muscular branches leave the internal pudendal both in the pelvis and in the gluteal region to supply related muscles.

6.95 The left uterine and ovarian arteries of a nullipara of 17½ years. Posterior aspect. (From a preparation by Hamilton Drummond.)

The inferior rectal artery branches off above the ischial tuberosity. Escaping through the connective tissue wall of the pudendal canal (p. 562), it divides into two or three stems which cross the ischiorectal fossa medially to supply the skin and musculature of the anal region. Small branches skirt the lower edge of gluteus maximus to reach the skin of the buttock. Through its branches the inferior rectal anastomoses with its fellow, the superior and middle rectal arteries, and with the perineal artery.

The perineal artery (**6**.96) branches from the internal pudendal near the anterior end of the pudendal canal; it turns down through the inferior fascia of the urogenital diaphragm (p. 560) and then runs forwards towards the scrotum in the superficial perineal space, or region, between bulbospongiosus and ischiocavernosus. Just after its exit from the diaphragm, and near the latter's base, it has a small *transverse branch*, which passes medially on the inferior surface of the superficial transverse perineal muscle to anastomose with the opposite vessel and with the posterior scrotal and inferior rectal arteries. This small branch supplies tissues between the anus and penile bulb. The *posterior scrotal arteries*, small vessels distributed to the scrotal skin and dartos muscle, are usually the terminals of the perineal artery, but they may also be derived from its transverse branch. They also supply the musculature of the perineum.

The artery of the bulb of the penis, a short vessel of considerable calibre, runs medially through the deep transverse perineal muscle and the inferior fascia of the urogenital diaphragm to reach the bulb of the penis. Penetrating into this, it supplies the erectile tissue of the bulb and posterior part of the corpus spongiosum. It sends a branchlet to the bulbo-urethral gland.

The urethral artery also pierces the inferior fascia to enter the corpus spongiosum, travelling therein as far as the glans penis. It supplies the urethra and surrounding erectile tissue.

The deep artery of the penis, a terminal branch of the internal pudendal, passes through the inferior fascia of the urogenital diaphragm to enter the crus penis of its own side. It traverses the corpus cavernosum in a central position and supplies its erectile tissue.

The dorsal artery of the penis is the other terminal branch of the internal pudendal. Leaving the inferior aspect of the urogenital diaphragm, it ascends between the crus penis and the pubic symphysis, passes through the suspensory ligament of the penis, and runs along its dorsum as far as the glans, where it forks into a branch to the glans itself and one to the prepuce. In the penis it is between the dorsal nerve and deep dorsal vein, the latter being most medial of the three structures. The artery supplies penile skin and the fibrous sheath of the corpus cavernosum, sending anastomotic branches through the sheath to the deep penile artery.

In the female the internal pudendal artery is naturally smaller, but its origin, course and branches are similar. *Posterior labial branches* supply the labia; the *artery of the bulb* is distributed to the erectile tissue of the vestibular bulb and vagina; a *deep artery of the clitoris* supplies the corpus cavernosum; and a *dorsal artery* supplies the dorsum, glans and prepuce of the clitoris.

Variations. Occasionally certain of the branches of the internal pudendal artery are derived from an *accessory pudendal*, usually a branch of the former before its exit from the pelvic cavity.

The inferior gluteal artery (**6**.94, 98), the larger terminal branch of the anterior trunk of the internal iliac, chiefly supplies the buttock and back of the thigh. It descends in front of the sacral plexus and piriformis, behind the internal pudendal artery. Passing between the first and second, or second and third sacral anterior rami, and then between piriformis and coccygeus, it traverses the lower part of the greater sciatic foramen to gain the gluteal region. It then descends between the greater trochanter and the ischial tuberosity with the sciatic and posterior femoral cutaneous nerves, covered by the gluteus maximus; it continues down the back of the thigh, supplying skin, and anastomosing with branches of the perforating arteries. Commonly, the inferior gluteal and internal pudendal arteries are a common stem from the internal iliac; the stem sometimes also includes the superior gluteal artery.

Surface Anatomy. The inferior gluteal artery leaves the pelvis at about the midpoint of a line joining the posterior superior iliac spine and the ischial tuberosity.

Branches:

Inside the pelvis: (*a*) to piriformis, coccygeus and levator ani; (*b*) to the fat around the rectum, and occasionally to take the place of the middle rectal artery; (*c*) vesical branches to the fundus of the bladder, seminal vesicles and prostate.

Outside the pelvis. Muscular branches supply gluteus maximus, obturator internus, the gemelli, quadratus femoris and the upper parts of the hamstring muscles; they anastomose with the superior gluteal, internal pudendal, obturator and medial circumflex femoral arteries.

Coccygeal branches run medially, pierce the sacrotuberous ligament, and supply the gluteus maximus and structures attached to the back of the coccyx.

The *artery to the sciatic nerve*, a long slender vessel, runs on the sciatic nerve for a short distance, penetrates it, and descends in its substance to the lower part of the thigh.

An *anastomotic branch* descends obliquely across obturator internus, the gemelli and quadratus femoris, to join the so-called *cruciate anastomosis* (p. 727) linking with the first perforating and the medial and lateral circumflex femoral arteries.

An *articular branch*, generally from the anastomotic, is distributed to the hip joint.

Cutaneous branches are distributed to the buttock and back of the thigh.

BRANCHES FROM THE POSTERIOR TRUNK OF THE INTERNAL ILIAC ARTERY

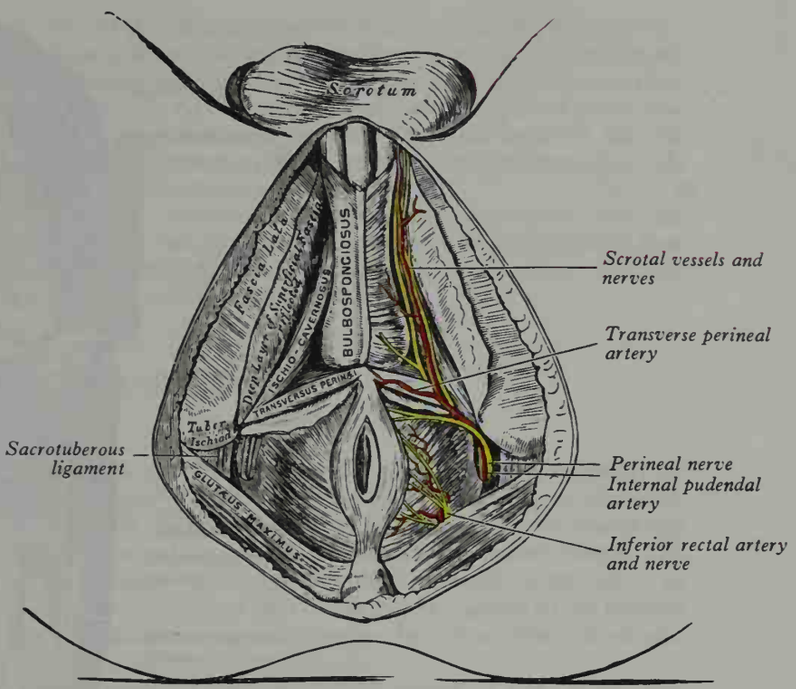
The iliolumbar artery (**6**.93) ascends laterally in front of the sacroiliac joint and lumbosacral trunk, behind the obturator nerve and external iliac vessels, to the medial border of psoas major, behind which it divides into a lumbar and iliac branch.

The lumbar branch supplies psoas major and quadratus lumborum, anastomoses with the fourth lumbar artery, and sends a small *spinal branch* through the intervertebral foramen between the fifth lumbar vertebra and the base of the sacrum, into the vertebral canal to supply the cauda equina.

The *iliac branch* supplies the iliacus; between the muscle and

the bone, it anastomoses with iliac branches of the obturator; one branch enters an oblique canal to supply the ilium, others run along the iliac crest supplying the gluteal and abdominal muscles and anastomosing with the superior gluteal, circumflex iliac and lateral circumflex femoral arteries.

The lateral sacral arteries (6.93) arise from the posterior trunk of the internal iliac; there are usually a superior and an inferior. The *superior*, and larger, passes medially, enters the first or second pelvic sacral foramen, supplies the sacral vertebrae and the contents of the sacral canal, and escapes by the corresponding dorsal sacral foramen to reach the skin and muscles on the dorsum of the sacrum, anastomosing with the superior gluteal artery. The *inferior* crosses obliquely in front of the piriformis and the sacral anterior rami, descends lateral to the sympathetic trunk, and anastomoses with the median sacral and opposite lateral sacral artery over the coccyx. Branches from this vessel enter the pelvic sacral foramina to be distributed like those of the superior lateral sacral.



The superior gluteal artery (6.93, 98) is the largest branch of the internal iliac artery, and is the short continuation of its posterior trunk. It runs backwards between the lumbosacral trunk and first sacral ramus, or between the first and second rami, passing out of the pelvis through the greater sciatic foramen above the piriformis, and dividing into a *superficial* and *deep branch*. Within the pelvis it supplies piriformis and obturator internus and a nutrient artery to the innominate bone.

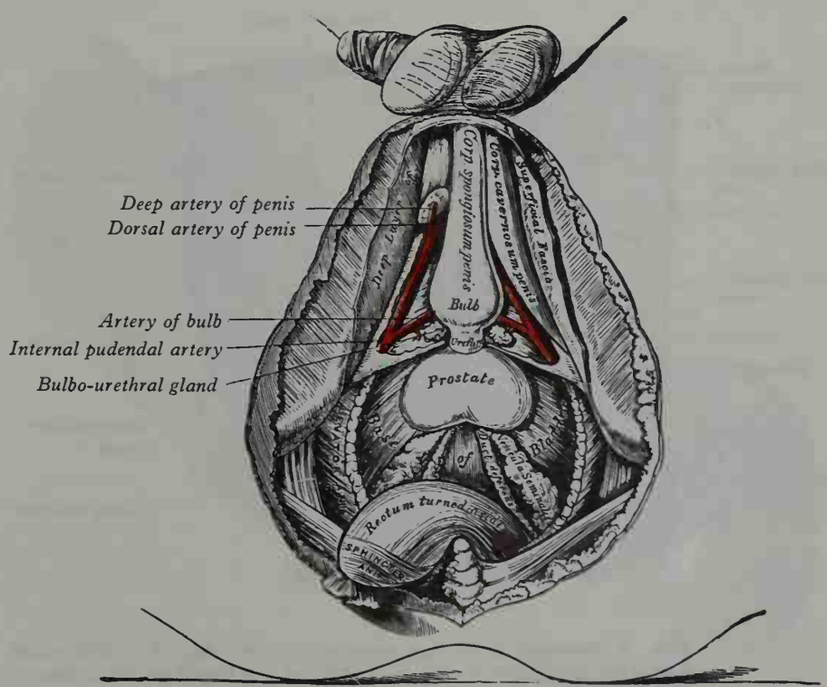
The *superficial branch* enters the deep surface of gluteus maximus, and has numerous branches; some supply the muscle and anastomose with the inferior gluteal artery; others perforate the tendinous origin of the muscle, to supply skin posterior to the sacrum, anastomosing with the posterior branches of the lateral sacral arteries.

The *deep branch* lies between gluteus medius and bone, soon forking into a superior and inferior division. The *superior* runs along the upper border of gluteus minimus to the anterior superior iliac spine, anastomosing here with the deep circumflex iliac and ascending branch of the lateral circumflex femoral artery. The *inferior division* crosses gluteus minimus obliquely, supplies it and the gluteus medius, and anastomoses with the lateral circumflex femoral artery; one branch enters the trochanteric fossa to join the inferior gluteal and the ascending branch of the medial circumflex femoral artery; other branches pierce the gluteus minimus and supply the hip joint.

The superior gluteal artery may arise from the internal iliac by a stem common to it and the inferior gluteal, and sometimes the internal pudendal.

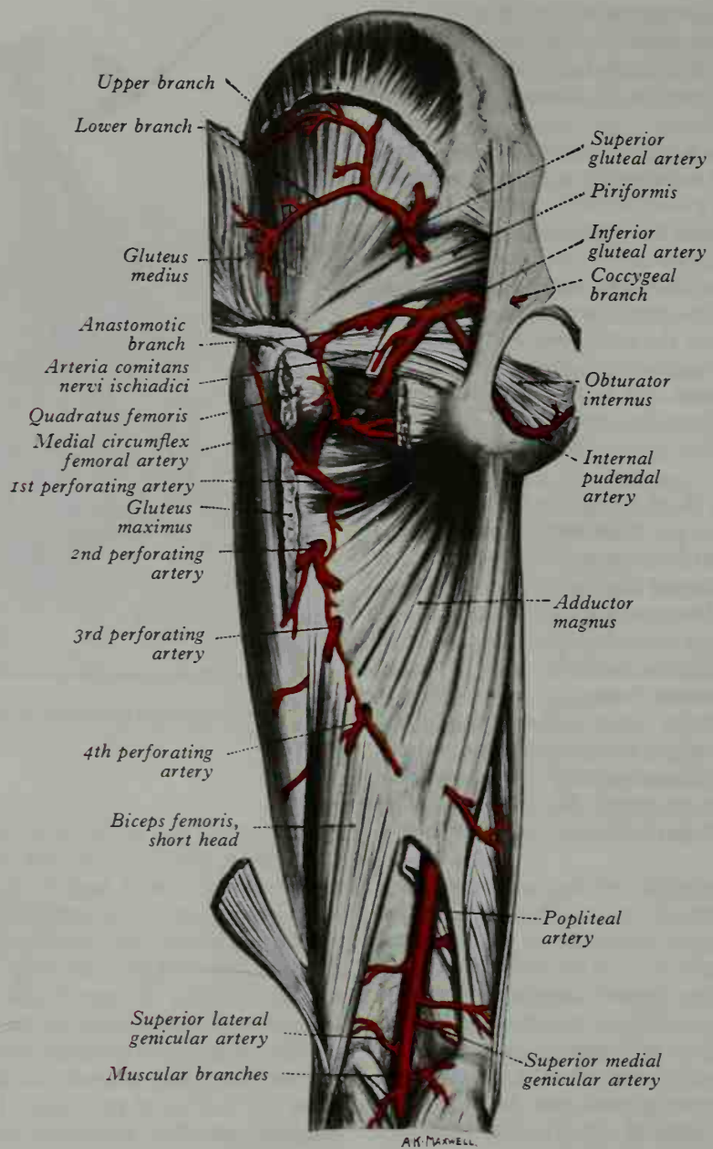
Surface Anatomy. The superior gluteal artery emerges from the pelvis at the junction of the upper and middle thirds of a line joining the posterior superior iliac spine to the apex of the greater trochanter of the femur.

6.96 The superficial branches of the internal pudendal artery, in the male.



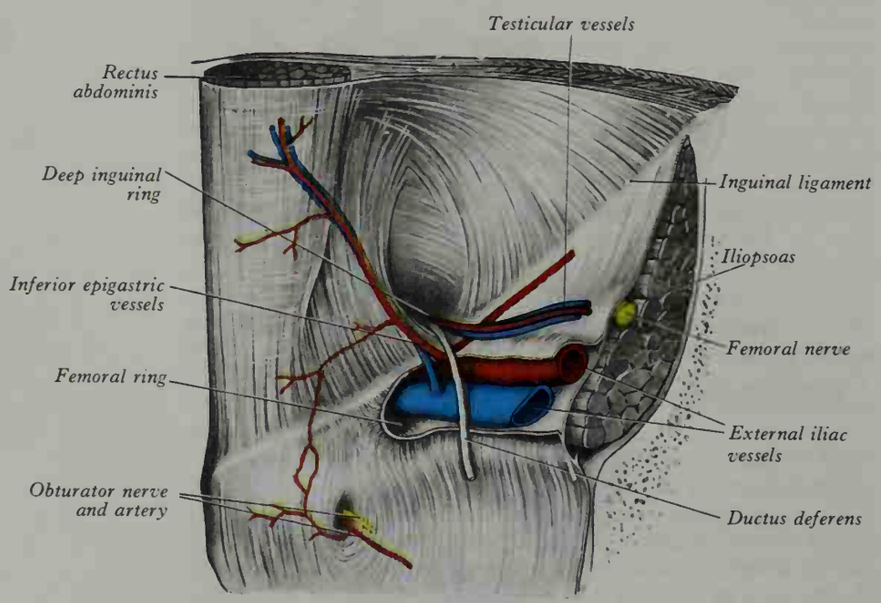
The External Iliac Arteries

The external iliac arteries (6.93, 99) are larger than the internal. Each runs obliquely down and laterally along the medial border of psoas major from the bifurcation of the common iliac artery to a point midway between the anterior superior iliac spine and symphysis pubis, where it enters the thigh behind the inguinal ligament to become the femoral artery.



In front and *medially* the external iliac artery is related to parietal peritoneum and extraperitoneal tissue, which separate the right artery from the terminal ileum and frequently the vermiform appendix, and the left artery from the sigmoid colon and some coils of small intestine. The beginning of the artery may be crossed by the ureter; in the female it is crossed by the ovarian vessels. The testicular vessels lie for some distance upon it near its termination, and here it is crossed by the genital branch of the genitofemoral nerve, the deep circumflex iliac vein, the ductus deferens or the round ligament of the uterus. *Posteriorly* it is separated from the medial border of psoas major by the iliac fascia. The external iliac vein is partly behind the upper part of the artery, but is medial to its lower part. *Laterally* it is related to psoas major, the iliac fascia being between them. Numerous lymph vessels and nodes lie on the front and sides of the vessel.

Branches. Besides supplying small branches to psoas major and neighbouring lymph nodes, the external iliac artery gives off inferior epigastric and deep circumflex iliac branches.



The inferior epigastric artery (5.52, 6.99) leaves the external iliac immediately above the inguinal ligament. It curves forwards in the extraperitoneal tissue, and ascends obliquely along the medial margin of the deep inguinal ring; continuing upward, it pierces the transversalis fascia, passes in front of the arcuate line, and ascends between rectus abdominis and the posterior lamina of its sheath. It finally divides into numerous branches, which anastomose, above the umbilicus, with those of the superior epigastric artery and the lower posterior intercostal arteries. The inferior epigastric artery thus skirts the lower and medial margins of the deep inguinal ring, and is behind the

6.97 The deeper branches of the internal pudendal artery, in the male.

6.98 The arteries of the left gluteal and posterior femoral regions.

6.99 A dissection of the deep aspect of the lower part of the abdominal wall of the right side below the level of the arcuate line of the rectus sheath. The femoral and deep inguinal rings are displayed, together with the vessels and other structures in relation to them.

commencement of the spermatic cord, separated from it by the transversalis fascia. It raises the parietal peritoneum on the posterior surface of the anterior abdominal wall, forming the *lateral umbilical fold* (p. 1324). The ductus deferens, or the round ligament of the uterus, winds round its lateral surface. The inferior epigastric artery supplies the following branches:

The *cremasteric artery* accompanies the spermatic cord, supplies cremaster and other coverings of the cord, and anastomoses with the testicular artery. In the female the artery is very small and accompanies the round ligament of the uterus.

A *pubic branch* descends, close to the femoral ring behind the pubis, and there anastomoses with the pubic branch of the obturator. Between 20 and 30 per cent of pubic branches are large, and take the place of the obturator (p. 721).

Branches are distributed to the abdominal muscles and peritoneum, and anastomose with the circumflex iliac and lumbar arteries.

Cutaneous branches perforate the aponeurosis of the external oblique, supply the skin and anastomose with branches of the superficial epigastric artery.

Variations. The inferior epigastric artery may arise from the femoral artery, and then it ascends in front of the femoral vein to enter the abdomen. It frequently comes from the external iliac artery by a common trunk with an abnormal obturator and, rarely, it arises from the obturator artery.

Applied Anatomy. The inferior epigastric artery is one of the principal means, through its anastomosis with the internal

thoracic, of establishing the collateral circulation after ligature of either the common or external iliac arteries. It is *medial* to the neck of the sac of an oblique inguinal hernia, but *lateral* to that of a direct inguinal hernia, as these emerge from the abdomen (p. 1367).

The deep circumflex iliac artery branches from the lateral side of the external iliac nearly opposite the inferior epigastric. It ascends laterally to the anterior superior iliac spine behind the inguinal ligament, in a sheath formed by junction of the transversalis and iliac fasciae. There it anastomoses with the ascending branch of the lateral circumflex femoral artery. It then pierces the transversalis fascia and passes along the inner lip of the crest of the ilium to about its middle, where it perforates the transversus abdominis and runs back between this muscle and the internal oblique, to anastomose with the iliolumbar and superior gluteal arteries. At the anterior superior iliac spine it gives off a large *ascending branch* (**5**.50), which runs between the internal oblique and transversus, supplying them, and anastomosing with the lumbar and inferior epigastric arteries.

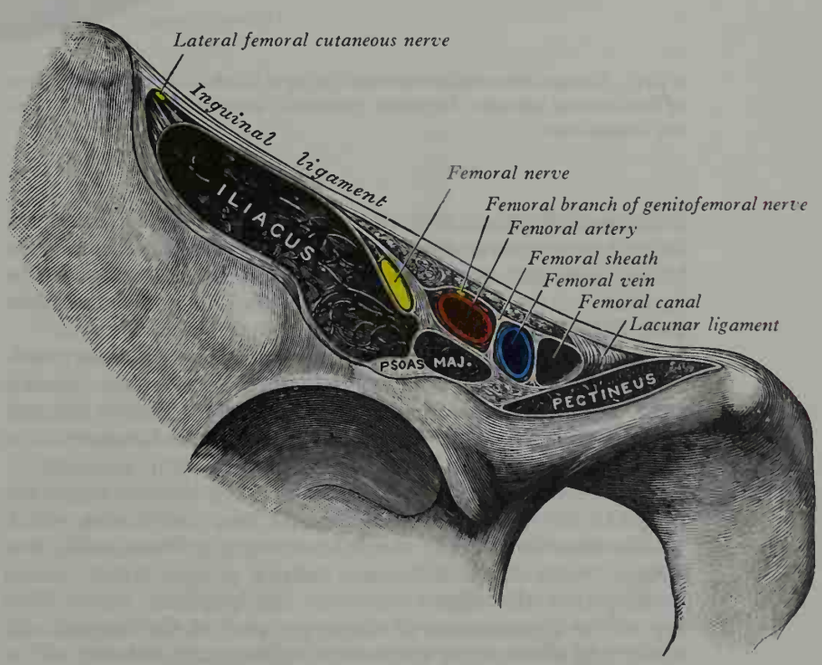
Collateral Circulation. A collateral circulation may be established in young adults after ligature of the common iliac artery; when the arterial walls are degenerated in older subjects it is unlikely to supply the limb efficiently.

THE ARTERIES OF THE LOWER LIMBS

The chief artery of the lower limb is the continuation of the external iliac. It extends from the level of the inguinal ligament to the lower border of popliteus, where it divides into the anterior and posterior tibial arteries. Its proximal part is the femoral artery, its distal, the popliteal.

The Femoral Artery

The femoral artery (**6**.100–104) is the continuation of the external iliac. It begins behind the inguinal ligament, midway between the anterior superior iliac spine and symphysis pubis, and passes down the front and medial side of the thigh. It ends at the junction of middle and inferior thirds of the thigh, where it passes through an opening in adductor magnus to become the popliteal. Above, the femoral artery is in the *femoral triangle*, below in the *adductor (subsartorial) canal*. The first 3 or 4 cm of the vessel are enclosed, with the femoral vein, in the *femoral sheath*.



The Femoral Sheath (**6**.100)

This is a downward prolongation, behind the inguinal ligament, of the transversalis fascia in front of the femoral vessels and the iliac fascia behind them. It has the form of a short funnel, wide end upwards, the lower, narrow end fusing with the fascial investment of the vessels, about 3 or 4 cm below the ligament. In the newborn the sheath is much shorter, becoming elongated after birth when extension of the thigh becomes habitual. The lateral wall of the sheath is vertical and perforated by the femoral branch of the genitofemoral nerve; the medial wall is directed obliquely down and laterally, and is pierced by the great (long) saphenous vein and lymphatic vessels. Like the carotid sheath the femoral sheath consists of a mass of connective tissue in which the femoral vessels are embedded. It is customary to describe three compartments; the lateral contains the femoral artery, the intermediate the femoral vein, while the medial and smallest compartment is named the *femoral canal*, and contains some lymph vessels and a lymph node, embedded in a small amount of areolar tissue; it is said to permit expansion of the vein. The canal is conical and measures 1·25 cm in length; its base, above, is the *femoral ring*, oval in form, its long or transverse diameter measuring 1·25 cm. The femoral ring (**6**.100) is bounded in front by the inguinal ligament, behind by pectineus and its fascia, medially by the crescentic edge of the lacunar ligament, and laterally by the femoral vein (*see*, however, p. 1367). The spermatic cord, or the round ligament of the uterus, lies immediately above the anterior margin of the ring, while the inferior epigastric vessels are close to the junction of its anterior and lateral boundaries. The ring is larger in women than in men due partly to the greater breadth of the female pelvis and partly to the smaller size of the femoral vessels. The femoral ring is filled by a condensed portion of the extraperitoneal tissue, the *femoral septum*, containing a small lymph node and covered by parietal peritoneum (see also p. 1367). The femoral septum is traversed by numerous lymph vessels connecting the deep inguinal to the external iliac lymph nodes.

The femoral triangle (**5**.85) underlies the depression immediately below the fold of the groin. Its apex is below, and its limits are, laterally, the medial margin of sartorius, medially, the medial margin of adductor longus, above the inguinal ligament. The triangle is gutter-like and is floored laterally by iliacus and psoas major, and medially by pectineus and adductor longus. The femoral vessels, extending from near the middle of its base to its apex, lie in the deepest part of the gutter. Lateral to the femoral artery the femoral nerve divides into branches. The triangle also contains some fat and lymph nodes.

The adductor (subsartorial) canal (**6**.102) is an aponeurotic tunnel in the middle third of the thigh, from the apex of the femoral triangle to the opening in adductor mangus, through which the femoral vessels pass to the popliteal fossa. It is triangular on transverse section, bounded, in front and laterally, by vastus medialis, behind, by adductor longus above and adductor magnus below, anteromedially by a strong aponeurosis extending between these muscles, across the femoral vessels, to the vastus medialis. The sartorius lies anterior to them. The canal contains the femoral artery and vein, the saphenous nerve, and the nerve to the vastus medialis proximally until it enters its muscle.

The relations of the femoral artery. In the femoral triangle (**6**.103) the artery is covered with skin and superficial fascia, the superficial inguinal lymph nodes, the fascia lata and the femoral sheath, and it is crossed by the superficial circumflex iliac vein in the superficial fascia. The femoral branch of the genitofemoral nerve travels a short distance in the lateral part of the femoral sheath, at first lateral to and then in front of the artery. Near the apex of the triangle the medial cutaneous nerve of the thigh crosses the artery from its lateral to its medial side.

6.100 The structures passing posterior to the right inguinal ligament. Inferior (distal) aspect.

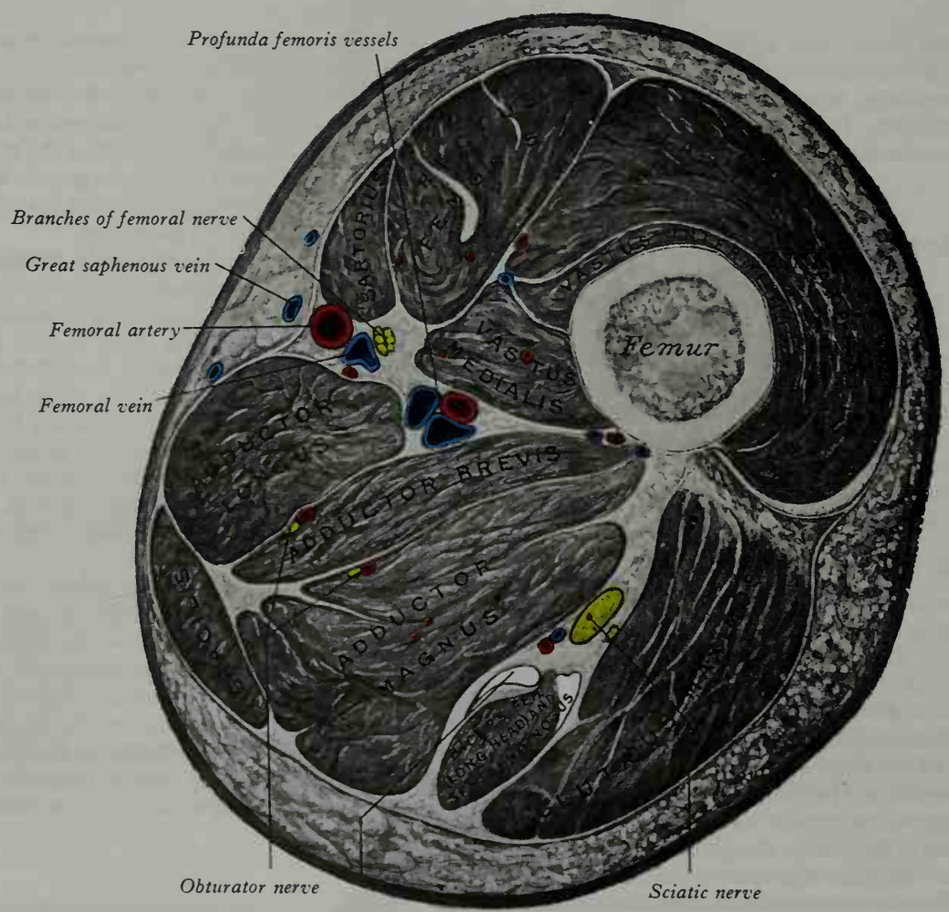
Behind, the artery is separated by the femoral sheath from the tendon of psoas major, pectineus and adductor longus, in this order distally. The artery is separated from the capsule of the hip joint by the tendon of psoas major, from pectineus by the femoral vein and profunda vessels, and from adductor longus by the femoral vein—the vessels having passed posterior to the adductor longus. The nerve to pectineus passes medially behind the upper end of the artery. Lateral to the artery is the femoral nerve. The femoral vein is medial to the artery in the upper part of the femoral triangle, and posterior in the lower part.

In the *adductor canal* (**6**.102, 103, 104) the femoral artery lies deeper, covered with skin, superficial and deep fasciae, sartorius and the fibrous roof of the canal. The saphenous nerve is at first lateral and then lies in front of it, and is medial below. Behind, the artery is related to adductor longus above, and adductor magnus below; anterolateral to it are vastus medialis and its nerve. The femoral vein lies posterior to the upper, and lateral to the lower parts of the artery.

Surface Anatomy. The artery corresponds to the upper two-thirds of a line joining a point midway between the anterior superior iliac spine and pubic symphysis to the adductor tubercle when the thigh is semiflexed, abducted and rotated laterally. The pulsations of the upper part of the vessel are readily palpable.

Variations. In rare cases the femoral artery divides, below the origin of the arteria profunda femoris, into two trunks, which reunite near the opening in adductor magnus. Occasionally it is absent, being replaced by the inferior gluteal artery, which accompanies the sciatic nerve to the popliteal fossa. This represents a persistence of the upper part of the original axis artery and the external iliac artery is then small, and ends as the arteria profunda femoris.

Applied Anatomy. Compression of the femoral artery is most effectual immediately below the inguinal ligament. Here the artery is superficial and separated from the superior pubic ramus merely by the tendon of psoas major.



Branches:

The superficial epigastric artery (**6**.103) arises from the front of the femoral about 1 cm below the inguinal ligament. Piercing the femoral sheath and cribiform fascia it ascends in front of the ligament, and between the two layers of the superficial fascia of the abdominal wall nearly to the umbilicus. It supplies the superficial inguinal lymph nodes, superficial fascia and skin; it anastomoses with branches of the inferior epigastric and with the opposite vessel.

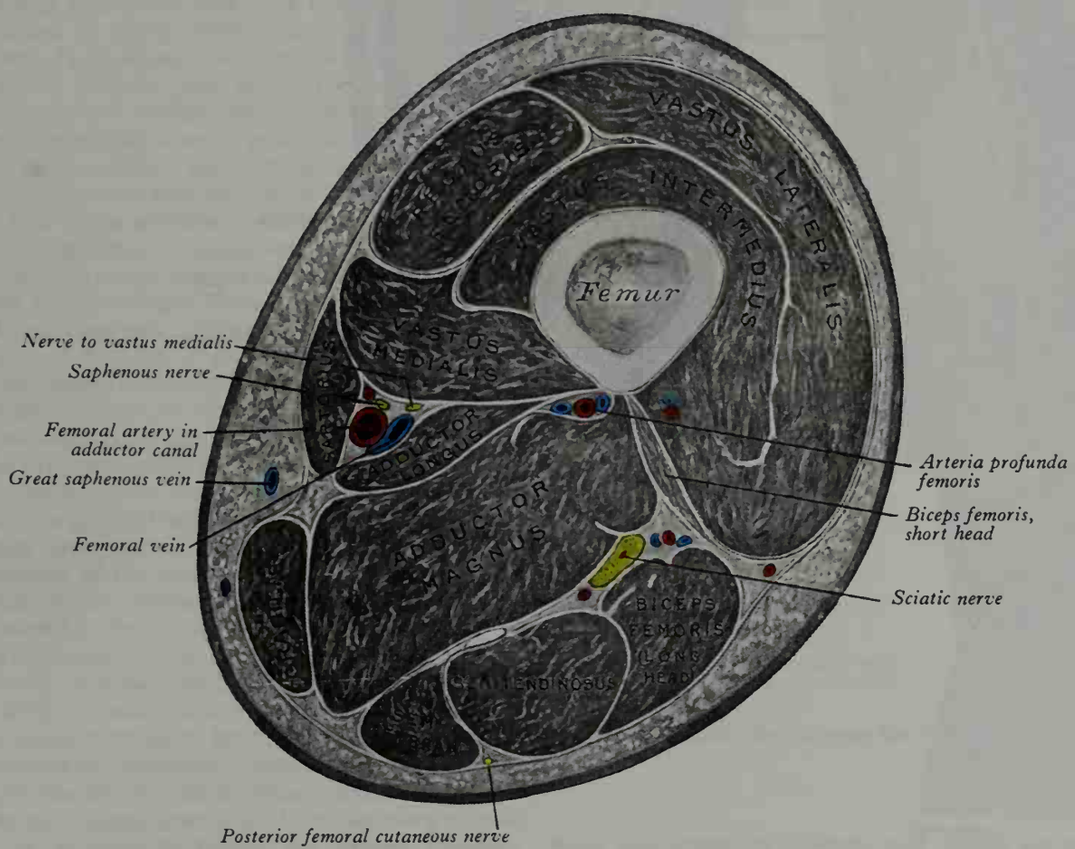
The superficial circumflex iliac artery (**6**.103), smallest of the superficial branches of the femoral, arises close to, or in common with, the superficial epigastric artery. It usually emerges through the fascia lata lateral to the saphenous opening and turns laterally just below the inguinal ligament toward the anterior superior iliac spine; it gives branches to skin, superficial fascia and superficial inguinal lymph nodes, and anastomoses with the deep circumflex iliac, superior gluteal and lateral circumflex femoral arteries.

The superficial external pudendal artery (**6**.103) arises from the medial side of the femoral artery, close to the preceding vessels. Emerging from the femoral sheath and cribriform fascia, it goes medially, usually deep to the great saphenous vein, across the spermatic cord (or round ligament of the uterus), to the skin on the lower abdomen, the penis and scrotum or the labium majus, anastomosing with branches of the internal pudendal artery.

The veins accompanying the superficial epigastric, superficial circumflex iliac and external pudendal arteries join the great saphenous vein before it enters through the saphenous opening.

6.101 A transverse section through the right thigh at the level of the apex of the femoral triangle. Superior (proximal) aspect. About four-fifths of the natural size.

The deep external pudendal artery (6.103) passes medially across pectineus and either in front of or behind adductor longus; it is covered by the fascia lata, which it pierces at the medial side of the thigh, and is distributed to the skin of the scrotum and perineum or the labium majus; its branches anastomose with the posterior scrotal (or labial) branches of the internal pudendal artery.



Muscular branches are supplied to the sartorius, vastus medialis and the adductor muscles.

The Arteria Profunda Femoris (6.102, 103, 104)

This is a large branch from the lateral side of the femoral about 3·5 cm below the inguinal ligament. At first lateral to the femoral, the profunda runs behind it and the femoral vein to the medial side of the femur, where it passes between pectineus and adductor longus and then between the latter and adductor brevis. It continues to descend between adductor longus and adductor magnus and ends by piercing the latter to anastomose with the upper muscular branches of the popliteal artery. This terminal part of the profunda is sometimes named the *fourth perforating artery*.

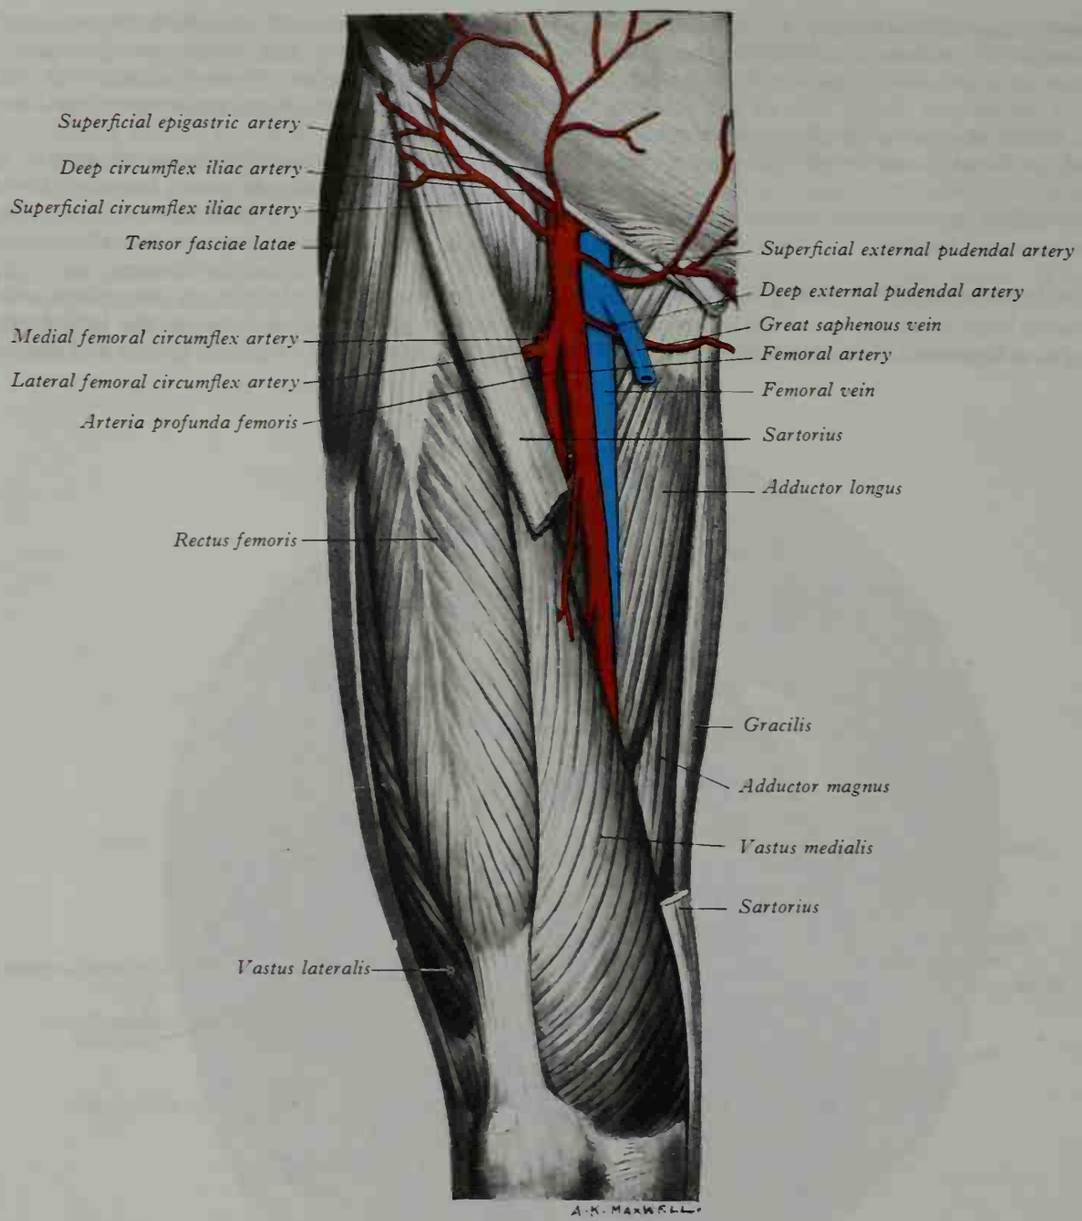
Relations. Behind, from above downwards, it is related to iliacus, pectineus, adductor brevis, and adductor magnus. *In front*, it is separated from the femoral artery by the femoral and profunda veins above, and by adductor longus below. *Laterally*, the origin of vastus medialis intervenes between the proximal part of the artery and the femur.

Variations. This vessel sometimes arises from the medial side, more rarely, from the back of the femoral artery. In the former condition it may cross in front of the femoral vein and then pass backwards round its medial side. The distance from the inguinal ligament of the origin of the vessel is variable. It is usually between 2·5 and 5 cm below it.

6.102 A transverse section through the middle of the right thigh. Superior (proximal) aspect. About four-fifths of natural size.

The arteria profunda femoris is the principal supply to the adductor, extensor and flexor muscles, and in addition it establishes a number of anastomoses with the internal and external iliac arteries above and the popliteal below.

Branches:



The lateral circumflex femoral artery arises from the lateral side of the profunda, passes laterally between the divisions of the femoral nerve, behind sartorius and rectus femoris, and divides into ascending, transverse and descending branches. Occasionally it arises from the femoral.

The *ascending branch* passes up along the intertrochanteric line, under the tensor fasciae latae, to the lateral side of the hip; it anastomoses with the superior gluteal and deep circumflex iliac arteries. It supplies the greater trochanter, and with branches of the medial circumflex femoral artery forms an anastomotic ring round the base of the neck of the femur, from which the femoral head and neck are supplied.

The *descending branch*, sometimes an independent branch direct from the profunda, or from the femoral, runs down behind the rectus femoris, along the anterior border of the vastus lateralis, which it supplies: one long branch descends in the latter muscle as far as the knee, and anastomoses with the lateral superior genicular branch of the popliteal artery. It is accompanied by the nerve to vastus lateralis.

The *transverse branch*, the smallest, passes laterally in front of vastus intermedius, pierces vastus lateralis, and winds round the femur, just below the greater trochanter, anastomosing on the back of the thigh with the medial circumflex femoral, inferior gluteal, and first perforating arteries (*cruciate anastomosis*).

The medial circumflex femoral artery usually arises from the posteromedial aspect of the profunda, but frequently from the femoral artery. It supplies the adductor muscles and then winds

6.103 The right femoral vessels and some of their branches.

medially round the femur, first between pectineus and psoas major and then between obturator externus and adductor brevis, and finally appears between quadratus femoris and the upper border of adductor magnus, where it divides into transverse and ascending branches. The *transverse branch* takes part in the cruciate anastomosis. The *ascending branch* runs obliquely upwards upon the tendon of obturator externus and in front of quadratus femoris towards the trochanteric fossa, where it anastomoses with branches of the gluteal arteries and lateral circumflex femoral artery. An *acetabular branch* from the medial circumflex femoral at the upper border of adductor brevis enters the hip joint below the transverse acetabular ligament with the acetabular branch of the obturator; it supplies fat in the acetabular fossa, and reaches the head of the femur along its ligament. For details of blood supply of the proximal extremity of the femur consult Crock (1965).

The perforating arteries (**6**.98), usually three, are so named because they perforate the insertion of the adductor magnus to reach the back of the thigh. They pass back close to the linea aspera of the femur under small tendinous arches in the insertion of the muscle, and give off muscular, cutaneous and anastomosing branches. Reduced in size, they pass deep to the short head of biceps femoris (the first usually pierces the insertion of gluteus maximus), go through the lateral intermuscular septum and enter the vastus lateralis. The first perforating artery is above the adductor brevis, the second in front of it, and the third immediately below it.

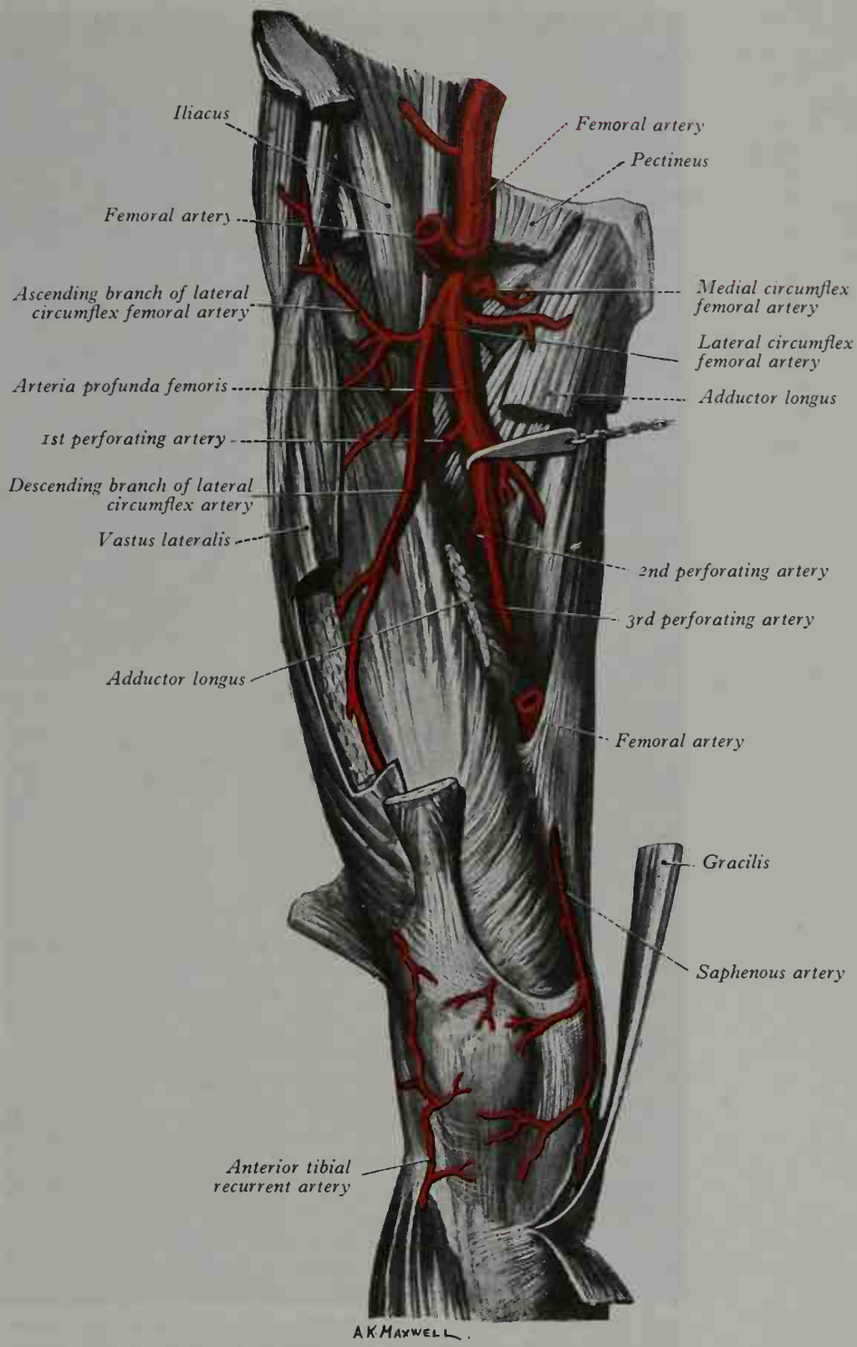
The *first perforating artery* passes back between pectineus and adductor brevis (sometimes it perforates the latter); it then pierces adductor magnus close to the linea aspera. It supplies adductor brevis, adductor magnus, biceps femoris and gluteus maximus, and anastomoses with the inferior gluteal, medial and lateral circumflex femoral, and second perforating arteries.

The *second perforating artery*, larger than the first, frequently arising in common with it, pierces the insertions of adductor brevis and adductor magnus, and divides into ascending and descending branches, which supply the posterior femoral muscles, anastomosing with the first and third perforating arteries. The *nutrient artery* of the femur usually comes from it; when two nutrient arteries exist, they usually come from the first and third perforating vessels.

The *third perforating artery* starts below adductor brevis, pierces the insertion of adductor magnus, and divides into branches to the posterior femoral muscles; it anastomoses above with the higher perforating arteries, and below with the termination of the profunda and the muscular branches of the popliteal. The nutrient artery of the femur may arise from this branch. Offshoots from the principal diaphysial nutrient arteries and other branches of the profunda, also provide subsidiary cortical arteries of the femur (Crock 1967).

The termination of the profunda, as already described, is sometimes called the *fourth perforating artery*.

The perforating arteries form a *double chain of anastomoses:* (*a*) in the adductor muscles and (*b*) close to the linea aspera.



Numerous muscular branches arise from the arteria profunda femoris; some end in the adductors, others pierce adductor magnus, give branches to the hamstrings, and anastomose with the medial circumflex femoral artery and with the superior muscular branches of the popliteal artery. The profunda femoris artery is the *main* supply to the thigh muscles.

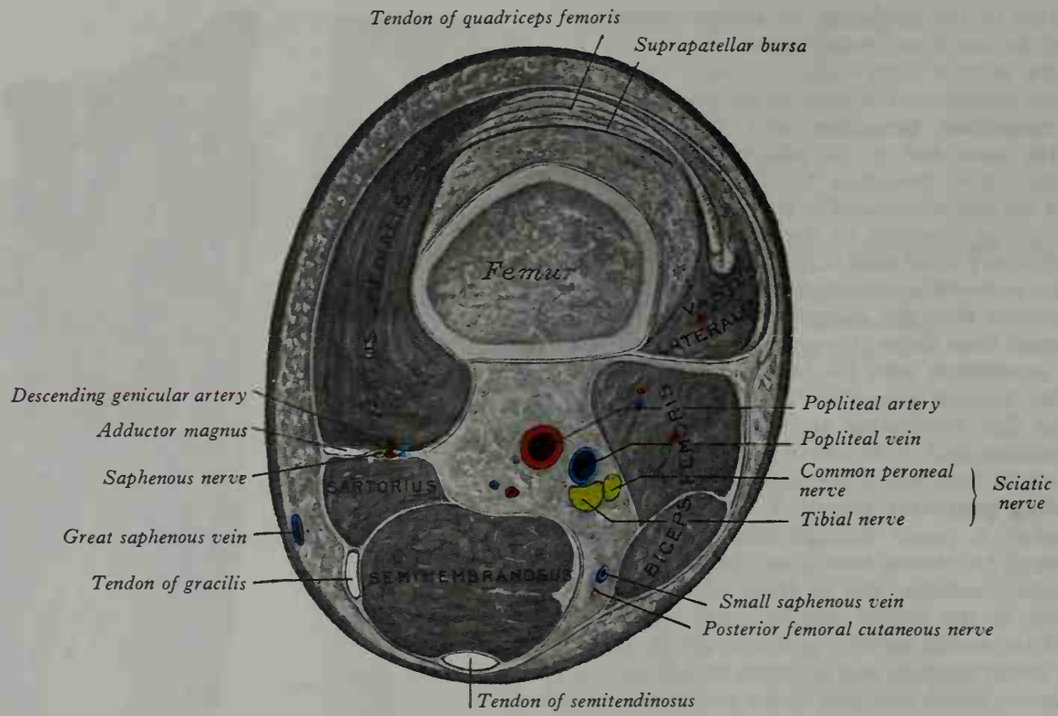
The *anastomosis on the back of the thigh.* This important chain of anastomoses stretches from the gluteal region to the popliteal fossa, and is formed from above downwards, as follows: (*a*) the gluteal arteries anastomose with the terminal branches of the medial circumflex femoral artery, (*b*) the circumflex femoral arteries with the first perforating artery, (*c*) the perforating arteries with each other, and (*d*) the fourth perforating artery with the superior muscular branches of the popliteal artery.

The descending genicular artery (**6**.108) arises from the femoral just before it passes through adductor magnus. It immediately gives off a *saphenous branch*, and then descends in the substance of vastus medialis, and in front of the tendon of adductor magnus, to the medial side of the knee, where it anastomoses with the medial superior genicular artery. *Muscular branches* supply vastus medialis and adductor magnus, and give off *articular branches*, which take part in the anastomosis round the knee joint. One of the articular branches crosses above the patellar surface of the femur, forming an arch with the lateral superior genicular artery, and supplying the knee joint.

The *saphenous branch* emerges through the lower part of the roof of the adductor canal and accompanies the saphenous nerve to the medial side of the knee. It passes between sartorius and gracilis, and is distributed to the skin of the upper and medial part of the leg, anastomosing with the medial inferior genicular artery.

Collateral Circulation. After ligation of the femoral artery above the origin of the profunda femoris artery, the main channels for carrying on the circulation are the following anastomoses: (1) the superior and inferior gluteal branches of the internal iliac artery with the medial and lateral circumflex femoral and first perforating branches of the arteria profunda femoris; (2) the obturator branch of the internal iliac artery with the medial circumflex femoral of the arteria profunda femoris; (3) the internal pudendal branch of the internal iliac artery with the superficial and deep external pudendal branches of the femoral artery; (4) the deep circumflex iliac branch of the external iliac artery with the lateral circumflex femoral branch of the arteria profunda femoris and the superficial circumflex iliac branch of the femoral artery; (5) the inferior gluteal branch of the internal iliac artery with the perforating branches of the arteria profunda femoris.

6.104 The right profunda femoris artery and its branches.



The Popliteal Fossa (**5**.100, **6**.106, **7**.216, **7**.217)

This is a diamond-shaped region at the back of the knee joint only apparent as a depression when disturbed by dissection. *Laterally*, it is bounded by biceps femoris above, the plantaris and lateral head of gastrocnemius below; *medially*, it is limited by semitendinosus and semimembranosus above and by the medial head of gastrocnemius below. *Anteriorly* the region is limited by the popliteal surface of the femur, the oblique popliteal ligament of the knee joint, the back of the upper end of the tibia and the fascia covering the popliteus, which collectively form a so-called floor. The fossa is covered *posteriorly* by the popliteal fascia.

Contents (**6**.106; **7**.216). Until its boundaries are disturbed, the popliteal fossa is only about 2·5 cm wide, and very little can be seen of its contents, especially so in the lower part of the space, where the two heads of gastrocnemius are in contact. When, however, the boundaries are drawn apart the fossa is seen to contain the popliteal vessels, tibial and common peroneal (medial and lateral popliteal) nerves, termination of the small saphenous vein, lower part of the posterior femoral cutaneous nerve, an articular branch from the obturator nerve, a few small lymph nodes and fat. The tibial nerve descends through the middle of the region lying anterior to the popliteal fascia, and crossing the vessels posteriorly from lateral to medial side. The common peroneal nerve descends laterally in the fossa, close to the tendon of biceps femoris. The popliteal vessels are on the floor of the fossa, the vein superficial to the artery and united to it by dense areolar tissue. The vein is thick-walled, and lateral to the artery above, and then crosses it posteriorly to its medial side below; sometimes it is double, the artery lying between the two veins, usually connected by short transverse branches. The articular branch from the obturator nerve descends upon the popliteal artery to the knee joint. The popliteal lymph nodes, six or seven in number, are embedded in the fat; one lies beneath the popliteal fascia near the termination of the small saphenous vein, another between the popliteal artery and the back of the knee joint, while the others flank the popliteal vessels.

The Popliteal Artery

The popliteal artery (**6**.105, 106, 107) is the continuation of the femoral, and traverses the popliteal fossa. It commences at the opening in adductor magnus, at the junction of middle and distal

6.105 A transverse section through the right thigh, 4 cm above the adductor tubercle of the femur. Superior (proximal) aspect. About four-fifths of natural size.

thirds of the thigh, and extends downwards and laterally to the intercondylar fossa of the femur. Thence it continues *obliquely* to the lower border of popliteus, where it divides into *anterior* and *posterior tibial arteries* (*see* **6**.107).

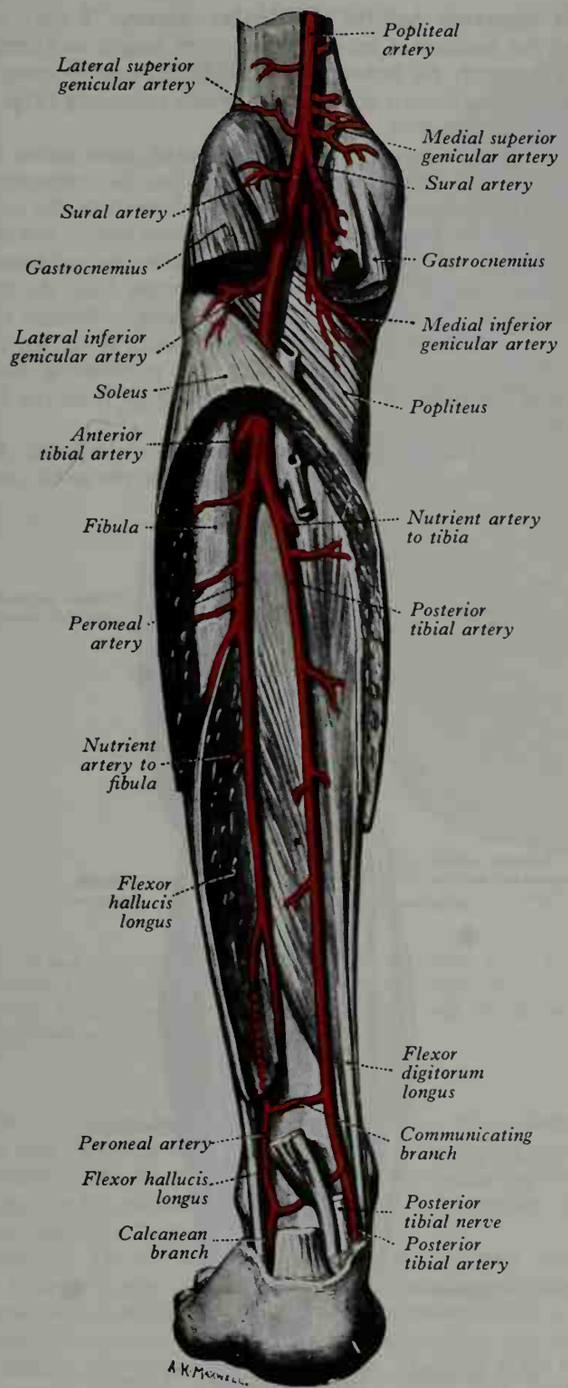
Relations. In *front*, from above downwards, are the fat covering the popliteal surface of the femur, capsule of the knee joint, and the fascia of popliteus. *Behind* (superficially), it is overlapped by semimembranosus above, and is covered by gastrocnemius and plantaris below. In the middle part of its course the artery is separated from skin and fasciae by fat, and is crossed from lateral to medial side by the tibial nerve and popliteal vein, the vein being between the nerve and the artery and closely adherent to the latter. *Laterally*, above, are biceps femoris, the tibial nerve, popliteal vein and lateral condyle of the femur, below, plantaris and the lateral head of gastrocnemius. On its *medial* side, above, are semimembranosus and the medial condyle of the femur, below, the tibial nerve, popliteal vein and medial head of gastrocnemius. The relations of the popliteal lymph nodes to the artery are described on p. 791.

Variations. Occasionally the popliteal artery divides into terminal branches above the level of popliteus, and then the anterior tibial artery descends *anterior* to it. The popliteal artery sometimes divides into the anterior tibial and peroneal arteries, the posterior tibial artery being wanting or rudimentary; occasionally it divides into three branches, the anterior and posterior tibial, and peroneal arteries.

Surface Anatomy. The popliteal artery is represented by a line from the junction of the middle and lower thirds of the thigh 2·5 cm medial to the middle line of the back of the limb, running down and laterally to the midline between the femoral condyles. It continues obliquely inferolaterally until the level of the tibial tuberosity.

Branches. The popliteal artery has cutaneous, muscular and genicular branches, reaching the tibiofibular interosseous gap.

The cutaneous branches leave either the popliteal artery or some of its branches; they descend between the two heads of gastrocnemius, and pass through the deep fascia to the skin of the back of the leg; one usually accompanies the small saphenous vein.



Superior muscular branches (two or three) arise from the upper part of the artery, and pass to adductor magnus and the hamstring muscles, anastomosing with the terminal part of the arteria profunda femoris.

Sural arteries (two in number and large) arise behind the knee joint to supply gastrocnemius, soleus and plantaris.

The superior genicular arteries (**6**.106, 108) diverge from the popliteal artery, and wind round the femur immediately above both condyles to gain the front of the knee joint. The *medial superior genicular artery* runs under semimembranosus and semitendinosus, above the medial head of gastrocnemius, and passes deep to the tendon of adductor magnus. It divides into a branch which supplies vastus medialis and anastomoses with the descending genicular and medial inferior genicular arteries, and one which ramifies on the surface of the femur and anastomoses with the lateral superior genicular artery. The size of the medial superior genicular artery varies inversely with that of the descending genicular. The *lateral superior genicular artery* passes under the tendon of biceps femoris, and divides into a superficial and a deep branch; the superficial supplies vastus lateralis, and anastomoses with the descending branch of the lateral circumflex femoral and the lateral inferior genicular artery; the deep branch anastomoses with the medial superior genicular artery and forms an arch across the front of the femur with the descending genicular.

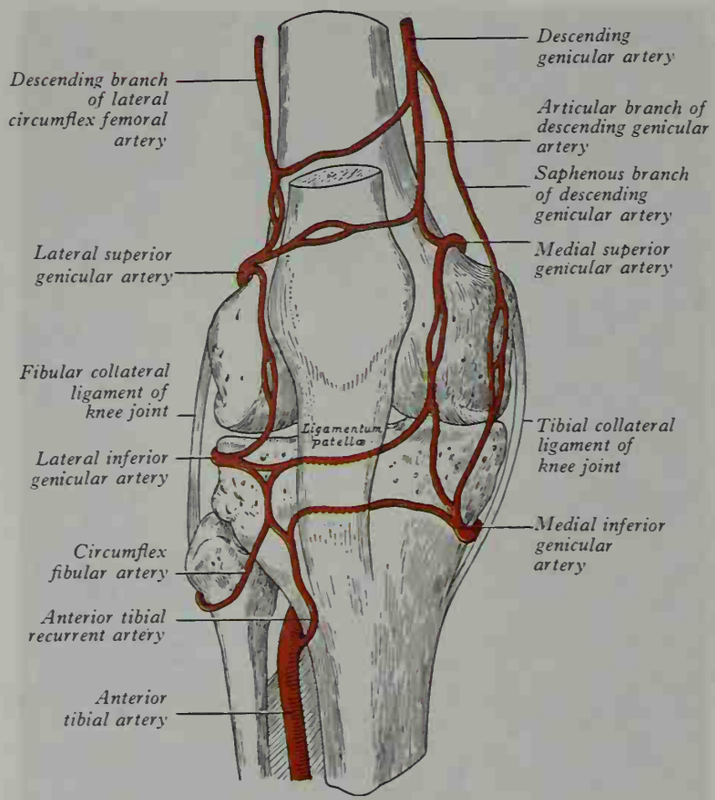
The middle genicular artery, a small branch, arises from the popliteal artery opposite the back of the knee joint; it pierces the oblique popliteal ligament, and supplies the cruciate ligaments and the synovial membrane of the knee joint.

The inferior genicular arteries (**6**.106, 108) arise from the popliteal artery under gastrocnemius. The *medial* lies deep to the medial head of gastrocnemius and descends along the upper margin of popliteus, which it supplies; it then passes below the medial condyle of the tibia and under the tibial collateral ligament of the knee; at the anterior border of this ligament it ascends to the front and medial side of the joint, supplies it and the upper end of the tibia, and anastomoses with the lateral inferior and medial superior genicular arteries. It also anastomoses with the anterior tibial recurrent artery and the saphenous branch of the descending genicular artery. The *lateral inferior genicular artery* runs laterally across popliteus, and then forwards above the head

6.106 The left popliteal, posterior tibial and peroneal arteries. Dorsal aspect.

6.107 Popliteal arteriogram. Anteroposterior view. (Adult male of 63 years.) The following arteries can be identified—1. Popliteal. 2. Descending genicular. 3. Superior medial and lateral genicular. 4. Inferior medial and lateral genicular. 5. Middle genicular. 6. Anterior tibial. 7. Posterior tibial. 8. Peroneal. Note the obliquity of the popliteal artery.

of the fibula to the front of the knee joint, passing under the lateral head of gastrocnemius, the fibular collateral ligament of the knee, and the tendon of biceps femoris. It divides into branches which anastomose with the medial inferior genicular, lateral superior genicular and anterior and posterior tibial recurrent, and circumflex fibular arteries.



The Genicular Anastomosis (**6**.108)

Around the patella, and the contiguous ends of femur and tibia, an intricate arterial anastomosis exists. A *superficial network* is situated between the fascia and skin around the patella and in the fat behind the ligamentum patellae. A *deep network* lies on the femur and tibia round the adjoining articular surfaces, supplying bone and marrow, the capsule and synovial membrane of the joint. The vessels involved are the medial and lateral genicular, the descending genicular, the descending branch of the lateral circumflex femoral, the circumflex fibular, and the anterior and posterior tibial recurrent arteries.

The Anterior Tibial Artery (**6**.106, 107, 109, 110)

This is a terminal branch of the popliteal, arising at the lower border of popliteus. At first in the back of the leg, it passes forwards between the two heads of tibialis posterior and through the upper part of the interosseous membrane to the front of the leg, medial to the neck of the fibula. Descending on the front of the interosseous membrane, it gradually approaches the tibia, lying on it lower in the leg (**6**.111). In front of the ankle it is midway between the malleoli, and is continued on the dorsum of the foot as the *dorsalis pedis artery*.

Relations. In its upper two-thirds, the anterior tibial artery descends upon the interosseous membrane, in the lower third, upon the front of the tibia and ankle joint. In its upper third, it is between tibialis anterior and extensor digitorum longus; in the middle third between tibialis anterior and extensor hallucis longus. At the ankle it is crossed superficially from the lateral to the medial side by the tendon of extensor hallucis longus, and is then between this and the first tendon of extensor digitorum

6.108 The arterial anastomosis around the knee joint. (Schematic.)

longus. Its upper two-thirds are covered by the muscles which flank it and by deep fascia, its lower third by the skin and fasciae, and the extensor retinacula.

Venae comitantes lie on each side of the artery. The deep peroneal nerve, coursing round the lateral side of the neck of the fibula, comes into relation with the lateral side of the artery shortly after it reaches the front of the leg; about the middle of the leg the nerve is in front of the artery; lower, it is generally lateral.

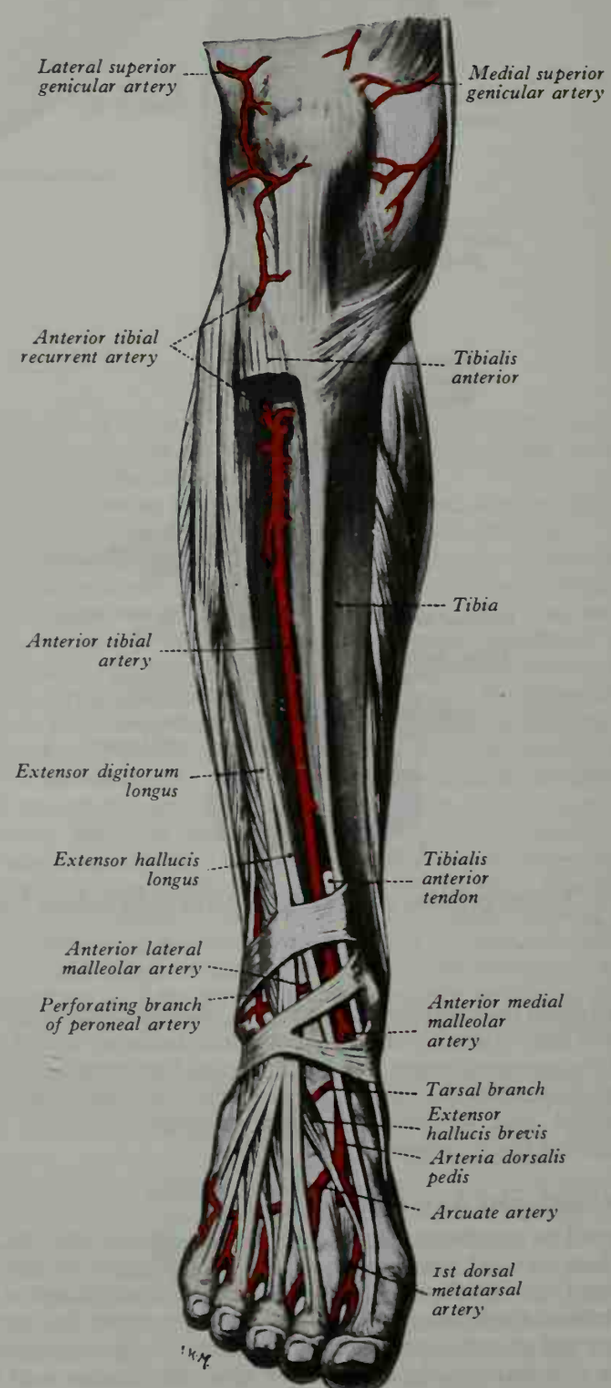
Surface Anatomy. In surface projection the anterior tibial artery begins 2·5 cm below the medial side of the head of the fibula and ends at the midpoint between the malleoli. The vessel can be felt pulsating lateral to the tendon of extensor hallucis longus at the ankle.

Variations. This vessel may be smaller than usual, or even absent, being replaced by perforating branches from the posterior tibial, or by the perforating branch of the peroneal artery. The artery occasionally deviates towards the fibular side of the leg, regaining its usual position at the front of the ankle.

Branches:

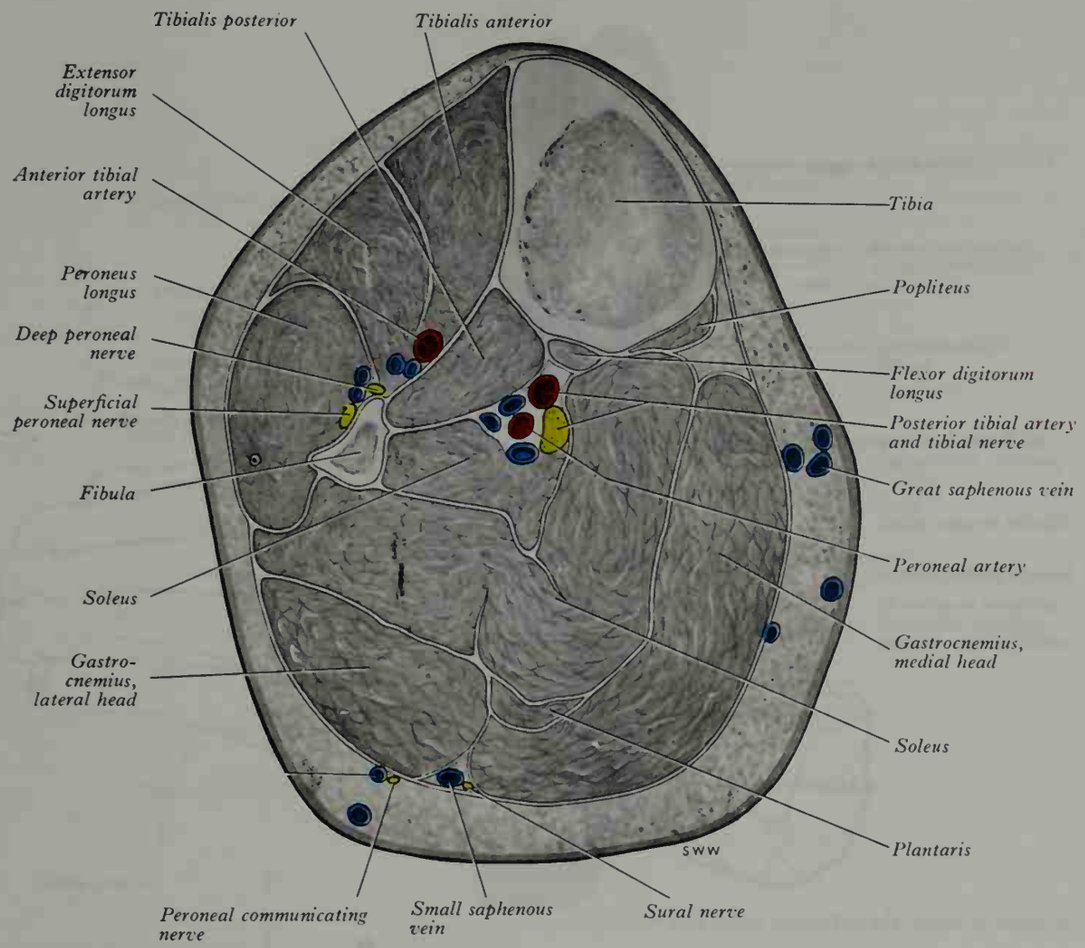
The posterior tibial recurrent artery—an inconstant branch—is given off from the anterior tibial before it reaches the front of the leg. It ascends in front of popliteus with the nerve to the muscle, anastomoses with the inferior genicular branches of the popliteal, and supplies the superior tibiofibular joint.

The anterior tibial recurrent artery (**6**.109) arises as soon as the anterior tibial has reached the front; it ascends in tibialis anterior, ramifies on the front and sides of the knee joint, and joins the patellar network, anastomosing with the genicular branches of the popliteal and the circumflex fibular artery.



Numerous muscular branches are distributed to the muscles on each side of the anterior tibial; some pierce deep fascia to supply skin, others pass through the interosseous membrane to anastomose with branches of the posterior tibial and peroneal arteries.

The anterior medial malleolar artery (**6**.109) starts about 5 cm above the ankle, passing behind the tendons of extensor hallucis longus and tibialis anterior to the medial side of the joint, where it joins branches of the posterior tibial and medial plantar arteries.



The anterior lateral malleolar artery (**6**.109) passes behind the tendons of extensor digitorum longus and peroneus tertius to supply the lateral side of the ankle, anastomosing with the perforating branch of the peroneal and ascending twigs from the lateral tarsal artery.

The arteries around the ankle joint anastomose freely (**6**.112) to form networks around and below the corresponding malleoli. The *medial malleolar network* is formed by the anterior medial malleolar branch of the anterior tibial artery, the medial tarsal branches of the dorsalis pedis, the malleolar and calcanean branches of the posterior tibial, and branches from the medial plantar artery. The *lateral malleolar network* is formed by the anterior lateral malleolar branch of the anterior tibial, the lateral tarsal branch of the dorsalis pedis, the perforating and the calcanean branches of the peroneal, and twigs from the lateral plantar artery.

The dorsal artery of the foot (arteria dorsalis pedis) (**6**.109) is the extension of the anterior tibial distal to the ankle joint. It

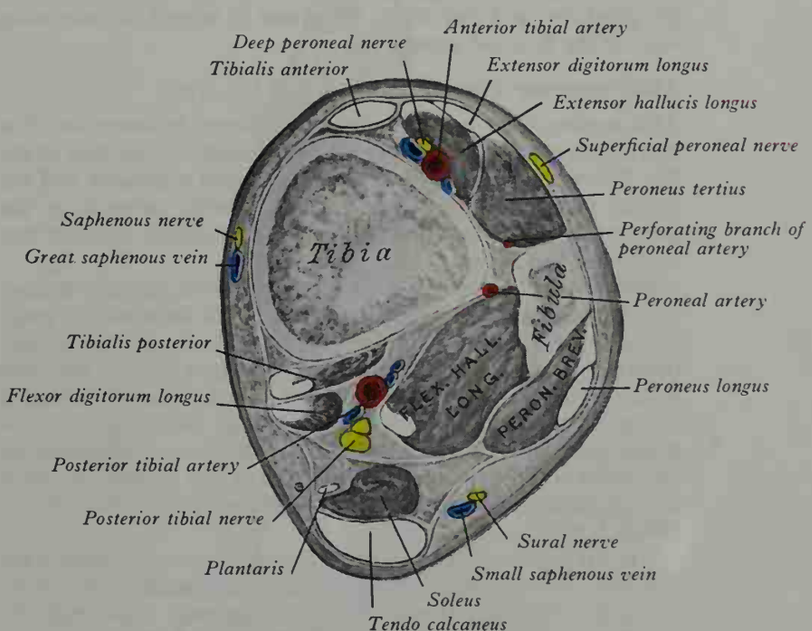
6.109 The right anterior tibial and dorsalis pedis arteries. A large part of the tibialis anterior has been excised and the extensor hallucis longus retracted laterally to expose the anterior tibial artery.

6.110 A transverse section through the right leg, about 10 cm below the knee joint. Inferior (distal) aspect. At a slightly lower level the flexor digitorum longus intervenes between the soleus and the fascia on the posterior surface of the tibialis posterior.

follows the tibial side of the dorsum of the foot to the proximal end of the first intermetatarsal space, where it turns into the sole of the foot between the two heads of the first dorsal interosseous muscle, to complete the plantar arch. At this junction it provides the *first plantar metatarsal artery*.

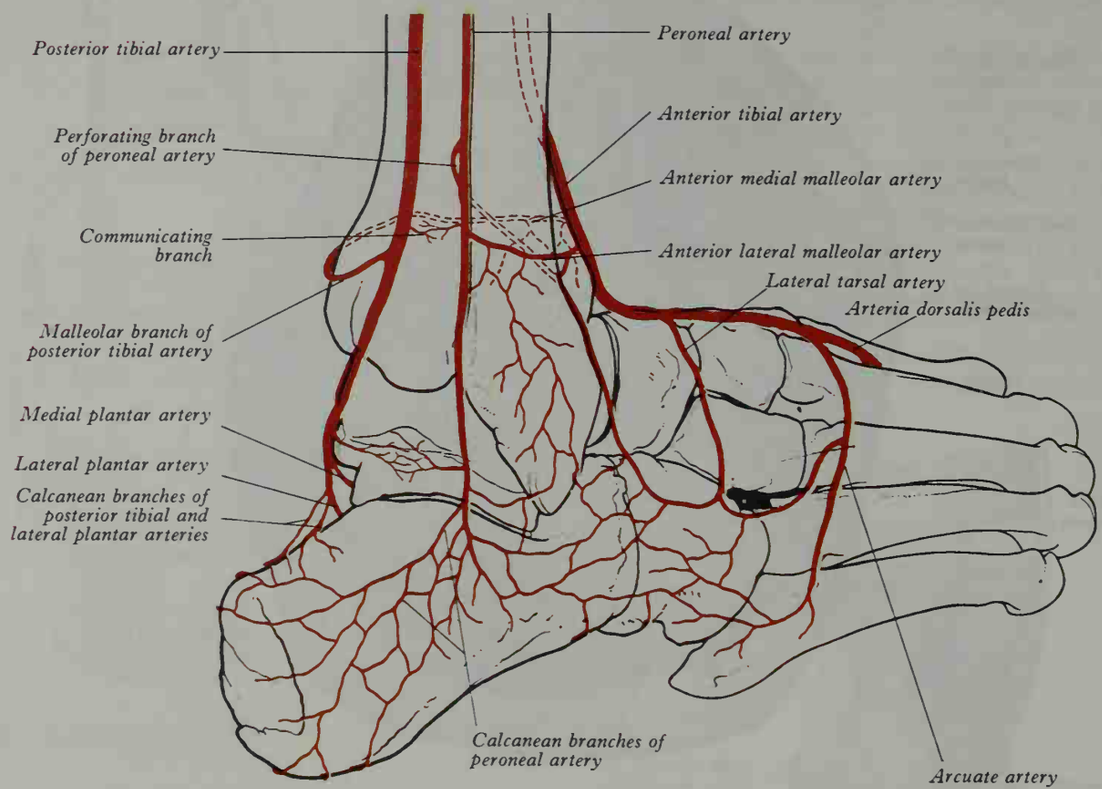
Relations. The dorsal artery of the foot successively crosses in front of the articular capsule of the ankle, the talus, navicular and intermediate cuneiform, and their ligaments. Superficial to it are the skin, fasciae and inferior extensor retinaculum and, near its termination, the extensor hallucis brevis. *Medially* is the tendon of extensor hallucis longus; *laterally* are the first tendon of extensor digitorum longus, and the medial terminal branch of the deep peroneal nerve.

Surface Anatomy. Being superficial, the vessel can be felt pulsating along a line from the midpoint between the malleoli to the proximal end of the first intermetatarsal space.



Variations. The dorsal artery of the foot may be larger than usual, to compensate for a small lateral plantar artery; or it may be replaced by a large perforating branch of the peroneal artery. It frequently curves laterally, diverging from its usual direct route.

Branches. The dorsal artery of the foot has tarsal, arcuate and first dorsal metatarsal branches.



The tarsal arteries, lateral and medial (**6**.109), come from the arteria dorsalis pedis as it crosses the navicular bone. The lateral branches outwards under extensor digitorum brevis; it supplies this and the articulations of the tarsus, and anastomoses with branches of the arcuate, anterior lateral malleolar, and lateral plantar arteries, and with the perforating branch of the peroneal.

Two or three medial tarsal branches ramify on the medial border of the foot and join the medial malleolar network.

The arcuate artery (**6**.109) arises from the dorsal artery of the foot opposite the medial cuneiform; it passes laterally over the bases of the metatarsal bones deep to the tendons of the extensores digitorum longus et brevis, and anastomoses with the lateral tarsal and lateral plantar arteries. It gives off the *second*, *third* and *fourth dorsal metatarsal arteries*, which run distally upon the corresponding dorsal interosseous muscles; in the clefts between the toes each divides into two dorsal digital branches for the sides of adjoining toes. At the proximal parts of the interosseous spaces

6.111 A transverse section through the right leg, about 6 cm above the tip of the medial malleolus. Superior (proximal) aspect.

6.112 The arterial anastomoses of the ankle and tarsus and metatarus.

the dorsal metatarsal arteries receive the *proximal perforating branches* from the plantar arch, and at the distal parts of the spaces they are joined by the *distal perforating branches* from the plantar metatarsal arteries. The fourth dorsal metatarsal artery gives off a branch to the lateral side of the fifth toe.

The first dorsal metatarsal artery arises just before the arteria dorsalis pedis passes into the sole; it runs distally on the first dorsal interosseous muscle, and at the cleft between the first and second toes divides into two, a branch passing beneath the tendon of extensor hallucis longus and distributed to the medial border of the great toe, and one which bifurcates to supply the adjoining sides of the first and second toes.

The Posterior Tibial Artery (6.106, 107, 110)

This begins at the lower border of popliteus, between the tibia and fibula, and passes downwards and medially on the back of the leg. Below, it is midway between the medial malleolus and the medial process of the tuber calcanei (medial tubercle of the calcaneus). It divides under the origin of abductor hallucis into the *medial* and *lateral plantar arteries*.

Relations. The posterior tibial artery lies successively behind tibialis posterior, flexor digitorum longus, the tibia and the ankle joint. Its upper part is covered by gastrocnemius and soleus, and deep transverse fascia of the leg, its lower part only by skin and fascia. It runs parallel with and about 2·5 cm in front of the medial border of the tendo calcaneus; its terminal part is deep to the flexor retinaculum and abductor hallucis. It is accompanied by two veins and the tibial nerve, which is at first medial, but soon crosses posteriorly, to become, in the greater part of its course, a lateral relation.

The arrangement of structures passing from the back of the leg into the sole under the flexor retinaculum is described on p. 611.

Surface Anatomy. The posterior tibial artery runs from the middle line of the calf at the level of the neck of the fibula to the midpoint between the medial malleolus and the prominence of the heel, where its pulsations can be felt.

Branches:

The circumflex fibular artery, sometimes a branch of the anterior tibial artery, passes laterally round the neck of the fibula, through soleus, to anastomose with the lateral inferior genicular, the medial genicular and anterior tibial recurrent arteries. It supplies bone and articular structures.

The peroneal artery (6.106) arising from the posterior tibial about 2·5 cm below the lower border of popliteus passes obliquely towards the fibula, and descends along its medial crest in a fibrous canal between tibialis posterior and flexor hallucis longus, or in the substance of the latter muscle. It is then behind the tibiofibular syndesmosis, and divides into calcanean branches, which ramify on the lateral and posterior surfaces of the calcaneus. Its *upper* part is covered by soleus and the deep transverse fascia, between this and the deep muscles; its *lower* part is overlapped by flexor hallucis longus.

Variations. The peroneal artery may spring from the posterior tibial higher than usual, or may even branch from the popliteal; sometimes it arises 7 or 8 cm below the inferior border of popliteus. It is more frequently increased than diminished in size; it either joins and reinforces the posterior tibial artery, or takes its place when large, in the lower leg and foot.

Branches:

Muscular branches supply soleus, tibialis posterior, flexor hallucis longus and the peronei. A *nutrient artery* is directed downwards into the fibula. A *perforating branch* traverses the interosseous membrane about 5 cm above the lateral malleolus, to reach the front of the leg, where it anastomoses with the anterior lateral malleolar artery; it then descends in front of the tibiofibular syndesmosis, supplies the tarsus, and anastomoses with the lateral tarsal artery. The perforating branch is sometimes enlarged, and may take the place of the dorsalis pedis artery. A *communicating branch* connects the peroneal artery about 5 cm above the lower end of the tibia to the communicating branch of the posterior tibial artery. The *calcanean* or terminal branches of the peroneal artery communicate with the anterior lateral malleolar artery

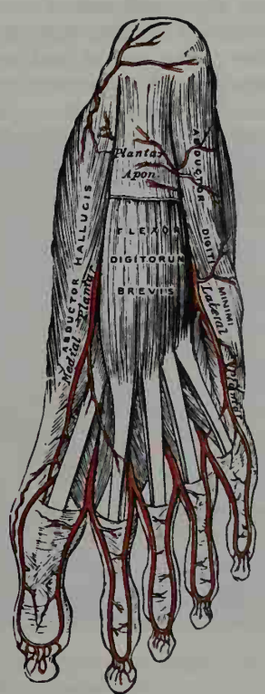
6.113 The plantar arteries of the right foot.

lateral to the heel and with the calcanean branches of the posterior tibial artery behind it.

The nutrient artery of the tibia arises from the posterior tibial artery near its origin; after supplying a few minute muscular branches, it descends into the nutrient canal in the bone, immediately below the soleal line. It is one of the largest nutrient arteries in the body.

Muscular branches of the posterior tibial artery are distributed to soleus and the deep muscles on the back of the leg.

The communicating branch runs transversely across the back of the tibia about 5 cm above its lower end, deep to flexor hallucis longus, and joins the communicating branch of the peroneal.



The medial malleolar branches wind round the tibial malleolus to the medial malleolar network.

The calcanean branches arise from the posterior tibial just above its division; they pierce the flexor retinaculum to supply fat and skin behind the tendo calcaneus and about the heel, and the muscles on the tibial side of the sole; they anastomose with the medial malleolar arteries and calcanean branches of the peroneal arteries.

The medial plantar artery (**6**.113, 114), the smaller terminal branch of the posterior tibial, passes distally along the medial side of the foot with the medial plantar nerve, which is lateral to it. At first deep to abductor hallucis, it runs distally between this and flexor digitorum brevis, supplying both. At the base of the first metatarsal bone, much diminished in size, it passes along the medial border of the first toe and anastomoses there with a branch of the first metatarsal artery. It supplies three small superficial digital branches which accompany the digital branches of the medial plantar nerve and join the first, second and third plantar metatarsal arteries.

Surface Anatomy. The trunk of the medial plantar artery begins midway between the medial malleolus and the prominence of the heel and runs forwards in the direction of the first interdigital cleft as far as the navicular bone.

The lateral plantar artery (**6**.113), the larger terminal branch of the posterior tibial, passes laterally and distally to the base of the fifth metatarsal bone with the lateral plantar nerve on its medial side. Turning medially, with the deep branch of the nerve, to the interval between the bases of the first and second metatarsal bones, it unites with the dorsalis pedis artery, thus completing the *plantar arch*. As the lateral plantar artery passes

6.114 The plantar arteries. Superficial dissection.

laterally, it is at first between the calcaneus and abductor hallucis, and then between flexor digitorum brevis and flexor accessorius; as it runs distally to the base of the fifth metatarsal it lies between flexor digitorum brevis and abductor digiti minimi, and is covered by the plantar aponeurosis, superficial fascia and skin.

Branches. The lateral plantar artery has muscular, superficial, and anastomotic branches. The *muscular branches* supply adjoining muscles; the *superficial branches* emerge along the line of the lateral intermuscular septum and supply skin and subcutaneous tissue in the lateral part of the sole; the *anastomotic branches* run to the lateral border, where they anastomose with branches of the lateral tarsal and arcuate arteries. In addition, the lateral plantar artery sometimes has a *calcanean* branch, which pierces the origin of abductor hallucis to supply the skin of the heel.

The Plantar Arch

This is deeply situated and extends from the base of the fifth metatarsal bone to the proximal part of the first interosseous space. Convex distally, it is plantar to the bases of the second, third and fourth metatarsal bones and corresponding interossei, and dorsal to the oblique part of adductor hallucis.

Branches. The plantar arch has three perforating and four plantar metatarsal branches, and distributes numerous small vessels to skin, fasciae and muscles in the sole.

The three perforating branches ascend through the proximal ends of the second, third and fourth interosseous spaces, between the heads of the dorsal interosseous muscles, and anastomose with the dorsal metatarsal arteries.

The four plantar metatarsal arteries (**6**.113) extend distally between the metatarsal bones in contact with the interossei. Each divides into two *plantar digital arteries*, which supply the sides of adjacent toes. Near its division each plantar metatarsal artery sends dorsally a *distal perforating branch* to join the corresponding dorsal metatarsal artery. The first plantar metatarsal artery springs from the junction between the lateral plantar and the dorsalis pedis arteries, and sends a digital branch to the medial side of the first toe. The digital branch for the lateral side of the fifth toe arises from the lateral plantar artery near the base of the fifth metatarsal bone.

Surface Anatomy. Beginning at the termination of the posterior tibial, the lateral plantar artery crosses the sole obliquely to a point 2·5 cm medial to the tuberosity of the fifth metatarsal bone. From here, a line drawn with a slight forward convexity to the proximal end of the first intermetatarsal space indicates the course of the plantar arch.

Applied Anatomy. Wounds of the plantar arch are always serious, on account of the depth of the vessel and the important structures which must be interfered with in an attempt to ligature it. They must be treated on similar lines to those of wounds of the palmar arches (p. 708).

THE VENOUS SYSTEM

The veins consist of three sets—pulmonary, systemic, and portal (p. 710).

The pulmonary veins contain oxygenated blood, which they return from the lungs to the heart.

The systemic veins return venous blood to the heart. The *superficial veins* lie in the superficial fascia and are very variable in their disposition. The *deep veins* are usually enclosed in the same connective tissue sheaths with the arteries that they accompany, an arrangement which helps venous return (p. 630). Smaller arteries are generally accompanied by a pair of veins, lying on either side of the artery (*venae comitantes*), while larger arteries have usually only one accompanying vein. Some arteries, however, have no companion veins.

In general the systemic veins are more variable than the corresponding arteries and anastomoses occur more frequently and between larger vessels in the venous system. In many situations, such as the pelvis and in and around the vertebral column, the veins form extensive anastomosing plexuses and are characteristically devoid of valves. These plexuses provide the basis of free anastomosis between the veins of the trunk; they may also act as reservoirs of variable capacity in the vascular system. At a number of points, often at topographic junctional regions, and in the neighbourhood of principal joints, valved *connecting veins* interconnect the superficial and deep systemic veins.

The portal vein receives the radicles which drain venous blood from almost the whole of the subdiaphragmatic intestinal tract and its associated intrinsic and extrinsic glands, and from the spleen: having approached the porta hepatis it divides and, entering the substance of the liver, continually subdivides, ultimately discharging its contained blood into the hepatic venous sinusoids.

The Pulmonary Veins

The pulmonary veins return the oxygenated blood from the lungs to the left atrium of the heart. They are most commonly four in number, two from each lung, and are destitute of valves. They commence in the capillary network in the walls of the alveoli of the lungs, and, joining together, form a single trunk from each lobe, three from the right lung and two from the left. The vein from the middle lobe of the right lung generally unites with that from the upper lobe, so that ultimately two veins, a superior and an inferior, leave each lung; they perforate the fibrous layer of the pericardium and open separately into the upper and posterior part of the left atrium (**6**.16). Occasionally the three veins on the right side remain separate. Sometimes the two left pulmonary veins unite to form a single trunk before entering the heart. Occasionally the two left pulmonary veins, each draining a single lobe, may be augmented by *accessory lobar veins*, one from each lobe, and these may unite to form a *third* left pulmonary vein. (Consult Corry and Valentine 1959 for further details.)

In the root of the lung (pp. 1255, 1266), the superior pulmonary vein lies in front of and a little below the pulmonary artery; the inferior is situated at the lowest part of the hilum of the lung and on a plane posterior to that of the superior vein. The principal bronchus is behind the pulmonary artery. On the right side the superior pulmonary vein passes behind the superior vena cava, and the lower behind the right atrium. On the left side both pulmonary veins pass in front of the descending thoracic aorta. Within the pericardium, their anterior surfaces are invested by the serous layer of this membrane. Between the veins of the right and left side is the oblique sinus of the pericardium.

The Systemic Veins

The systemic veins may be arranged into three groups: (1) the veins which drain and discharge into *the heart*; (2) the veins of the upper limbs, head, neck and thorax, all of which end in *the superior vena cava*; (3) the veins of the lower limbs, abdomen and pelvis, all of which end in *the inferior vena cava*.

THE CARDIAC VEINS

The veins which drain the heart may be systematized in three groups: (*a*) *The coronary sinus* and its tributaries, which return the blood to the right atrium from all the heart (including its septa) except the anterior region of the right ventricle, and variable, but small parts of both atria and the left ventricle. (*b*) *The anterior cardiac veins*, whose tributaries drain the anterior part of the right ventricle, and a region extending round the 'acute' right border of the heart when the right marginal vein joins this group. (*c*) *The venae cordis minimae* (Thebesian veins), which open directly into the right atrium and ventricle and, to a lesser extent, into the left atrium and sometimes the left ventricle.

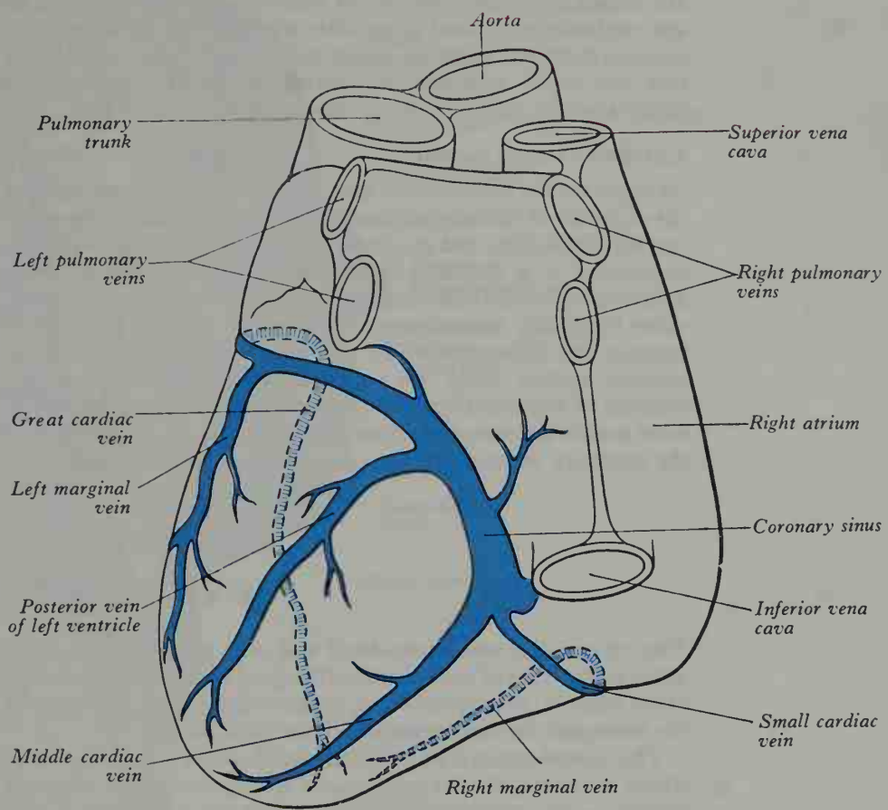
THE CORONARY SINUS

Most of the cardiac veins drain into the coronary sinus. This wide venous channel, about 2 or 3 cm long, is in the posterior part of the coronary sulcus (atrioventricular groove), between the left atrium and left ventricle (**6**.115). It ends in the right atrium between the opening of the inferior vena cava and the right atrioventricular orifice, its opening displaying a semilunar flap, the *valve of the coronary sinus* (**6**.18).

Its tributaries are the great, small, and middle cardiac veins, posterior vein of the left ventricle and oblique vein of the left atrium, all of which, except the last, have valves at their orifices.

The great cardiac vein (**6**.115) begins at the apex of the heart and ascends in the anterior interventricular sulcus to reach the coronary sulcus. It follows this groove round to the left and to the back of the heart, entering the beginning of the coronary sinus. It receives tributaries from the left atrium and both ventricles, including the *left marginal vein*, which ascends along the left aspect ('obtuse border') of the heart and is of considerable size.

The small cardiac vein (**6**.115) runs in the coronary sulcus between the right atrium and ventricle posteriorly, and opens into the end of the coronary sinus, i.e. near its termination. It receives blood from the back of the right atrium and ventricle; the *right marginal vein* passes to the right along the lower margin ('acute border') of the heart and may join the small cardiac vein in the coronary sulcus, more often it opens directly into the right atrium.

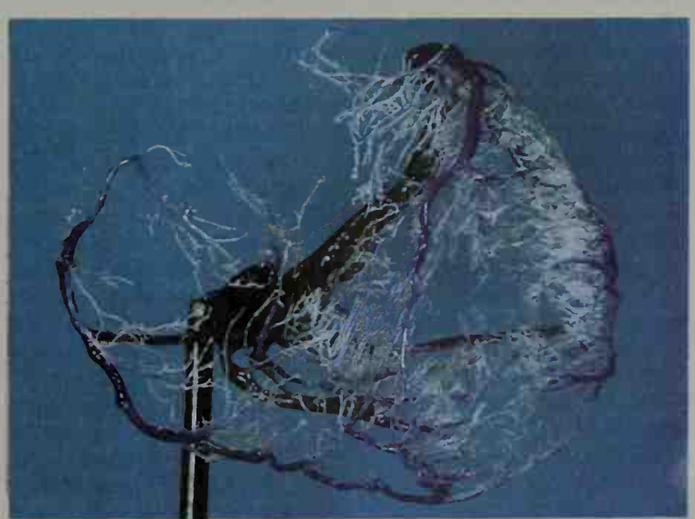


The middle cardiac vein (**6**.115) begins at the apex of the heart, runs backwards in the posterior interventricular groove, and ends in the coronary sinus near its termination.

The posterior vein of the left ventricle (**6**.115) runs on the diaphragmatic surface of the left ventricle a little to the left of the middle cardiac vein; it usually opens into the coronary sinus, but may end in the great cardiac vein.

The oblique vein of the left atrium, a small vessel, descends obliquely on the back of the left atrium to join the coronary sinus near its left extremity; it is continuous above with the *ligament of the left vena cava* (p. 193), and the two structures are remnants of the left common cardinal vein (**2**.119).

THE ANTERIOR CARDIAC VEINS



The *anterior cardiac veins* draw their tributaries from the anterior part of the right ventricle. Usually two or three in number, though as many as five may occur (Baroldi and Scomazzoni 1967), they ascend in the subepicardial stratum to cross the right part of the atrioventricular sulcus, where they pass deep or superficial to the right coronary artery. They terminate in the right atrium, close to the sulcus, either separately or by variable junctions. A subendocardial collecting channel, into which all may open, has been described (James 1961). **The right marginal vein**, which courses along the right 'border' of the heart, draining adjacent parts of the right ventricle, usually opens independently into the right atrium, but it may join the anterior cardiac veins or even, less frequently, the coronary sinus. Because of its usual independence it is sometimes grouped with the venae cordis minimae, but it is considerably larger in calibre, being comparable in size with the anterior cardiac veins, or even larger. It is perhaps better considered as one of the latter, which also sometimes drain with it into the coronary sinus. Mechanik (1934) described all the cardiac veins as draining into the coronary sinus in early fetal stages.

6.115A The principal veins of the heart.

THE VENAE CORDIS MINIMAE

The existence of 'the smallest veins' or *venae cordis minimae*, opening into all the cavities of the heart, has been confirmed by many experimenters subsequent to their first recorded description by Thebesius (1708). They are, however, much more difficult to demonstrate than the larger cardiac vessels. Their numbers are highly variable, as is their size. Aho (1950)

6.115B A coloured resin cast of the coronary sinus and its tributaries. Of course, the venae cordis minimae and anterior cardiac veins are not filled. Compare with **6**.115A. (Specimen by Dr. D. H. Tompsett, Department of Anatomy, Royal College of Surgeons of England.)

demonstrated 'minimal' veins of up to 2 mm in diameter opening into the right atrium, and of about 0·5 mm into the right ventricle. He considered venae minimae as numerous in the right atrium and ventricle, occasional in and often absent from the left atrium, and rare in the left ventricle. Grant and Regnier (1926) considered that the venae minimae are derived from the pronounced intertrabecular spaces of the developing mammalian heart.

Cardiac Venous Anastomoses

As in the case of the coronary arteries, most investigators agree to the existence of widespread anastomosis at all levels of the cardiac venous circulation, and on a scale exceeding that of the arteries, amounting to a veritable venous network according to some authorities (Baroldi and Scomazzoni 1967). Not only are adjacent veins frequently interconnected, but there are also connexions between the tributaries of the coronary sinus and those of the anterior cardiac veins (*see* e.g. Mierzwa and Kozielec 1975). Regions of particularly marked anastomosis are the apex of the heart and its anterior and posterior aspects. As also in the case of the coronary arteries (p. 673), the cardiac veins connect with extracardiac vessels, chiefly with the vasa vasorum of the large vessels entering and leaving the heart.

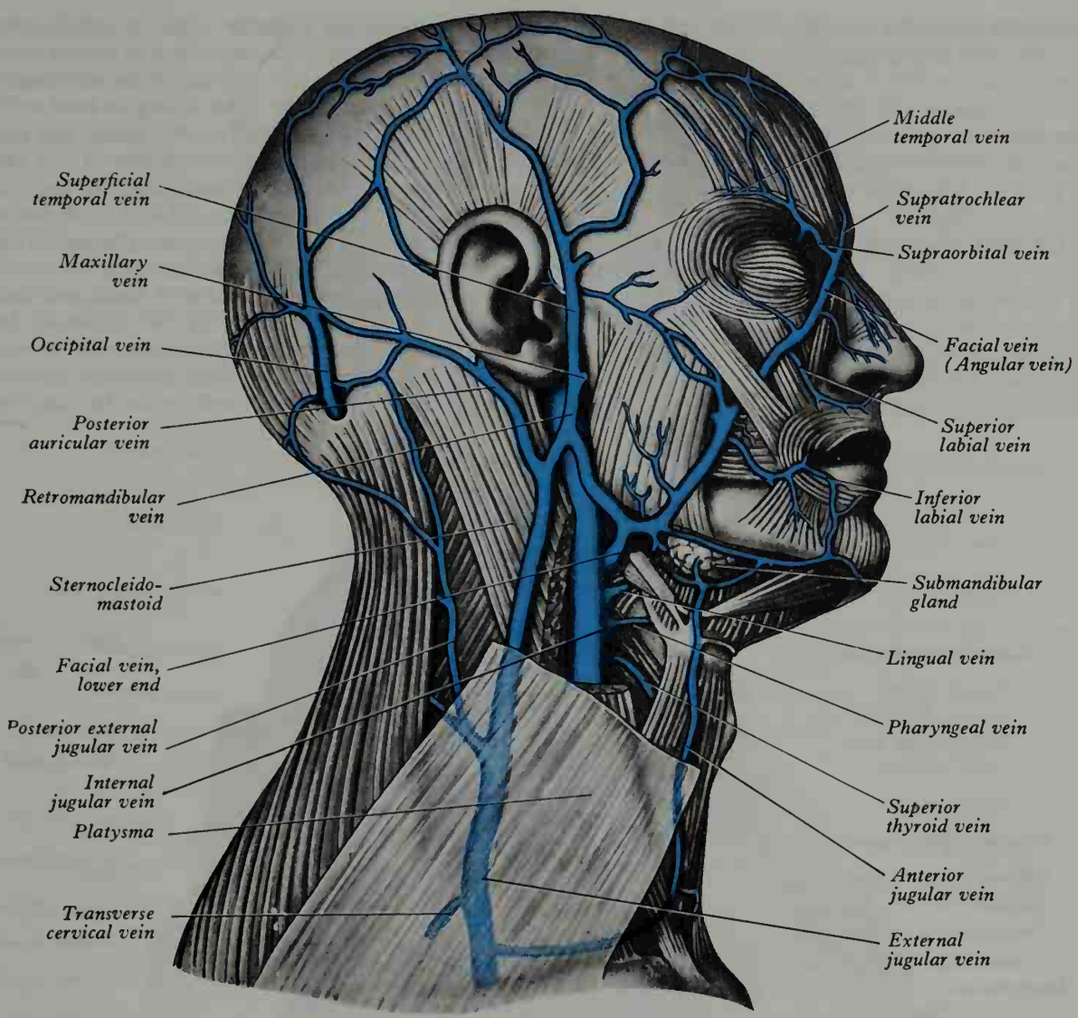
Variation in the Cardiac Veins

Attempts have been made to categorize the individual variations encountered in the cardiac venous circulation (*see* Aho 1950) into a number of 'types', but these have not produced any agreed pattern. The major variations concern the general directions of drainage. The coronary sinus may receive all the cardiac veins (except the venae minimae), including the anterior cardiac veins (33 per cent). The latter may be reduced, by diversion of some of them into the small cardiac vein and thus to the coronary sinus (28 per cent). The percentages represent the views of Aho (1950), the remainder (39 per cent) representing the 'normal', most usual pattern, as described above. Baroldi and Scomazzoni (1967) distinguished two major variants: a majority (70 per cent), in which the small cardiac vein is independent, small or even absent, and a less frequent pattern (30 per cent) in which the small cardiac vein, though variable in size, connects with both the coronary and anterior cardiac 'systems'.

THE VEINS OF THE HEAD AND NECK

The venous channels of the head and neck may be subdivided into: (1) the veins of the exterior of the head and face; (2) the veins of the neck; (3) the diploic veins, the meningeal veins, the veins of the brain and the venous sinuses of the dura mater.

This classification is particularly significant at the cranial level, where the veins, like the arteries, are arranged as a three-layered system: (*a*) the vessels of the scalp, (*b*) the dural vessels, and (*c*) the cerebral and cerebellar vessels. There are, however, some differences between the arteries and veins, largely in respect of the interconnexions between the three levels. The arteries of the scalp and dura, both derived from the external carotid system, intercommunicate to a limited extent, as do the corresponding veins; the latter although quite variable usually communicate to a more extensive degree (*see* Emissary Veins, p. 749). The dural or meningeal arteries, on the other hand, are completely independent of the cerebral and cerebellar arteries, derived from the internal carotid, whereas the dural venous sinuses share a common drainage into the internal jugular vein, with the veins of the cerebrum and cerebellum. To this concept it is possible to add a fourth venous tier—the diploic veins; since these, however, drain directly into the dural veins, they are here grouped with the latter, following the schema of Browder and Kaplan (1976). It must be added at once that the intracranial veins communicate at many points with extracranial vessels by emissary and other veins (p. 749).



In usual accounts of the venous sinuses these channels are for the most part described as if they were simple arrangements with a single lumen. In embryological development, of course, these sinuses emerge as venous *plexuses*; and it is clear, from angiographic studies and examination of corrosion casts, that most of the sinuses preserve a *plexiform* arrangement to a variable degree. Browder and Kaplan (1976) have studied human venous sinuses in hundreds of corrosion casts, and they have observed complex vascular plexuses adjoining, in particular, the superior and inferior sagittal and straight sinus, and with a lesser incidence in the transverse sinuses. The details of these arrangements show much individual variation, and departures from 'average' patterns are specially frequent in the earlier years of life. For example, the falx cerebelli may, in infancy, contain large plexiform channels and even venous lacunae, augmenting the occipital sinus. Such individual variations obviously cannot be minutely considered in a general text, and must in any case be established for the individual by angiography when clinical necessity arises. It is important to recognize, however, the wide variations possible in the structure of the venous sinuses within the cranium, and also their frequent plexiform nature and wide connexions with cerebral and cerebellar veins. One other kind of connexion may be mentioned here. Experimental evidence (Rowbotham and Little 1962; Browder and Kaplan 1976) shows that some parts of the sinus system (and even the diploic veins) can be filled by injectants forced into the internal carotid artery, suggesting the existence of arteriovenous shunts. Browder and Kaplan, by injection of the middle meningeal artery, established a connexion between this vessel and the superior sagittal sinus. The precise location of such anastomoses requires further investigation.

External Veins of Head and Face (6.116)

The supratrochlear vein starts on the forehead from a venous network which communicates with the frontal tributaries of the superficial temporal vein. Veins converge from the network into a single trunk, which descends on the forehead near the midline parallel with its fellow. At the root of the nose the two supratrochlear veins are joined transversely by the *nasal arch*, draining small veins from the dorsum of the nose. The supratrochlear veins then diverge, and at the medial angle of the orbit, each joins with a *supraorbital vein* to form the (*anterior*) facial *vein*. Occasionally the supratrochlear veins unite in a single trunk, which divides at the root of the nose into the two anterior facial veins.

The supraorbital vein begins near the zygomatic process of the frontal bone, where it communicates with the superficial and middle temporal veins. It courses medially along the upper margin of the orbital opening under orbicularis oculi, and, near the medial angle of the eye, pierces this muscle to form, with the supratrochlear, the *facial vein*. It sends a branch through the supraorbital notch into the orbital cavity to join the superior ophthalmic vein; as this branch traverses the supraorbital notch it is joined by the frontal diploic vein and by a vein draining the frontal air sinus..

The facial vein, formed by junction of the supratrochlear and supraorbital veins, runs obliquely downwards on the side of the root of the nose to the level of the lower margin of the orbital opening. It then runs downwards and backwards behind the facial artery, but follows a less tortuous course. It passes under zygomaticus major, risorius and platysma, descends along the anterior border of and then on the surface of masseter, crosses the body of the mandible, and runs obliquely backwards deep to platysma and superficial to the submandibular gland, digastric and stylohyoid. A little below and in front of the angle of the mandible it is joined from above and behind by the anterior division of the retromandibular vein, and then, descending across the loop of the lingual artery, hypoglossal nerve and external and internal carotid arteries, it enters the internal jugular vein near the

6.116 The veins of the right side of the head and neck. Parts of the right sternocleidomastoid and platysma have been excised to expose the trunk of the internal jugular vein. The external jugular vein is visible through the lower part of the platysma.

greater cornu of the hyoid bone. Near the termination of the facial vein a branch of considerable size often diverges down the anterior border of sternocleidomastoid to the lower part of the anterior jugular vein.

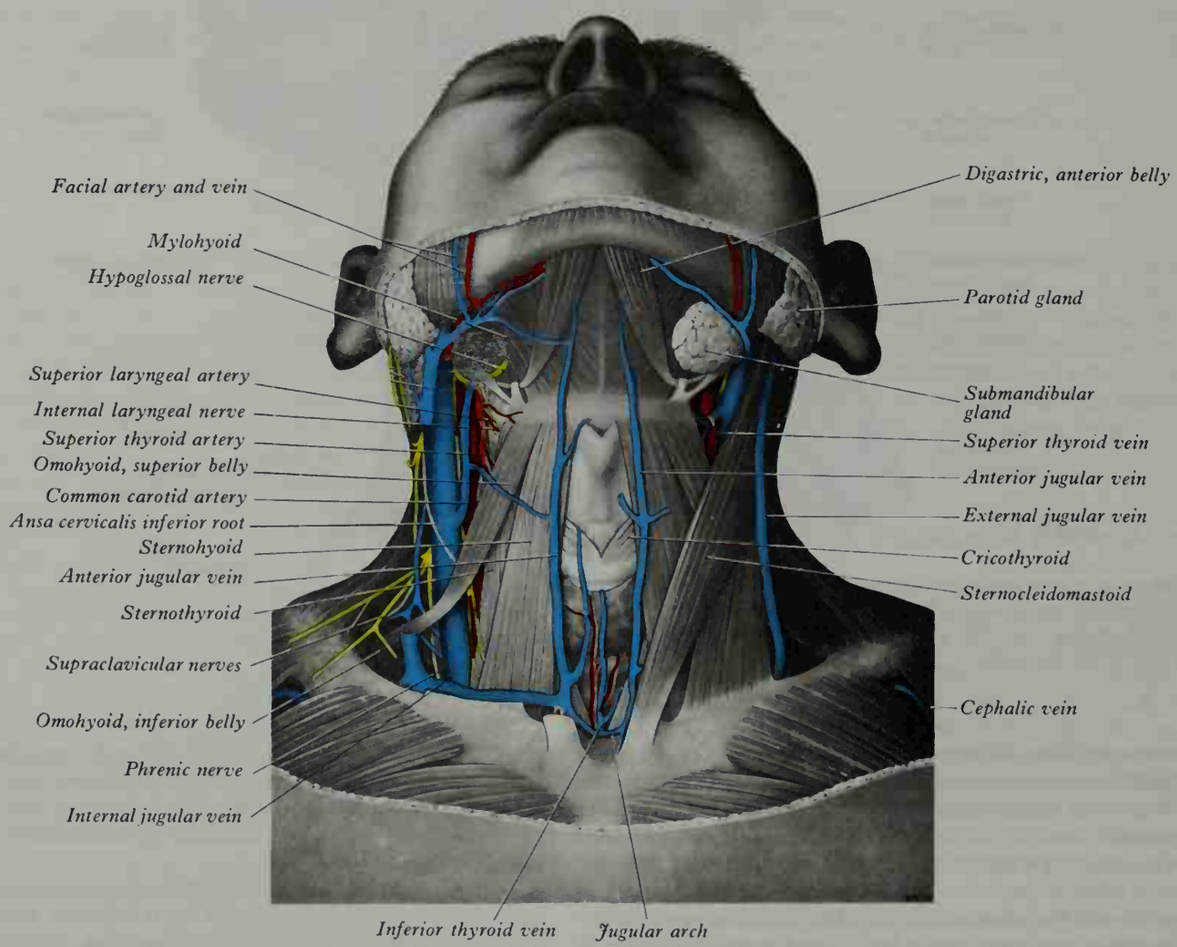
Above its junction with the superior labial vein (*vide infra*) the facial vein is often termed the *angular vein.*

Tributaries. At the commencement the facial vein connects with the superior ophthalmic vein both directly and also through the supraorbital vein (*vide supra*). The facial vein is thus connected with the cavernous sinus through the superior ophthalmic vein. It receives the veins of the ala nasi and, at a lower level, a large branch, the *deep facial vein*, from the pterygoid venous plexus. It is also joined by the inferior palpebral, superior and inferior labial, buccinator, parotid and masseteric veins. Below the mandible it receives the submental, tonsillar, external palatine (paratonsillar) and submandibular veins. The facial vein may be joined by the vena comitans of the hypoglossal nerve, and often also the pharyngeal and superior thyroid veins.

Applied Anatomy. The facial vein has no valves and it communicates with the cavernous sinus by two routes; firstly, through connexions directly with the ophthalmic vein or with its tributary, the supraorbital; secondly, by the deep facial vein, which links it to the pterygoid plexus and hence also to the cavernous sinus. Thus infective thrombosis of the facial vein may extend into the intracranial venous sinuses.

The superficial temporal vein (**6**.116) begins in a network which extends widely over the scalp. Through this it is joined to the corresponding vein of the opposite side, and with the supratrochlear, supraorbital, posterior auricular and occipital veins, all of which drain the same network. Anterior and posterior tributaries unite above the zygomatic arch to form the superficial temporal vein, which is joined here by the *middle temporal vein.* It then crosses the posterior root of the zygomatic arch, enters the parotid gland, and unites with the maxillary to form the *retromandibular vein.*

Tributaries. The superficial temporal vein receives some veins from the parotid gland, articular veins from the temporomandibular joint, anterior auricular veins from the external ear, and the *transverse facial* from the face. The middle temporal vein, after receiving the *orbital vein*, formed by lateral palpebral branches, passes back between the layers of the temporal fascia and then becomes superficial to join the superficial temporal vein.



The pterygoid plexus is of considerable size, and is placed partly between the temporalis and lateral pterygoid, and partly between the two pterygoids. The sphenopalatine, deep temporal, pterygoid, masseteric, buccal, dental, greater palatine and the middle meningeal veins, and a branch or branches from the inferior ophthalmic vein are all tributaries. The pterygoid plexus anastomoses with the facial vein through the *deep facial*; it is also connected with the cavernous sinus by veins which pass through the sphenoidal emissary foramen, foramen ovale and foramen lacerum. The deep temporal veins frequently connect with the tributaries of the anterior diploic vein (p. 743) and, through these, with the middle meningeal veins.

The maxillary vein, a short trunk, accompanies the first part of the corresponding artery and is formed by confluence of the veins of the pterygoid plexus. It passes back between the sphenomandibular ligament and the neck of the mandible, and unites with the superficial temporal to form the retromandibular vein.

The retromandibular vein (posterior facial), descends in the parotid gland, superficial to the external carotid artery but deep to the facial nerve. It divides into two branches, an anterior which passes forwards and unites with the facial vein, and a posterior which joins the posterior auricular to form the external jugular vein. Occasionally the retromandibular vein is not connected with the external jugular, and then the latter is small and the anterior jugular vein often very large.

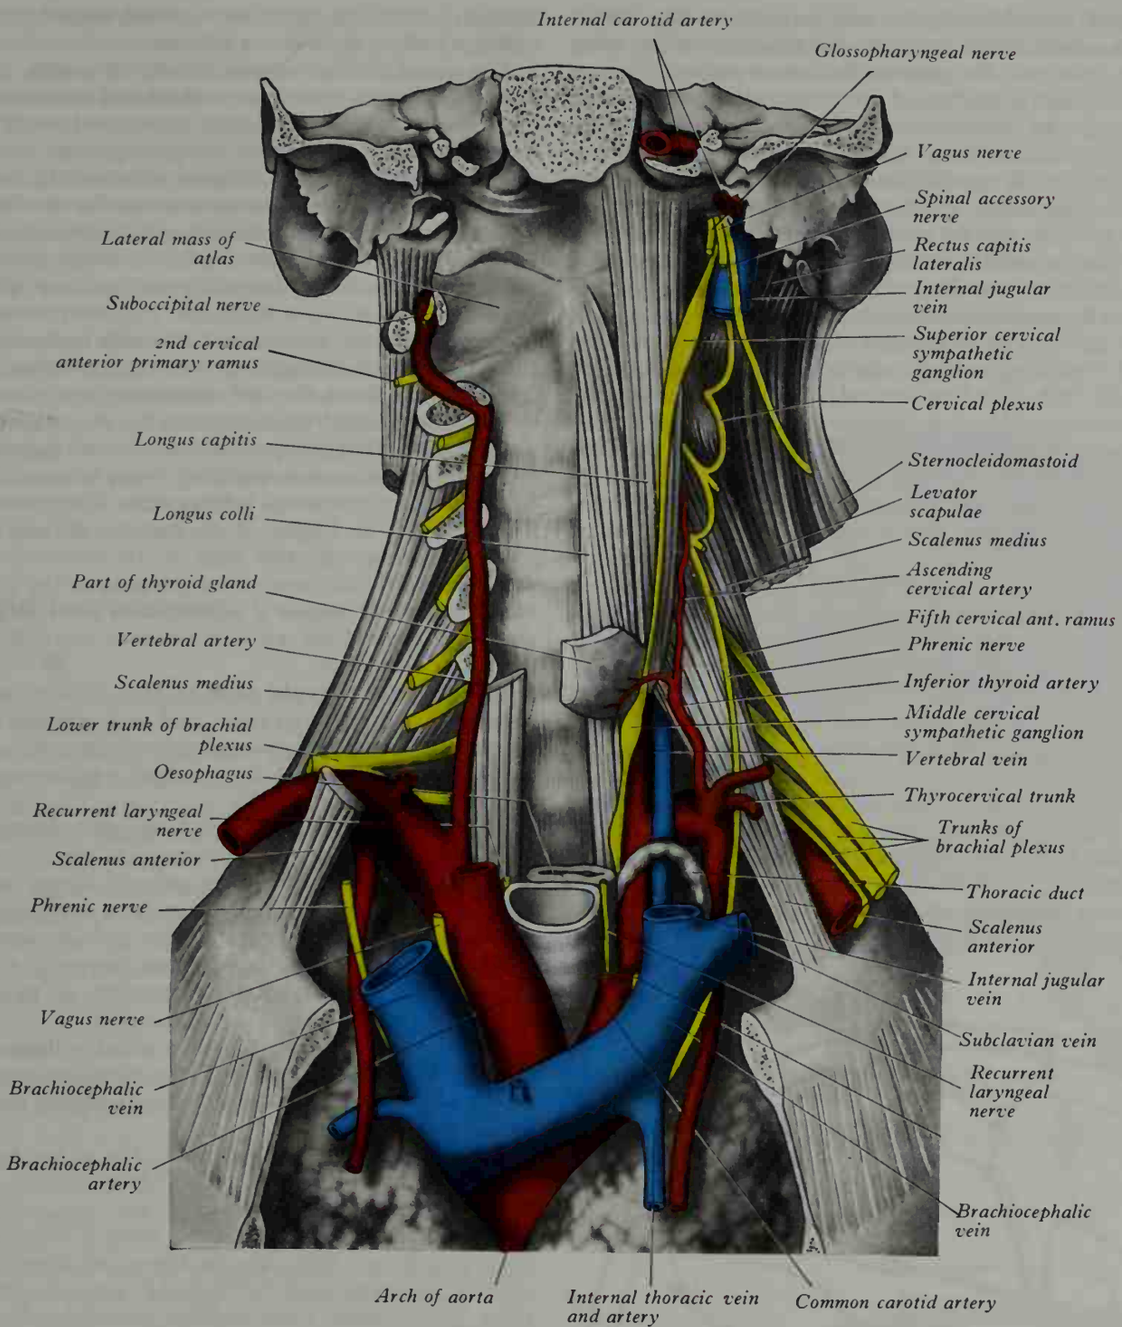
The posterior auricular vein (**6**.116) begins in the posterior part of the scalp in a network which communicates with the tributaries of the occipital and superficial temporal veins. It descends behind the auricle, and joins the posterior division of the retromandibular vein in or just below the parotid gland to form the external jugular vein. It receives the stylomastoid vein and tributaries from the cranial surface of the auricle.

The external jugular vein (**6**.116) receives blood mostly from the scalp and face, including its deeper parts. It is formed by union of the posterior division of the retromandibular vein with the posterior auricular vein. It begins level with the mandibular angle just below, or in the parotid gland, and runs down the neck from the angle towards the middle of the clavicle. It crosses sternocleidomastoid obliquely, and in the subclavian triangle perforates the deep fascia to end in the subclavian vein, lateral to, or in front of, the scalenus anterior; the wall of the vein is adherent to the circumference of the opening in the deep fascia. It is covered by platysma, superficial fascia and skin, and separated from sternocleidomastoid by the investing layer of the deep cervical fascia; it crosses the transverse cervical nerve, and its upper half runs parallel with the great auricular nerve, which ascends behind it. The vein varies in size, bearing an inverse

6.117 Anterior view of the veins of the neck.

The occipital vein (**6**.116) begins in a venous network at the posterior part of the scalp. It pierces the cranial attachment of trapezius, dips into the suboccipital triangle and joins the deep cervical and vertebral veins. Occasionally it follows the occipital artery and ends in the internal jugular vein; sometimes it joins the posterior auricular vein and, through it, opens into the external jugular vein. The parietal emissary vein connects it with the superior sagittal sinus, and the mastoid emissary vein connects it with the transverse sinus. The occipital diploic vein sometimes joins it.

Veins of the Neck (**6**.116, 117, 131)



The veins of the neck may be divided into those superficial to the deep fascia and those deep to it; but the two groups are not entirely independent. The superficial veins, tributaries of the external jugular, drain a much smaller volume of tissue than the deep veins, which collect blood from all except subcutaneous structures, returning it largely into the internal jugular vein.

proportion to the other veins of the neck; it is occasionally double. It has two pairs of valves, a lower at its entrance into the subclavian vein, an upper about 4 cm above the clavicle. The part of the vein between the two sets of valves is often dilated, and is sometimes termed the *sinus*. These valves do not prevent regurgitation of blood.

Tributaries. In addition to its formative tributaries, the external jugular vein receives the posterior external jugular and, near its end, the transverse cervical, suprascapular and anterior jugular veins; in the parotid gland it is frequently joined by a branch from the internal jugular vein. The occipital vein occasionally drains into it.

The posterior external jugular vein begins in the occipital region and returns the blood from the skin and superficial muscles in the upper and posterior part of the neck. It opens into the middle part of the external jugular vein.

The anterior jugular vein (**6**.116, 117) starts near the hyoid bone by the confluence of several superficial veins from the submandibular region. It descends between the anterior median

6.118 A dissection to show the prevertebral region and the superior mediastinum. On the right the costal elements of the upper six cervical vertebrae have been removed to expose the cervical part of the vertebral artery. On the left most of the deep relations of the common carotid artery and the internal jugular vein are exposed.

line and anterior border of sternocleidomastoid; low in the neck it turns laterally posterior to this muscle, but superficial to the depressors of the hyoid bone, and opens into the termination of the external jugular veins, or directly into the subclavian vein. Its size varies considerably, and is usually inverse to that of the external jugular vein. It communicates with the internal jugular and receives some laryngeal veins, and occasionally a small thyroid vein. There are usually two anterior jugular veins, a right and a left; just above the sternum they are united by a large transverse trunk, the *jugular arch*, which receives tributaries from the inferior thyroid veins. The anterior jugular veins have no valves. They may be replaced by a single trunk which descends in the anterior midline of the neck.

Surface Anatomy. Usually the *external jugular vein* is easily seen crossing the sternocleidomastoid obliquely. When it is not obvious, it can be brought into view by the effort of blowing with the mouth closed. The *anterior jugular vein* can often be rendered visible in the upper two-thirds of the neck in a similar manner. The terminal part of the facial vein runs from a point on the lower border of the mandible at the anterior border of masseter to join the internal jugular just below the greater cornu of the hyoid bone.

The internal jugular vein (**6**.117) collects blood from the brain, superficial parts of the face, and the neck. It begins at the base of the skull in the posterior compartment of the jugular foramen, as a direct continuation of the sigmoid sinus. At its origin is a dilatation, the *superior bulb*, below the posterior part of the floor of the tympanic cavity. The vein runs downwards through the neck within the carotid sheath (p. 537), and, behind the sternal end of the clavicle, it unites with the subclavian to form the brachiocephalic vein. The internal jugular vein is also dilated near its termination as the *inferior bulb*; directly above this the vein contains a pair of valves. *Posterior* to the internal jugular vein, from above downwards, are the rectus capitis lateralis, the transverse process of the atlas, levator scapulae, scalenus medius and the cervical plexus, then scalenus anterior, the phrenic nerve, the thyrocervical trunk, the vertebral vein and first part of the subclavian artery; on the left side the vein passes in front of the

thoracic duct (**6**.118). *Medially* the vein is related to the internal and common carotid arteries and the vagus nerve, the last lying between the vein and the arteries but on a posterior plane. *Superficially* the vein is overlapped by the upper part, and covered by the lower part, of sternocleidomastoid, and is crossed by the posterior belly of digastric and the superior belly of omohyoid. Above the digastric, the parotid gland and the styloid process are superficial, and the accessory nerve and the posterior auricular and occipital arteries cross the vein. Between the digastric and the omohyoid, the sternocleidomastoid arteries and the inferior root of the ansa cervicalis cross the vein, but the nerve often passes between it and the common carotid artery. Below the omohyoid, it is covered by the infrahyoid muscles, in addition to sternocleidomastoid, and crossed, superficial to the infrahyoid muscles, by the anterior jugular vein. The deep cervical lymph nodes lie along the course of the vein, mainly on its superficial aspect. At the root of the neck the right internal jugular vein is a little distant from the common carotid artery, while the left vein usually overlaps its artery. At the base of the skull the internal carotid artery is in front of the internal jugular vein, and is separated from it by the last four cranial nerves.

Surface Anatomy. The internal jugular vein is represented in surface projection by a broad band drawn from the lobule of the ear to the medial end of the clavicle; its lower bulb lies behind the lesser supraclavicular fossa, projecting into the interval between the sternal and clavicular heads of sternocleidomastoid (**6**.47).

Tributaries. The internal jugular vein is joined by the inferior petrosal sinus, the facial, lingual, pharyngeal, superior and middle thyroid veins, and sometimes the occipital vein. In the upper neck it may communicate with the external jugular vein. The thoracic duct opens into the angle of union of the left subclavian and internal jugular veins, and the right lymphatic duct at the same site on the right.

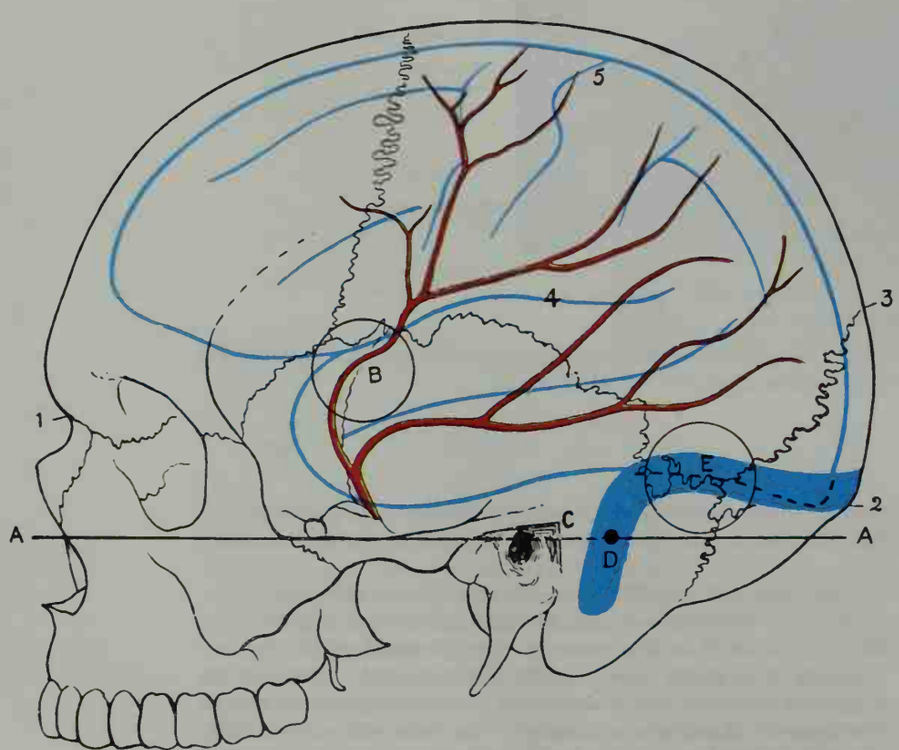
The inferior petrosal sinus leaves the skull through the anterior part of the jugular foramen and, crossing either lateral or medial to the ninth, tenth and eleventh cranial nerves, joins the superior bulb of the internal jugular.

The veins of the tongue follow two routes. (1) The *dorsal lingual veins* drain the dorsum and sides of the tongue and join the *lingual veins*, which accompany the lingual artery, lying in the interval between hyoglossus and genioglossus. Near the greater cornu of the hyoid bone the lingual veins join the internal jugular. (2) The *deep lingual vein* commences near the tip of the tongue and runs backwards close to the mucous membrane on its inferior surface (**8**.74). Near the anterior border of hyoglossus it joins the *sublingual vein*, from the sublingual salivary gland, to form the *vena comitans nervi hypoglossi* (the vein accompanying the hypoglossal nerve), which runs backwards in the interval between the mylohyoid and hyoglossus with the hypoglossal nerve to end by joining the facial, the internal jugular, or the lingual vein.

The pharyngeal veins begin in the *pharyngeal plexus* on the outer surface of the pharynx, and, after receiving some meningeal veins and the vein corresponding to the artery of the pterygoid canal, end in the internal jugular vein. They occasionally open into the facial, the lingual, or the superior thyroid vein.

The superior thyroid vein (**6**.116, 117) is formed by deep and superficial tributaries corresponding to the branches of the superior thyroid artery. It accompanies the artery, receives the superior laryngeal and cricothyroid veins, and ends in the internal jugular or facial vein.

The middle thyroid vein (**6**.117) collects blood from the lower part of the thyroid gland, and receives some veins from the larynx and trachea. It crosses anterior to the common carotid, and joins the lower part of the internal jugular vein behind the superior belly of omohyoid.



The facial and occipital vein have been described (pp. 738, 740), and the inferior thyroid veins on p. 754.

Applied Anatomy. When thrombosis occurs in the superior bulb of the internal jugular vein (as a complication of otitis media), the glossopharyngeal, vagus and accessory nerves may cease to conduct. The hypoglossal nerve is also sometimes affected by extension of the thrombus to the veins of the hypoglossal canal.

The internal jugular vein is surrounded by deep cervical lymph nodes; when these are enlarged in tuberculous or malignant disease, their adherence to the vessel may render removal difficult and dangerous.

Venous pulsation is often observable in the external jugular veins at the root of the neck. There are no valves in the brachiocephalic veins or superior vena cava; consequently, the systole of the right atrium causes a wave of distension to pass up these vessels, and when the conditions are favourable this wave appears as a somewhat feeble flicker over the external jugular veins, quite distinct from, and just preceding, the more forcible impulse transmitted from the underlying common carotid artery and due to ventricular systole. This atrial systolic venous impulse is much increased in conditions in which the right atrium is abnormally distended with blood or is hypertrophied, as is often the case in disease of the mitral valve.

The vertebral vein is formed in the suboccipital triangle from numerous small tributaries from the internal vertebral plexuses which issue from the vertebral canal above the posterior arch of the atlas. They unite with small veins from the deep muscles in the upper part of the back of the neck, and form a vessel which enters the foramen in the transverse process of the atlas, and descends, as a dense plexus around the vertebral artery, through the transverse foramina of successive cervical vertebrae. This plexus ends in the vertebral vein, which emerges from the transverse foramen of the *sixth* cervical vertebra, and runs downwards, at first anterior and then anterolateral to the vertebral artery, to open into the upper and posterior part of the brachiocephalic vein, the opening guarded by a pair of valves. In its course the vertebral vein descends behind the internal jugular, and in front of the first part of the subclavian artery (**6**.118). A small vein, termed the *accessory vertebral vein*, usually descends from the plexus around the vertebral artery, passes through the transverse foramen of the *seventh* cervical vertebra, and curves forwards between the subclavian artery and the cervical pleura to join the brachiocephalic vein.

6.119 The relations of the brain, the middle meningeal artery and the transverse and sigmoid sinuses to the surface of the skull. 1. Nasion. 2. Inion. 3. Lambda. 4. Lateral cerebral sulcus. 5. Central sulcus. AA. = Frankfurt plane, which traverses the lower margin of the orbital opening and the upper margin of the external acoustic meatus. B. Point for trephining over the frontal branch of the middle meningeal artery. C. Suprameatal triangle. D. Sigmoid sinus. E. Point for trephining over the transverse sinus, exposing dura mater of both cerebrum and cerebellum. The outline of the cerebral hemisphere and its major sulci are indicated in blue; the course of the middle meningeal artery is in red.

Tributaries. The vertebral vein communicates with the sigmoid sinus inside the skull by a vein which passes through the posterior condylar canal, when this canal exists. It also receives branches from the occipital vein, from the prevertebral muscle and from the internal and external vertebral plexuses. It is joined by the anterior vertebral and the deep cervical veins (*vide infra*); close to its termination it is sometimes joined by the first intercostal vein.

The anterior vertebral vein commences in a plexus around the transverse processes of the upper cervical vertebrae, descends in company with the ascending cervical artery between the scalenus anterior and longus capitis, and opens into the terminal part of the vertebral vein.

The deep cervical vein accompanies its artery between the semispinales capitis et cervicis. It begins in the suboccipital region by communicating branches from the occipital vein and small veins from the deep muscles at the back of the neck. It receives tributaries from the plexuses around the spines of the cervical vertebrae, and passes forwards between the transverse process of the seventh cervical vertebra and the neck of the first rib to end in the lower part of the vertebral vein.

Cranial and Intracranial Veins

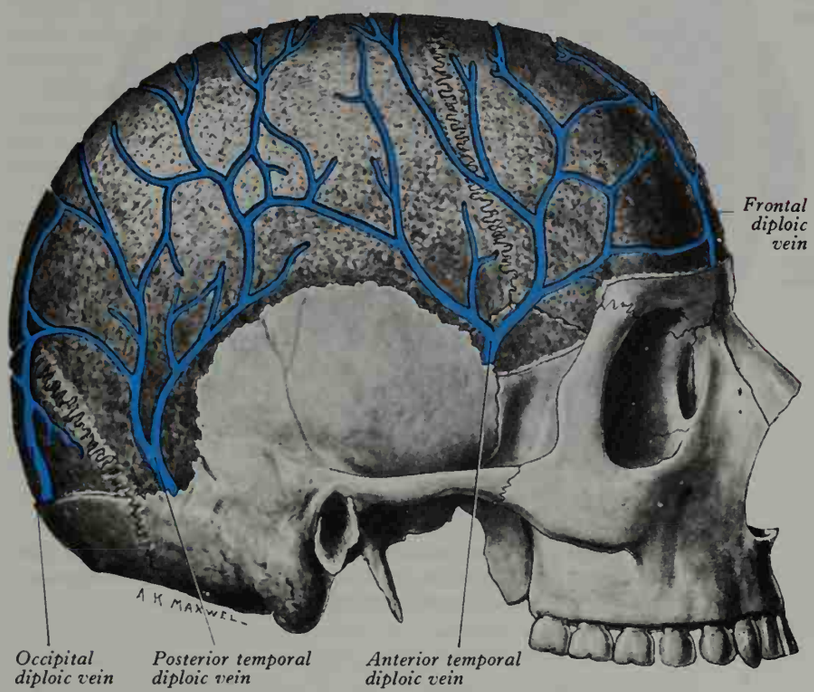
DIPLOIC VEINS

The diploic veins occupy channels in the diploë of the cranial bones and are devoid of valves. They are large, and exhibit pouch-like dilatations at irregular intervals; their walls are thin, and formed merely of endothelium supported by a layer of elastic tissue. In radiographs of the skull the diploic veins may show as relatively transparent bands some 3 or 4 mm wide. They are absent from the skull of the newly born and begin to develop with the diploë at the age of about two years.

They communicate with the meningeal veins, the sinuses of the dura mater, and the veins of the pericranium. Recognizably regular channels are (1) the *frontal diploic vein,* which emerges from the bone at the supraorbital foramen and opens into the supraorbital vein; (2) the *anterior temporal (parietal)* diploic vein, which is confined chiefly to the frontal bone and pierces the greater wing of the sphenoid bone to end in the sphenoparietal sinus or the anterior deep temporal vein; (3) the *posterior temporal (parietal) diploic vein,* which is situated in the parietal bone; it descends to the mastoid angle of the parietal bone and joins the transverse sinus through an aperture placed at that angle or through the mastoid foramen; and (4) the *occipital diploic vein,* the largest of the four, which is confined to the occipital bone and opens into the occipital vein, or into the transverse sinus near the confluence of the sinuses, or into the occipital emissary vein. Numerous small diploic veins (7.166) pierce the inner table close to the margins of the superior sagittal sinus and terminate in the venous lacunae (p. 745).

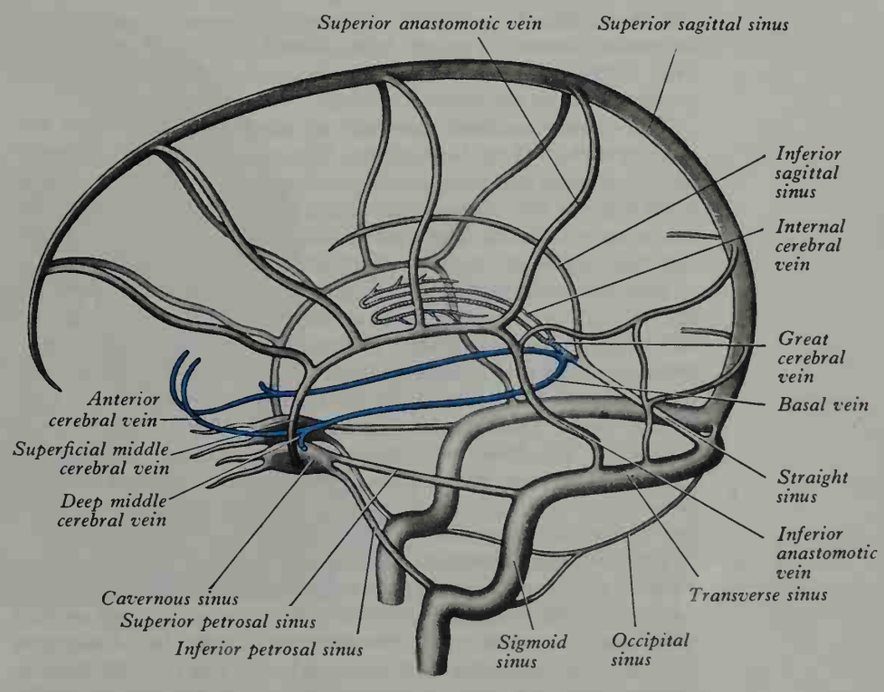
MENINGEAL VEINS

The meningeal veins begin from plexiform vessels in the dura mater and drain into efferent vessels which lie in the outer layer of the dura. The efferents communicate with the lacunae of the superior sagittal sinus, with other cranial sinuses, including those which accompany the middle meningeal arteries (p. 683), and with the diploic veins.



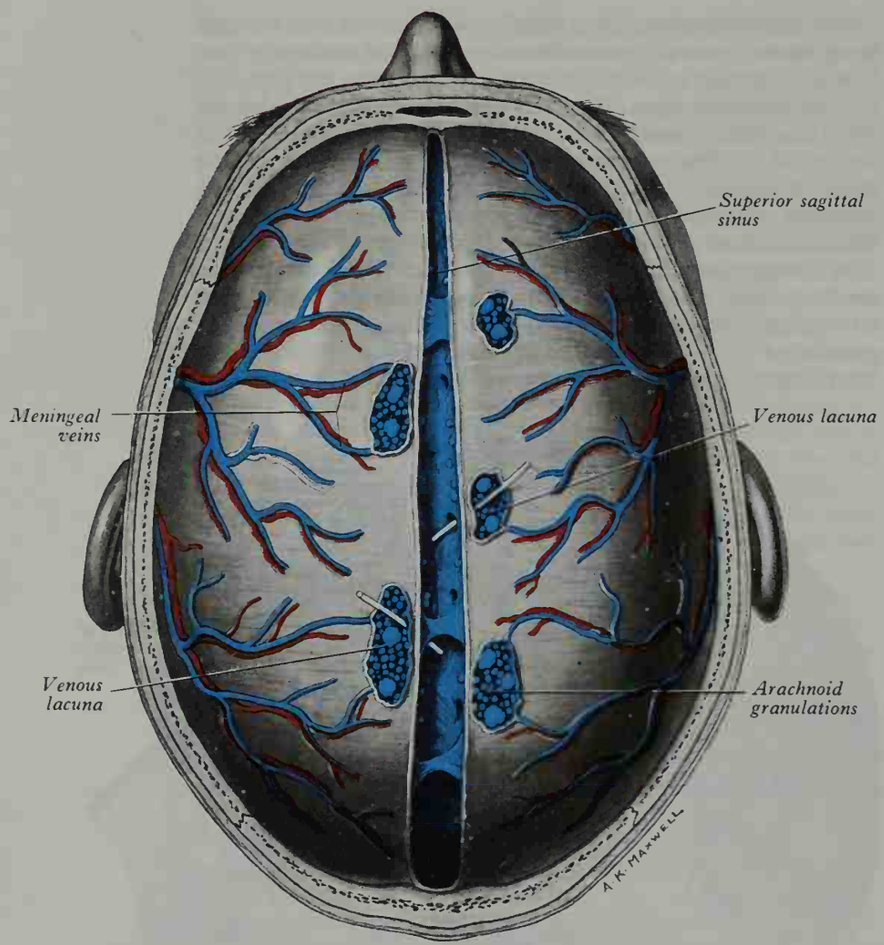
CEREBRAL AND CEREBELLAR VEINS

The veins of the brain (for details *see* p. 1044) have no valves, and their walls, from which muscular tissue is absent, are extremely thin. They pierce the arachnoid mater and the inner layer of the dura mater, and open into the cranial venous sinuses. They comprise the cerebral and cerebellar veins and the veins of the brain stem.



The cerebral veins (6.121) are divisible into external and internal groups, draining the surfaces or the inner regions of the hemispheres.

The external cerebral veins form *superior, middle* and *inferior* groups.



The *superior cerebral veins,* eight to twelve in number on each hemisphere, drain the superolateral and medial surfaces of the hemispheres, and mainly follow the sulci between the gyri, but some run across the gyri. They ascend to the superomedial border of the hemisphere, where they receive small veins from the medial surface of the hemisphere, and open into the superior sagittal sinus; the anterior veins run nearly at right angles to the sinus; the posterior and larger veins are directed obliquely forwards, and thus open into the sinus against the current of the blood within it. This arrangement may prevent the collapse of the thin-walled cerebral veins which might otherwise result from a rise of intracranial pressure, but the causative factor is the backward growth of the cerebral hemispheres and the consequent displacement of the vessels during development.

6.120 The veins of the diploë, displayed by the removal of the outer table of the skull.

6.121 A schema of the venous sinuses of the dura mater and their connexions with the cerebral veins. The more deeply placed cerebral veins are shown in *blue,* and those inside the brain are shown in *interrupted blue.*

6.122 The superior sagittal sinus laid open after removal of the cranial vault. Some of the fibrous bands which cross the sinus are clearly seen; from two of the venous lacunae, bristles are passed into the sinus.

The *superficial middle cerebral vein* begins on the lateral surface of the hemisphere, and, following the posterior ramus and the stem of the lateral sulcus, ends in the cavernous sinus. The *superior anastomotic vein* runs backwards and upwards between the middle cerebral vein and the superior sagittal sinus, and thus a communication is established between the superior sagittal and cavernous sinuses. A second vein, named the *inferior anastomotic vein*, courses over the temporal lobe, and connects the middle cerebral vein to the transverse sinus.

The *inferior cerebral veins* are of small size, and drain the inferior surface of the hemisphere. Those on the orbital surface of the frontal lobe join the superior cerebral veins, and through these open into the superior sagittal sinus; those of the temporal lobe anastomose with the basal and middle cerebral veins, and empty into the cavernous, superior petrosal and transverse sinuses.

The *basal vein* begins at the anterior perforated substance by the union of (*a*) a small *anterior cerebral vein*, which accompanies the anterior cerebral artery, (*b*) the *deep middle cerebral vein*, which receives the tributaries from the insula and neighbouring gyri, and runs in the floor of the lateral cerebral sulcus, and (*c*) the *striate veins*, which pass through the anterior perforated substance. The basal vein passes backwards round the cerebral peduncle and ends in the great cerebral vein (**6.121**); it receives tributaries from the interpeduncular fossa, the inferior horn of the lateral ventricle, the parahippocampal gyrus and the midbrain.

The internal cerebral veins, right and left, drain the deep parts of the hemisphere; each is formed near the interventricular foramen by the union primarily of the *thalamostriate* and *choroid veins* (but numerous smaller veins from surrounding structures also converge becoming confluent near here). They run backwards parallel with each other, between the layers of the tela choroidea of the third ventricle, and below the splenium of the corpus callosum, where they unite to form the *great cerebral vein* (**6.121**).

The *thalamostriate vein* runs in the groove between the caudate nucleus and the thalamus, receives numerous veins from both of these structures, and unites behind the anterior column of the fornix with the choroid vein, to form the internal cerebral vein. The *choroid vein* runs along the whole length of the choroid plexus, and receives veins from the hippocampus, the fornix, and the corpus callosum and numerous adjacent structures.

The great cerebral vein starts from the union of the two internal cerebral veins, as a short median trunk which curves sharply upwards around the splenium of the corpus callosum and opens into the anterior end of the straight sinus, after receiving the right and left basal veins.

The cerebellar veins are placed on the surface of the cerebellum, and consist of superior and inferior sets. Some of the *superior cerebellar veins* pass forwards and medially, across the superior vermis, to end in the straight sinus or in the great cerebral vein; others run laterally to the transverse and superior petrosal sinuses. The *inferior cerebellar veins* include a small median vessel, which runs backwards on the inferior vermis to enter the straight or one of the sigmoid sinuses, and laterally coursing vessels which join the inferior petrosal and occipital sinuses.

The *veins of the brain stem* form a superficial venous plexus deep to the arteries. The veins of the midbrain may drain upwards into the great cerebral vein or basal vein. Over the pons the veins tend to form a lateral channel on each side which, with the upper medullary veins, may drain into the petrosal sinuses, the transverse sinus, cerebellar veins or the venous plexus of the foramen ovale. Sometimes a median pontine vein drains the pons and may join one of the basal veins above. The veins of the lower part of the medulla oblongata communicate with the veins of the spinal cord and drain into the adjacent venous sinuses, or along very variable radicular veins following the last four cranial nerves to the inferior petrosal or occipital sinuses, or to the upper part of the internal jugular vein. Anterior and posterior median veins may run along the anterior medial fissure or the posterior median sulcus respectively, continuous with the veins in the corresponding positions on the spinal cord (see also pp. 896, 1045).

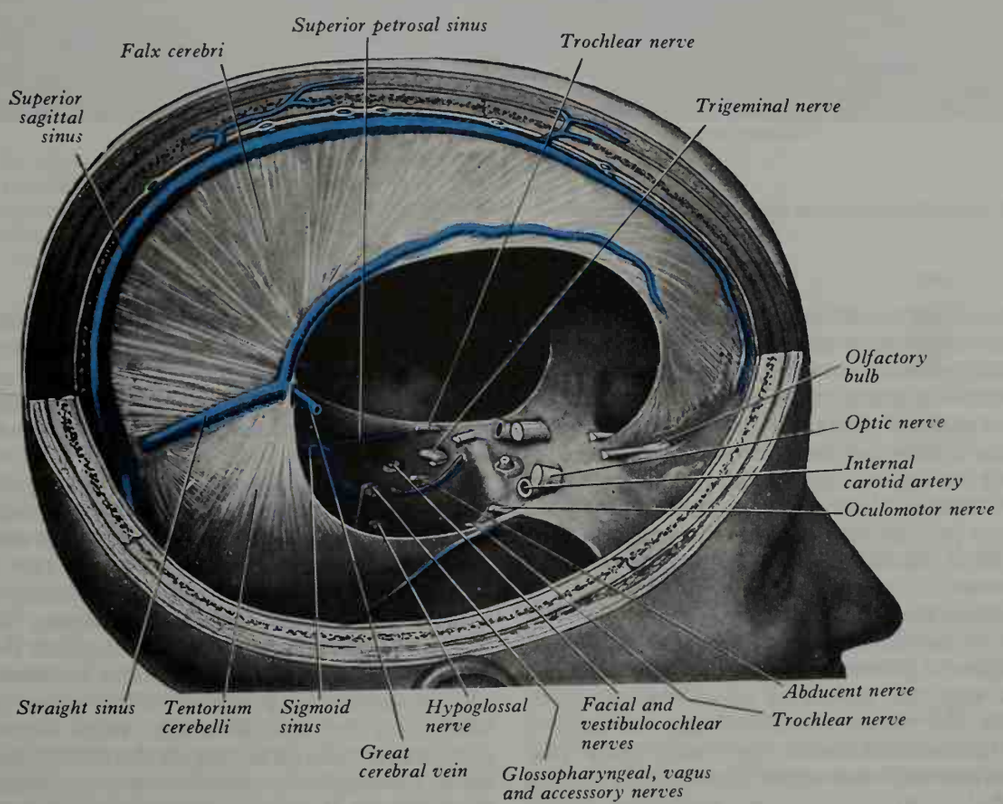
CRANIAL DURAL VENOUS SINUSES

The sinuses of the dura mater are venous channels which drain the blood from the brain and the bones of the cranium; they are situated between the two layers of the dura mater and are lined by endothelium continuous with that which lines the veins; they contain no valves, and their walls are devoid of muscular tissue. (It should be noted here that although most accounts present the sinuses as, in most cases, simple smooth channels, recent researches have emphasized their complex 'cavernous' or plexiform nature in many sites—*see* Browder and Kaplan 1976; also p. 747.) They may be divided into two groups: (1) a posterosuperior, in the upper and posterior parts of the cranial cavity, and (2) an antero-inferior, on the base of the skull.

1. *The posterosuperior group of venous sinuses*: superior sagittal, inferior sagittal, straight, two transverse, two petrosquamous, two sigmoid, and occipital sinuses.

The superior sagittal sinus (**6.121**, 122, 123) occupies the attached, convex margin of the falx cerebri. It commences in front of the crista galli, where it receives a vein from the nasal cavity on the rare occasions when the foramen caecum is patent. Kaplan *et al.* (1973) found no such venous tributary to the superior sagittal sinus in 201 specimens, in only 9 per cent of which did the sinus begin as far forward as the foramen. In most instances the first tributaries were cortical veins from the adjacent frontal poles of the cerebral hemispheres, the *ascending frontal veins* of Krayenbühl (1967). The sinus usually begins a few millimetres posterior to the foramen caecum. It runs backwards, grooving the inner surface of the frontal bone, the adjacent margins of the two parietal bones, and the squamous part of the occipital bone. Near the internal occipital protuberance it deviates to one or other side (usually the right), and is continued as the corresponding transverse sinus. It is triangular in cross-section, and gradually increases in size as it passes backwards. Its inner surface presents the openings of the superior cerebral veins, projecting arachnoid

granulations, and numerous fibrous bands which cross the inferior angle of the sinus; the sinus also communicates through small openings with irregularly shaped *venous lacunae*, which are situated in the dura mater near the sinus. There are usually three lacunae on each side of the sinus: a small frontal, a large parietal, and an occipital, intermediate in size. In elderly subjects these lacunae tend to become continuous with one another as one elongated lacuna on each side. Many fine fibrous bands cross the lacunae, and numerous arachnoid granulations project into them from below. The superior sagittal sinus receives the superior cerebral veins, and, near the posterior extremity of the sagittal suture, veins from the pericranium which pass through the parietal foramina; the venous lacunae drain the diploic and meningeal veins.

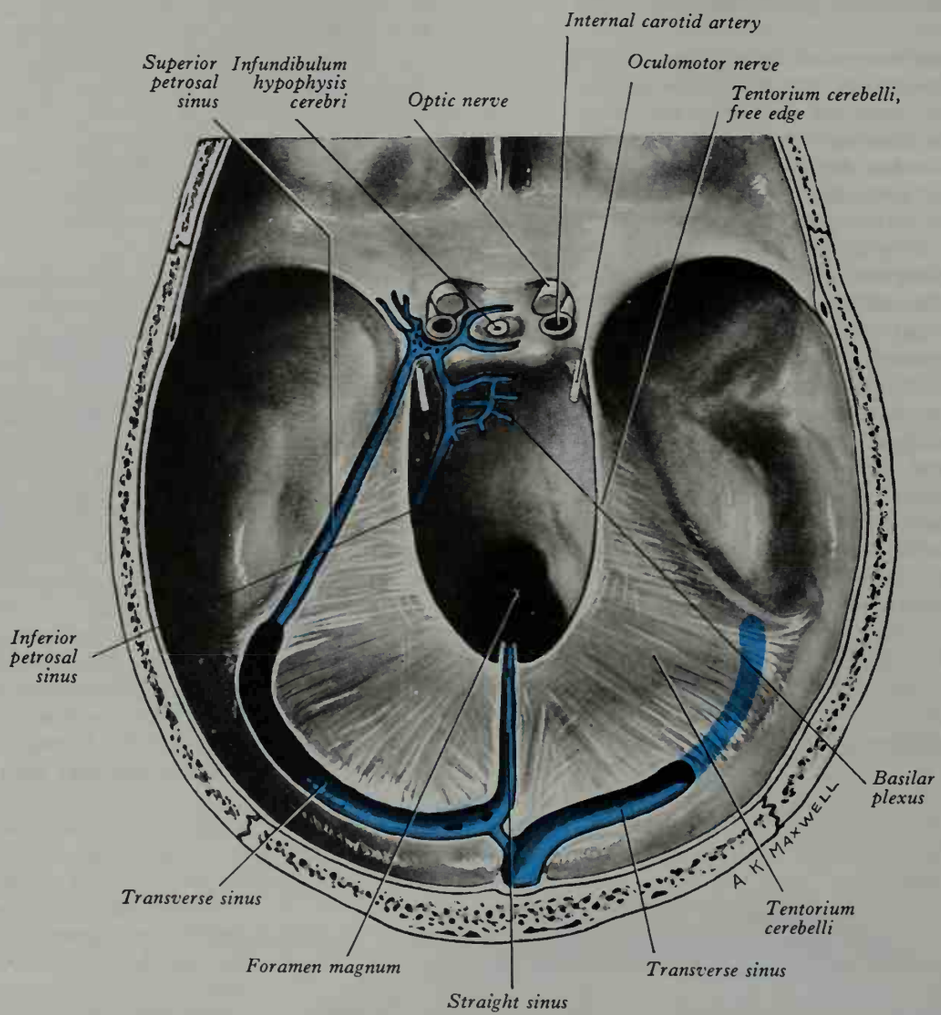


The complexity of the lateral lacunae of the superior sagittal sinus and of the sinus itself have been somewhat obscured by over-simplification in general texts of anatomy; but these complexities have often been emphasized (*see*, for example, LeGros Clark 1920, and Baló 1950), and corrosion cast studies (Browder and Kaplan 1976) and cerebral angiography have more recently revived these earlier views. The lateral lacunae are frequently so complex as to be almost plexiform and are rarely the simple venous spaces usually depicted. All the observers cited above have described plexiform arrangements of small veins in association with the sagittal, transverse, and straight sinuses, and LeGros Clark and Baló regarded these venous masses as cavernous tissue. Masses of this kind commonly adjoin all the sinuses which inter-communicate at the confluence of the sinuses. Ridges of such spongy venous tissue frequently project into the lumen of the superior sagittal and transverse sinuses. The function of these arrangements can only be conjectured (*see* p. 1050). The lumen of the superior sagittal sinus is also invaded, in its intermediate third, by variable bands and projections of its dural walls, which may even extend as horizontal shelves, dividing its lumen into superior and inferior channels for considerable distances. All these variable factors make it impossible to give a simple description of this or other venous sinuses. Their variations have been noted in detail by Browder and Kaplan (1974) in a large series of corrosion casts; even with this information individual variations can only be established by angiography in the living.

The confluence of the sinuses (**6**.124) is the term applied to the dilated posterior extremity of the superior sagittal sinus. It is one side (generally the right) of the internal occipital protuberance, and from it the transverse sinus of the same side is derived. It receives also the blood from the occipital sinus, and connects with the commencement of the opposite transverse sinus. The size and degree of inter-communication of the venous channels which meet at the confluence are highly variable (consult Browder and Kaplan 1974, for the statistics of 215 specimens). In more than half of specimens examined all the venous channels which converge towards the internal occipital protuberance do in fact interconnect, and this includes the straight and occipital sinuses. In many instances communications are lacking or tenuous. Any of the sinuses involved may be reduplicated, narrowed, or widened as it approaches the confluence. The variety of arrangements is too great to make particularization useful until much larger series than that quoted above become available.

Applied Anatomy. The communications between the superior sagittal sinus and the veins of the nose, scalp, and diploë explain the occasional spread of infective thrombosis from suppurative processes in these parts.

The inferior sagittal sinus (**6**.123) is in the posterior half or two-thirds of the free margin of the falx cerebri. It increases in size posteriorly, and ends in the straight sinus. It receives several veins from the falx, and occasionally a few from the medial surfaces of the cerebrum.



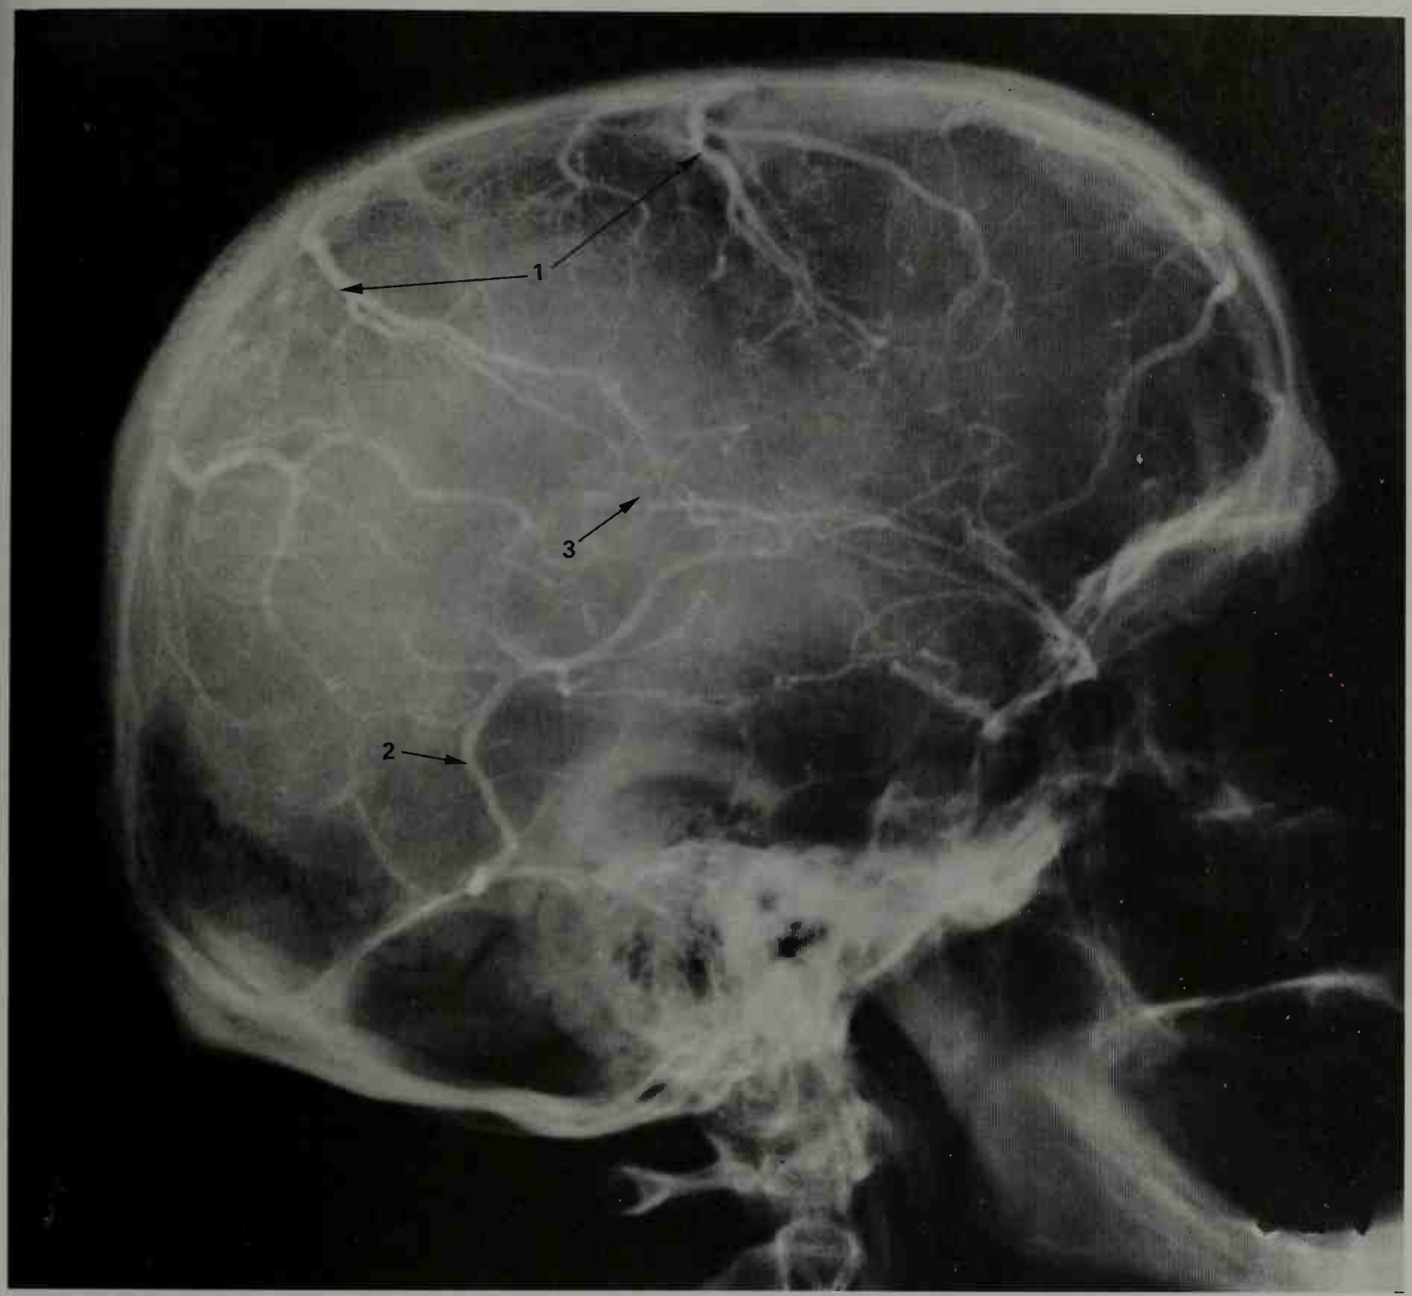
The straight sinus (**6**.123, 124) is in the junction of the falx cerebri and tentorium cerebelli. It is triangular in cross-section and displays a few transverse bands. It runs backwards and downwards, continuing the inferior sagittal sinus to the transverse sinus of the side opposite to that into which the superior sagittal sinus is prolonged. Its terminal part communicates with the confluence of the sinuses. Besides the inferior sagittal sinus, it receives some of the superior cerebellar veins, and, at its commencement, the great cerebral vein, the site of the opening of this vein being marked by a dilatation. A small body, resembling an arachnoid granulation, projects into the floor of the sinus at its angle of union with the great cerebral vein. This body, which contains a sinusoidal plexus of blood vessels, is believed to become engorged from time to time and may then act as a ball-

6.123 The dura mater, its processes, and venous sinuses. Right aspect.

valve mechanism controlling the outflow from the great cerebral vein and thus affecting the secretion of cerebrospinal fluid by the choroid plexuses of the lateral ventricles. As noted, other masses of cavernous tissue have been described in relation with many dural sinuses. Engorgement possibly influences the blood flow through them: structural data make this unlikely (*vide supra*).

The transverse sinuses (**6**.124, 126) are of large size and begin at the internal occipital protuberance, one, generally the right, being the direct continuation of the superior sagittal sinus, the other of the straight sinus. Each transverse sinus passes laterally and forwards to the posterolateral part of the petrous part of the temporal bone, where it curves down as the sigmoid sinus. It lies in the attached margin of the tentorium cerebelli, at first on the squama of the occipital bone and then on the mastoid angle of the parietal. It describes a gentle curve, convex upwards, and increases in size as it proceeds forwards. The transverse sinuses are triangular on transverse section, and are frequently of unequal size, the one draining the superior sagittal sinus being the larger. Where they become continuous with the sigmoid sinuses, they are joined by the superior petrosal sinuses; and in their course they receive inferior cerebral, inferior cerebellar, and diploic veins, and the inferior anastomotic vein (p. 744).

6.124 The tentorium cerebelli and venous sinuses. Superior aspect.

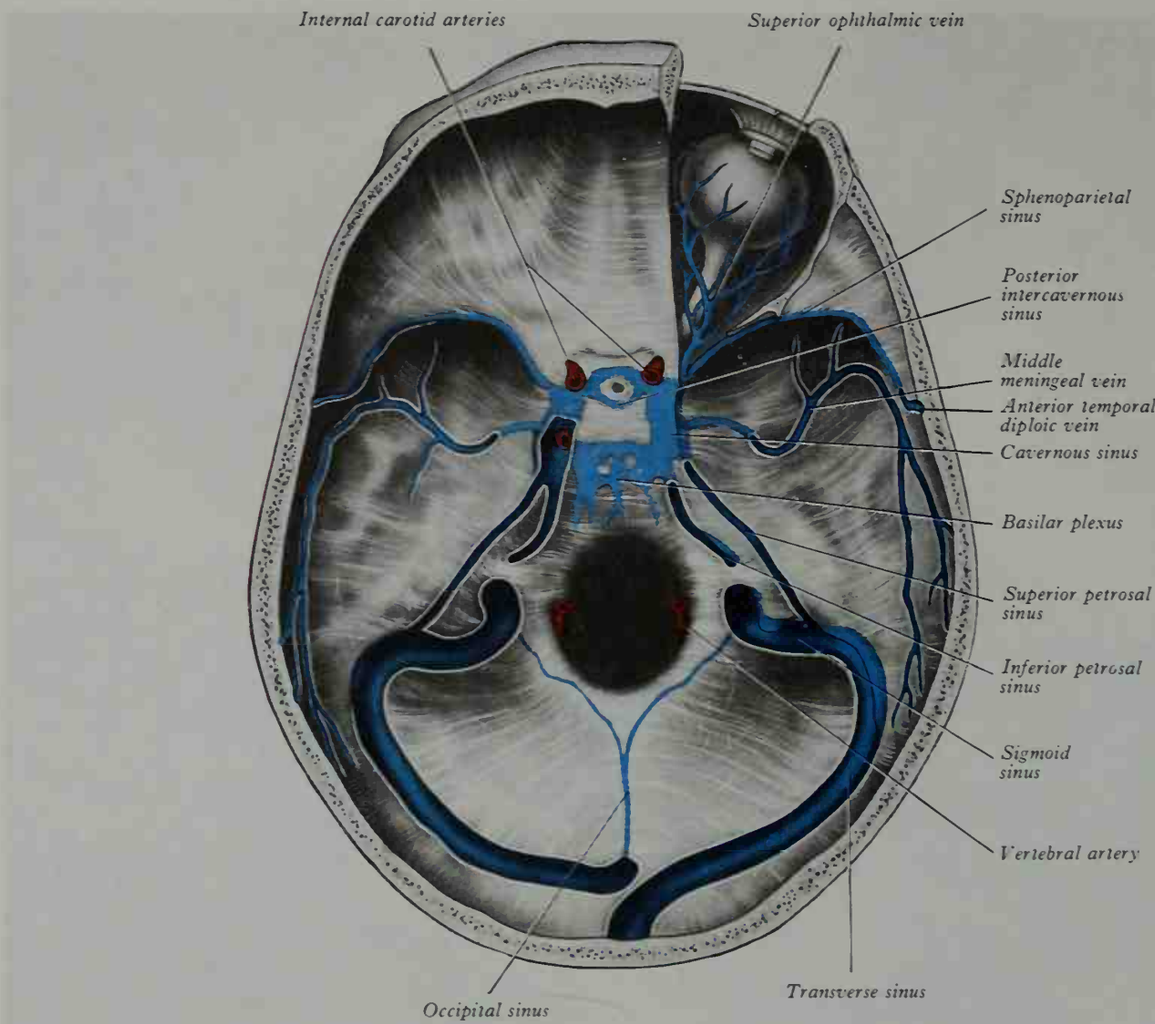


The petrosquamous sinus runs backwards in a groove, the posterior part of which may be converted into a canal, along the junction of the squama and petrous portion of the temporal bone, and opens behind into the transverse sinus. Anteriorly, it communicates with the retromandibular vein through a postglenoid or a squamosal foramen (pp. 327, 328). The petrosquamous sinus may be absent or may drain entirely into the retromandibular vein.

The sigmoid sinuses (**6**.126) are direct continuations of the transverse sinuses, beginning where the latter leave the tentorium cerebelli. Each sigmoid sinus curves downwards and medially in a deep groove on the mastoid part of the temporal bone, crosses the jugular process of the occipital bone, and then turns forwards to become the superior bulb of the internal jugular vein in the posterior part of the jugular foramen. Anteriorly, only a thin plate of bone separates the upper part of the sigmoid sinus from the mastoid antrum and mastoid air cells. Each sinus communicates with the veins of the pericranium by means of the mastoid and condylar emissary veins.

The occipital sinus (**6**.126), the smallest of the cranial sinuses, is in the attached margin of the falx cerebelli, and is occasionally paired. It commences near the margin of the foramen magnum in several small venous channels, one of which joins the terminal part of the sigmoid sinus; it communicates with the internal vertebral plexuses, and ends in the confluence of the sinuses.

2. *The antero-inferior group of venous sinuses*: cavernous, intercavernous, inferior petrosal, sphenoparietal, superior petrosal, basilar, and the middle meningeal veins.



The cavernous sinuses (**6**.121, 126, 127) are placed one on each side of the body of the sphenoid bone, and are so named because they present a spongy structure, due to their being traversed by numerous interlacing filaments. It is claimed that the distended sinus in the adult contains few filaments (trabeculae), and mostly at the periphery of the sinus near the entry of tributaries, and that these may result from incorporation of plexiform tributaries during the developmental expansion of the sinus. Furthermore, when the sinus is collapsed, as is usual in dissecting-room cadavers, its cavity is encroached upon by the nerves and arachnoid granulations in its wall which thus give a

6.125 Internal carotid arteriogram (right), venous phase. Lateral view. (Same subject as **6.54** and **6.55**, p. 633.) 1. Superior cerebral veins. spurious resemblance to cavernous tissue (Butler 1957). From a study of corrosion-cast preparations Parkinson (1973) concluded that the sinus is, in fact, usually a plexus (as during its development), a finding which is in accord with some earlier descriptions. Pernkopf (1963), for example, depicted the 'sinus' as a venous plexus (*see* **6.127**B, C). Browder and Kaplan (1976) have also examined a large series of corrosion casts of cavernous sinuses, prepared in human cadavers; they described the sinus as 'reticulated' in external view. It is not clear whether this signified *plexiform* or *cavernous*, but the latter seems more probable. It extends from the superior orbital fissure in front, to the apex of the petrous part of the temporal bone behind, and has an average length of 2 cm and width of 1 cm. The internal carotid artery, surrounded by a plexus of sympathetic nerves, passes forwards through the sinus; the abducent nerve, in this part of its course, lies inferolateral to the artery; the oculomotor and trochlear nerves, and the ophthalmic and maxillary divisions of the trigeminal nerve (**6.127**) are frequently described as being *in the thickness* of the lateral wall of the sinus. In fact, they are of such diameters that they project considerably into the sinus itself (**6.127**A); and while they may be surrounded by dural connective tissue, in some cases, they are usually covered medially by little more than endothelium. (Consult McGrath (1977), for a survey of this and other details of this region.) The sphenoidal air sinus and the hypophysis cerebri are medial to the cavernous sinus. The trigeminal cave is close to the lower and posterior part of its lateral wall, and extends backwards beyond the sinus, enclosing the trigeminal ganglion. The uncus forms an additional relation of the lateral wall.

The tributaries of the cavernous sinus are the superior ophthalmic vein, a branch from the inferior ophthalmic vein (or the whole vessel), the superficial middle cerebral vein, inferior cerebral veins, and the sphenoparietal sinus; the central vein of the retina and the frontal tributary of the middle meningeal vein sometimes open into it. The cavernous sinus drains into the transverse sinus through the superior petrosal sinus, into the internal jugular vein by way of the inferior petrosal sinus and a plexus of veins on the internal carotid artery, into the pterygoid venous plexus by veins which pass through the emissary sphenoidal foramen, foramen ovale, and foramen lacerum, and

6.126 The sinuses at the base of the skull. The sinuses coloured dark blue have been opened up.

into the facial vein through the superior ophthalmic vein. The two sinuses also communicate with each other by means of the anterior and posterior intercavernous sinuses and the network of the basilar plexus. All these communications are valveless, and therefore the direction of flow in them is reversible.

The expulsion of blood from the cavernous sinus is due partly to the expansile pulsation of the internal carotid artery in its interior. It is also influenced to some extent by gravity and the position of the head.

Applied Anatomy. An arteriovenous communication may occur between the cavernous sinus and the internal carotid artery, giving rise to a pulsating swelling in the orbit. This may result from various injuries, such as a bullet wound, or a fracture of the base of the skull. Ligation of the internal or common carotid artery has been performed in these cases with considerable success.

Suppuration in the upper nasal cavities and certain paranasal sinuses may lead to septic thrombosis of the cavernous sinuses, with subsequent meningitis.

The ophthalmic veins (**6**.126, 128) superior and inferior, are devoid of valves.

The *superior ophthalmic vein* is formed behind the medial part of the upper eyelid by two tributaries which communicate anteriorly with the facial and supraorbital veins (p. 738). It runs with the ophthalmic artery, receives tributaries corresponding to its branches, passes through the superior orbital fissure, and ends in the cavernous sinus.

The *inferior ophthalmic vein* begins in a venous network near the forepart of the floor and medial wall of the orbit; it receives veins from the rectus inferior, obliquus inferior, lacrimal sac and eyelids, and runs backwards above the rectus inferior. It frequently joins the superior ophthalmic vein, but may open separately into the cavernous sinus. It communicates with the pterygoid venous plexus by small veins passing through the inferior orbital fissure.

The central vein of the retina first traverses the optic nerve behind the lamina cribrosa and then leaves it to pursue a long course in the subarachnoid space before piercing the dura mater to enter either the cavernous sinus or the superior ophthalmic vein. Within the nerve it receives a central vein draining its proximal part.

The sphenoparietal sinuses (**6**.126) are inferior to the lesser wings of the sphenoid bone, next to periosteum and near their posterior edges. Each receives small veins from the adjacent part of the dura mater and sometimes the frontal trunk of the middle meningeal vein; it opens into the anterior part of the cavernous sinus. The sinus frequently receives connecting rami, in the middle part of its course, from the superficial middle cerebral vein, and its tributaries may also include veins from the temporal pole of the cerebrum, and the anterior temporal diploic vein. When these cerebral venous connexions are well developed the sphenoparietal sinus is a particularly large channel.

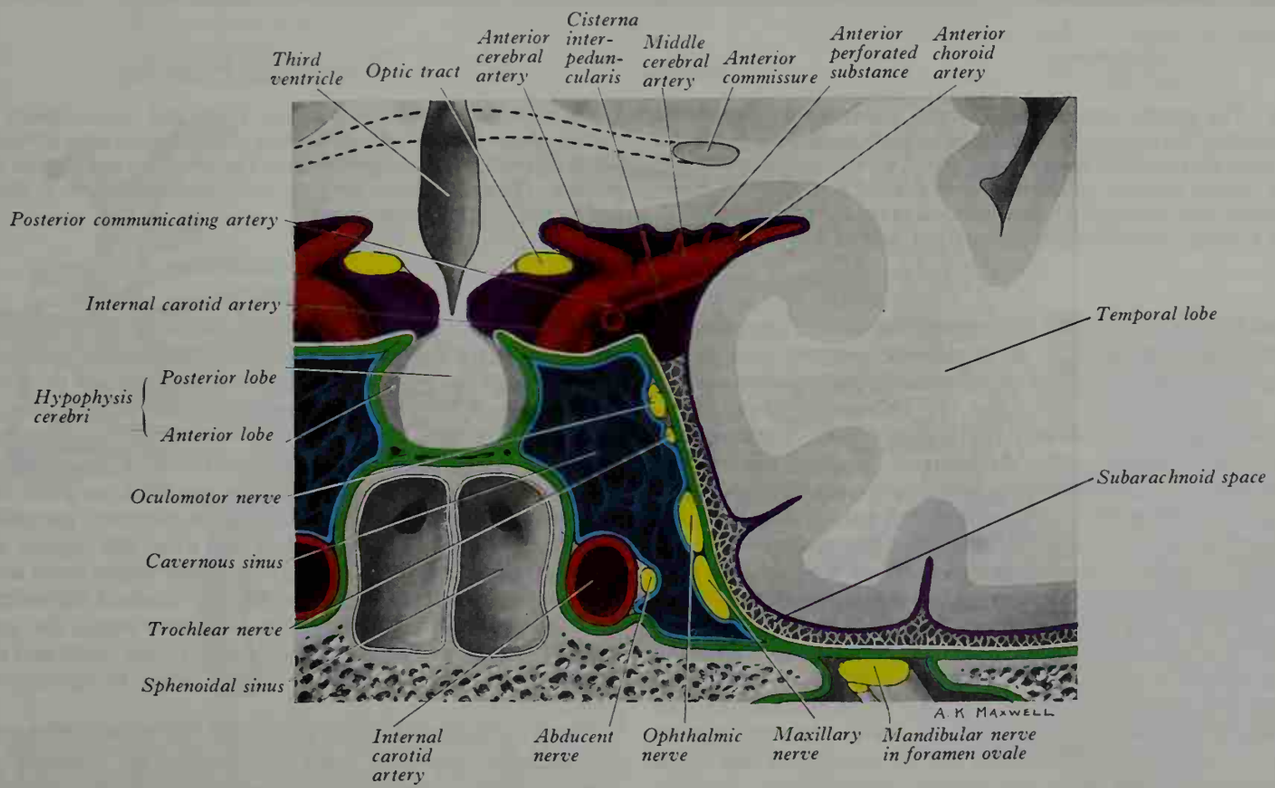
The intercavernous sinuses, an anterior and a posterior, connect the cavernous sinuses across the median plane, and are in the anterior and posterior attached borders of the diaphragma sellae; with the cavernous sinuses they thus form a venous circle (*circular sinus*, **6**.126). Small, irregular venous sinuses which lie below the hypophysis cerebri drain into the intercavernous sinuses. The *inferior intercavernous sinuses* were studied by casts in 27 specimens by Kaplan *et al.* (1976), who emphasized their size and plexiform arrangement, factors of importance in the trans-nasal surgical approach to the hypophysis cerebri.

The superior petrosal sinuses (**6**.126), small and narrow, drain the cavernous into the transverse sinuses. Leaving the

posterosuperior part of the cavernous sinus, each superior petrosal sinus runs backwards and laterally in the attached margin of the tentorium cerebelli. It crosses above the trigeminal nerve and then lies in a groove on the superior border of the petrous part of the temporal bone. Finally, it terminates by joining the transverse sinus where the latter curves downwards to become the sigmoid sinus. It receives some cerebellar and inferior cerebral veins, and veins from the tympanic cavity. It also has connexions with the inferior petrosul sinus and basilar venous plexus.

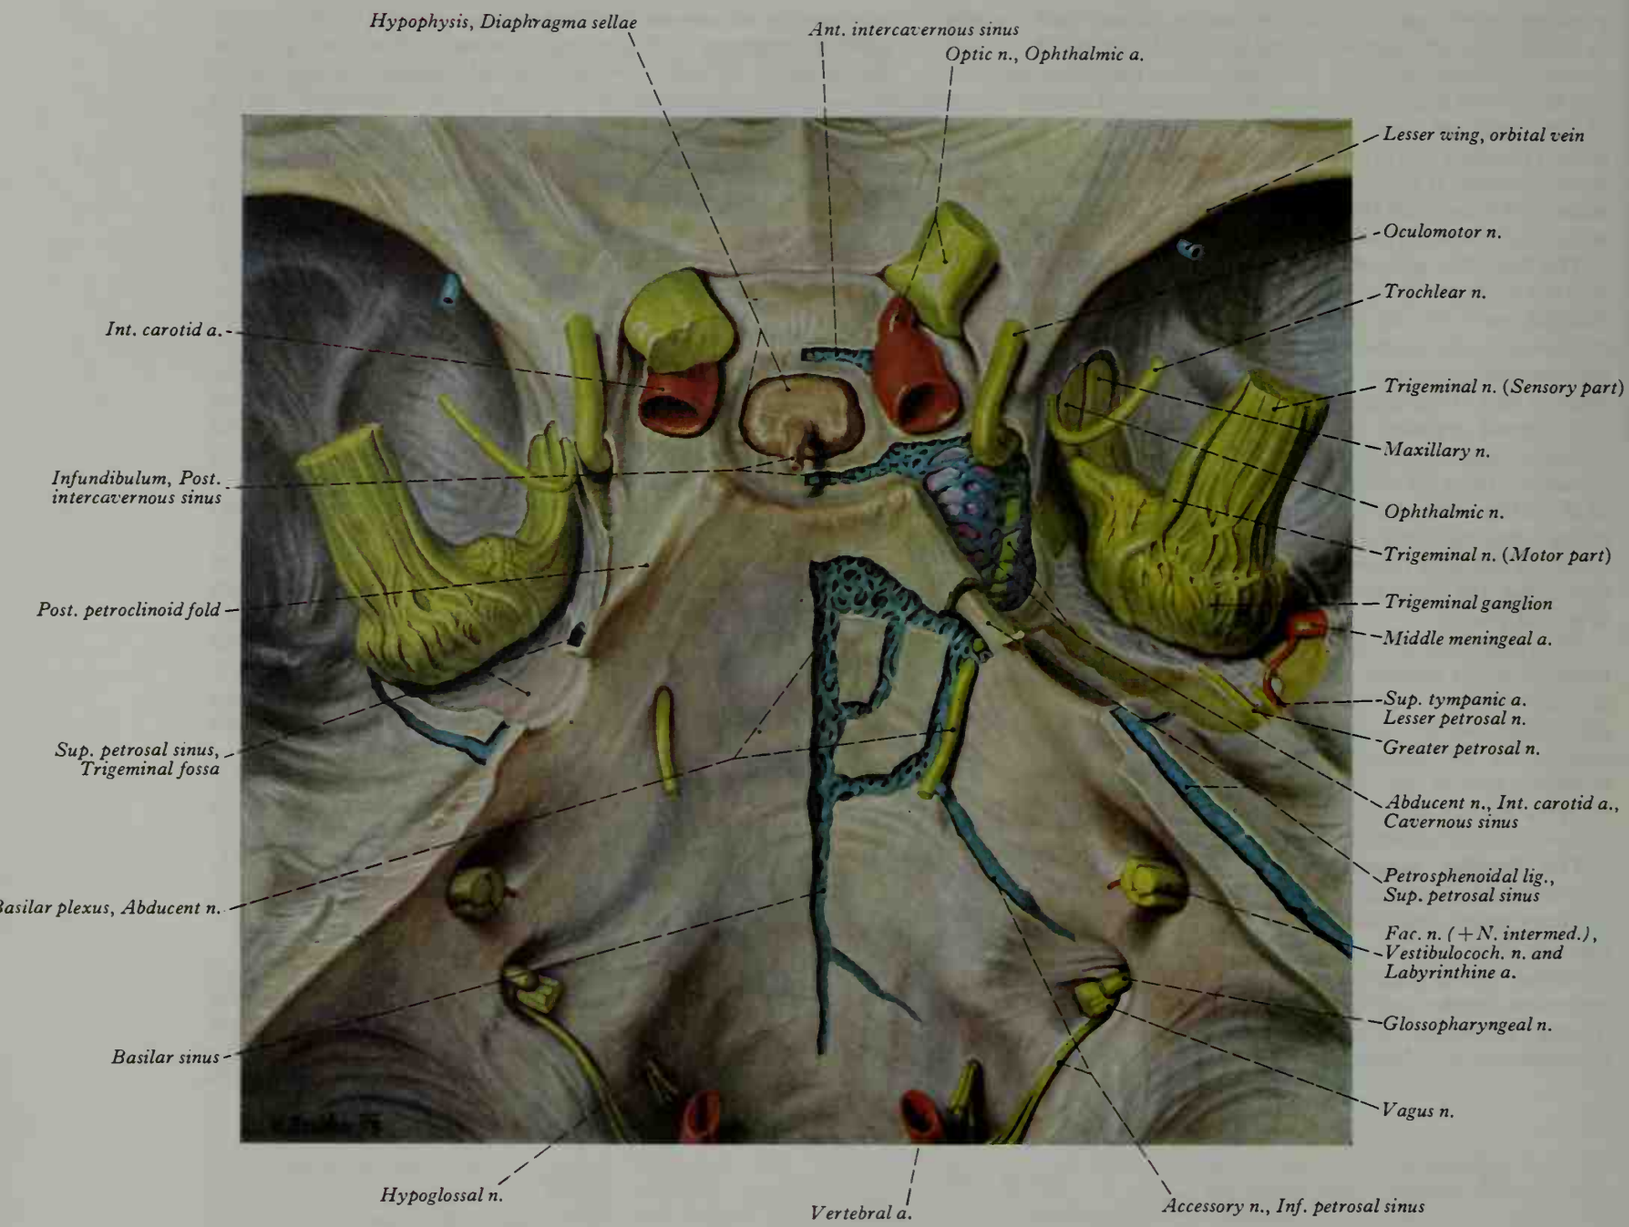
The inferior petrosal sinuses drain the cavernous sinuses into the internal jugular vein. Each (**6**.126) begins in the postero-inferior part of the corresponding cavernous sinus, runs backwards in the groove between the petrous part of the temporal and the basilar part of the occipital bone. Passing through the anterior part of the jugular foramen it ends in the superior bulb of the internal jugular. It receives *labyrinthine veins* from the cochlear canaliculus, from the aqueduct of the vestibule, and tributaries from the medulla oblongata, pons, and inferior surface of the cerebellum. According to Browder and Kaplan (1976) the inferior petrosal sinus is more often a venous plexus than a single vessel. They also reported that it sometimes drains by a vein traversing the hypoglossal canal to end in the suboccipital vertebral plexus.

The relations of the structures transmitted through the jugular foramen are as follows: the inferior petrosal sinus lies medially and anteriorly with the meningeal branch of the ascending pharyngeal artery, and is directed obliquely downwards and backwards; the sigmoid sinus is situated at the lateral and posterior part of the foramen with a meningeal branch of the occipital artery; between the two sinuses are the glossopharyngeal, vagus, and accessory nerves (*see* p. 1082).



The basilar venous plexus (**6**.126) consists of several interconnecting venous channels situated between the layers of the dura mater over the clivus of the skull; it connects the two inferior petrosal sinuses, and communicates with the internal vertebral venous plexus. The plexus usually connects with the cavernous sinuses and the superior petrosal sinuses at its anterior (rostral) extremity. When the marginal sinuses are large they communicate anteriorly with the basilar venous plexus. There may then be an almost complete venous channel encircling the foramen magnum and forming communications between the basilar plexus and the inferior petrosal, sigmoid, and occipital sinuses at the intracranial level, and variable connexions with the extracranial vertebral plexuses in the suboccipital region.

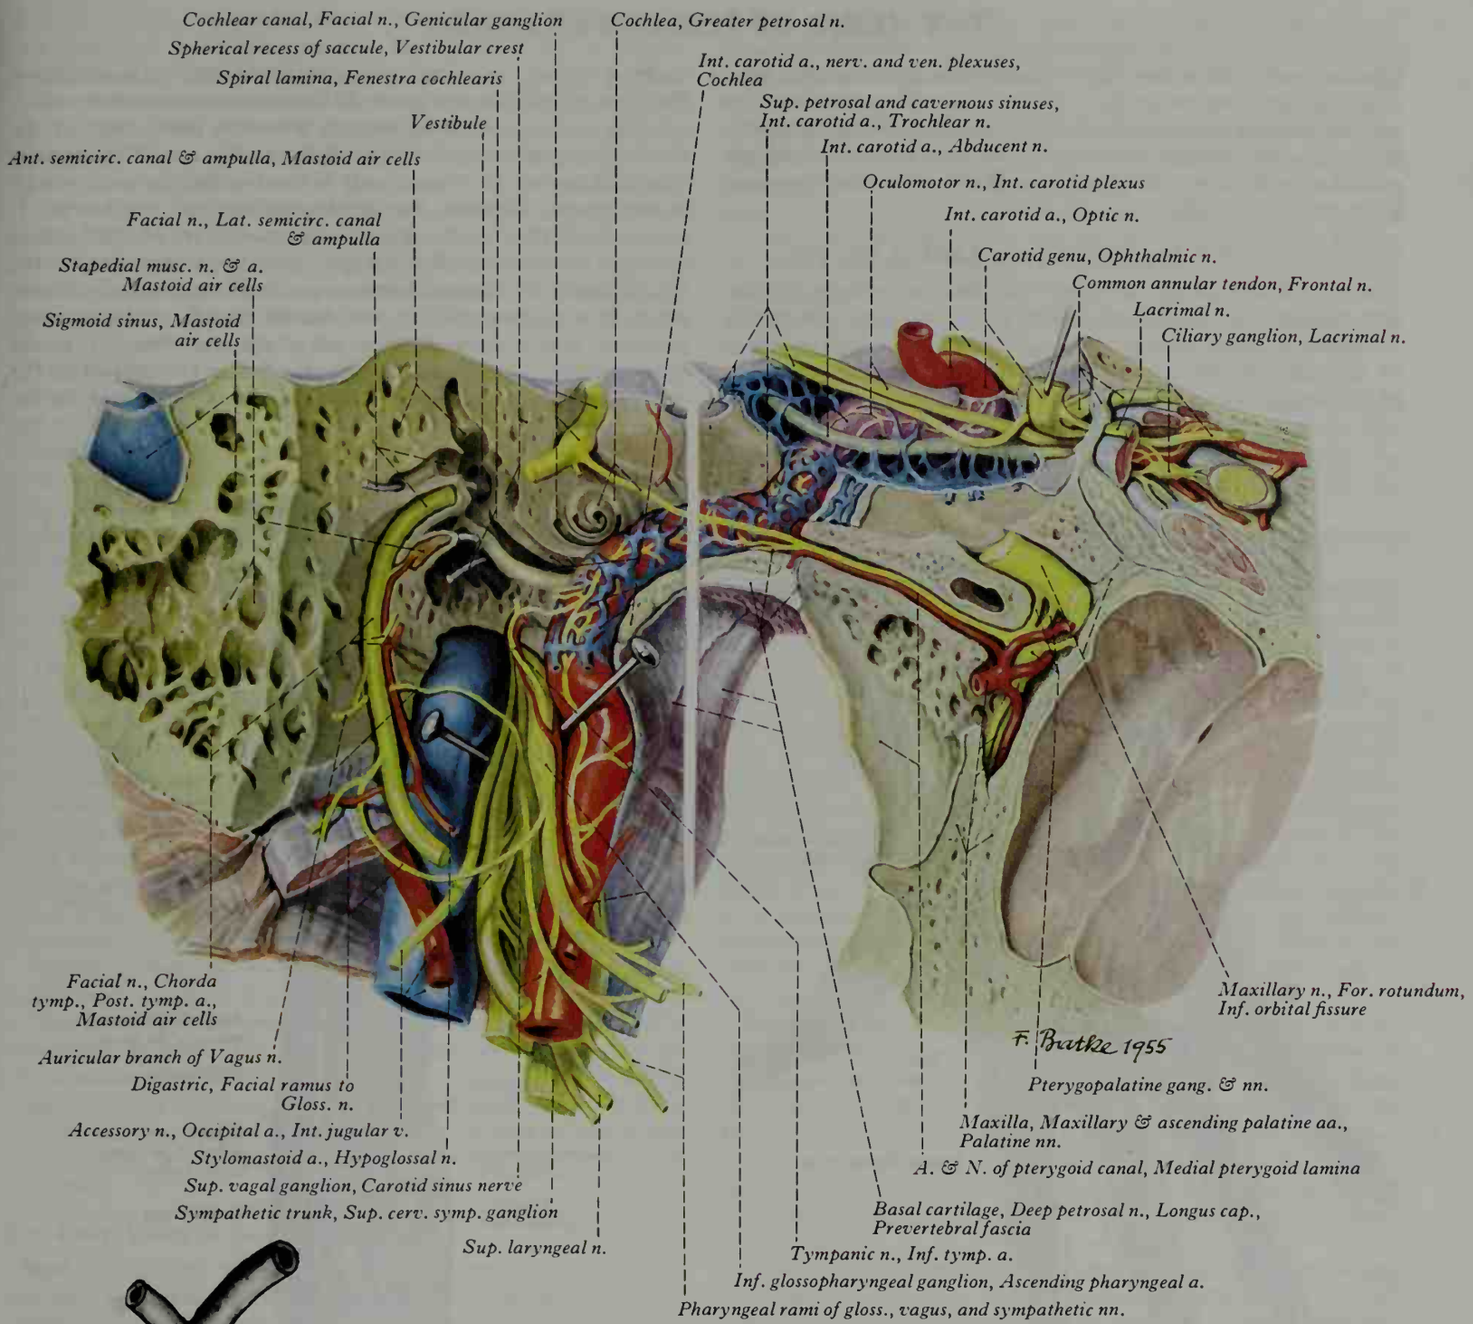
The middle meningeal veins (**6**.126) communicate above with the superior sinus through the adjoining venous lacunae, and unite to form two principal trunks, a frontal and a parietal, which accompany the branches of the middle meningeal arteries more or less closely in the grooves on the inner surface of the parietal bone; the veins are closer to bone than the arteries and sometimes they occupy separate grooves. The grooves on the inner surfaces of the parietal bones are in reality impressed not by the arteries but by the middle meningeal veins which are liable to be torn when the bones are fractured (Wood Jones 1911). Their ending is subject to variation. The parietal trunk may pass through the foramen spinosum into the pterygoid plexus. The frontal trunk may reach the pterygoid plexus through the foramen ovale, or it may end in the sphenoparietal or cavernous sinus. Besides their meningeal tributaries they receive some small inferior cerebral veins, and communicate with the diploic veins and the superficial middle cerebral vein. Browder and Kaplan (1976) state that the middle meningeal 'veins' are histologically *sinuses*, which in places almost surround the middle meningeal artery; they also report the frequent occurrence of arachnoid granulations in these channels.



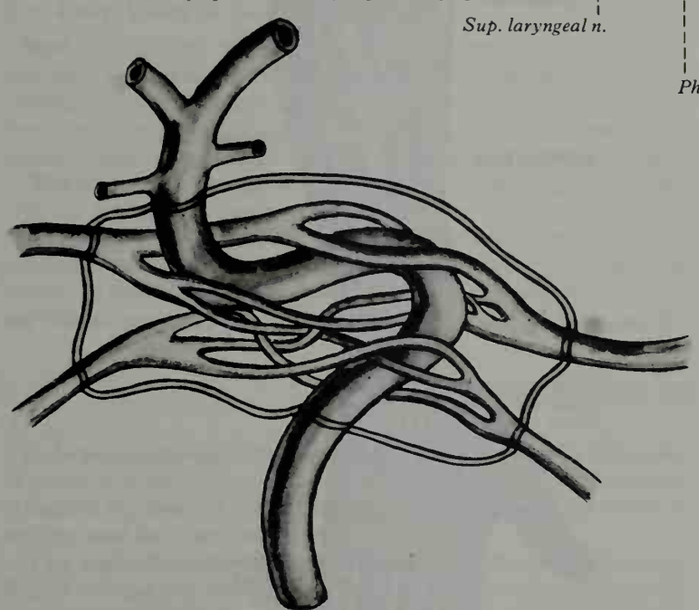
Surface Anatomy of the Venous Sinuses. The *superior sagittal sinus* runs from the glabella (p. 298) to the inion (**3**.126). Narrow anteriorly, it widens posteriorly until it is about 1 cm wide. The *transverse sinus* begins at the inion and runs laterally, with a slight upward convexity to the base of the mastoid process. From this the *sigmoid sinus* passes downwards just in front of the posterior border of the mastoid process to a point about 1 cm from its tip. These sinuses are usually a little more than 1 cm wide.

The Emissary Veins

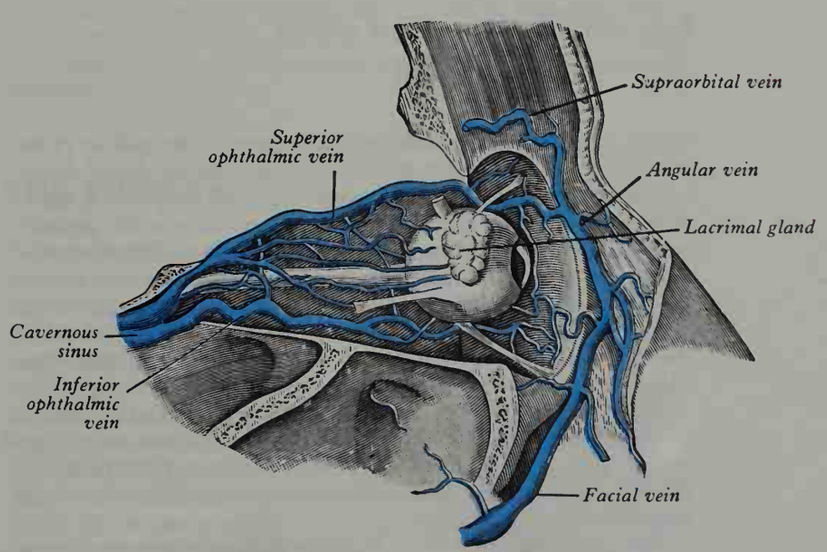
The emissary veins pass through apertures in the cranial wall and establish communications between the venous sinuses inside the skull and the veins external to it. Some are constant, but others sometimes absent. (1) A *mastoid emissary vein* runs through the



6.127A A coronal, slightly oblique section through the middle cranial fossa, showing the cavernous and cerebral portions of the internal carotid artery and the cavernous sinus. Pia mater—mauve; arachnoid mater—white; layers of dura mater—green; mesothelium of dura mater not indicated, endothelium of cavernous sinus—blue.



6.127B The middle cranial fossa, viewed from above to show the termination of the internal carotid artery, its branches and the cavernous sinus. Note the plexiform nature of the 'sinus', which communicates with similar venous plexuses in the hypophysial fossa and over the clivus. These have been exposed by partial removal of the dura mater.
C An oblique vertical section through the cranial base to display in lateral view the right internal carotid artery and the continuity of the venous plexus around the intra-osseous and cavernous parts of the artery. (Both figures from Pernkopf's *Atlas of Topographical and Applied Human Anatomy*, English Edition 1963, by kind permission of W. B. Saunders and Urban and Schwarzenberg.)

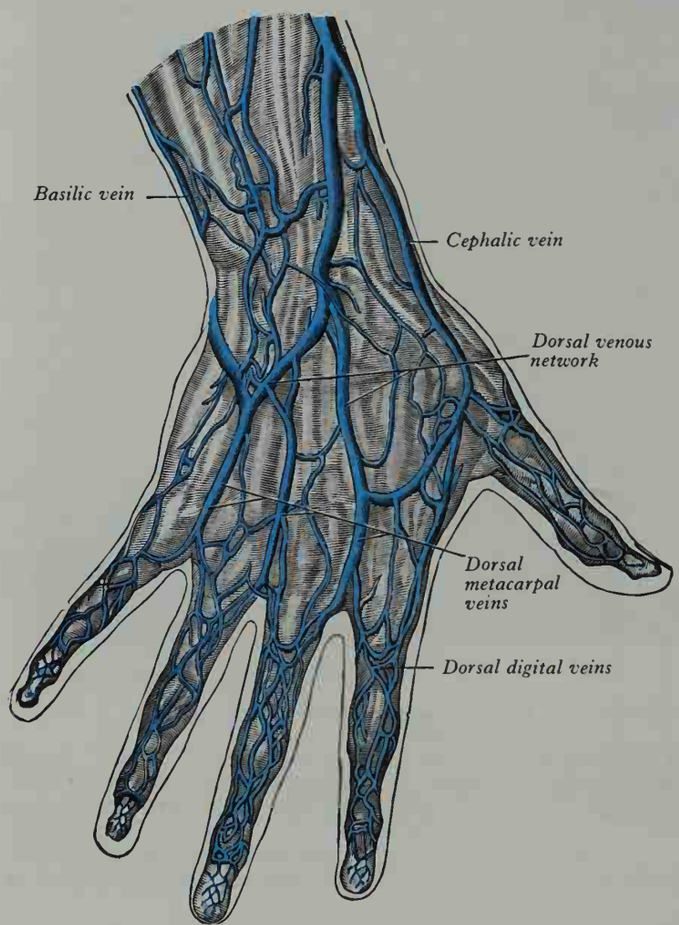


mastoid foramen and unites the sigmoid sinus with the posterior auricular or occipital vein. (2) A *parietal emissary vein* passes through the parietal foramen and connects the superior sagittal sinus with the veins of the scalp. (3) The *venous plexus of the hypoglossal canal*, or occasionally a single vein, traverses the hypoglossal canal and joins the sigmoid sinus to the internal jugular vein. (4) A *posterior condylar emissary vein* passes through the condylar canal and connects the sigmoid sinus with the veins in the suboccipital triangle. (5) A network of emissary veins (the *venous plexus of the foramen ovale*) unites the cavernous sinus with the pterygoid plexus through the foramen ovale. (6) Two or three small emissary veins run through the foramen lacerum and connect the cavernous sinus with the pharyngeal veins and pterygoid plexus. (7) A vein traverses the emissary sphenoidal foramen (of Vesalius) and connects the same vessels. (8) The *internal carotid venous plexus* accompanies the internal carotid artery through the carotid canal of the temporal bone and unites the cavernous sinus with the internal jugular vein. (9) The petrosquamous sinus (p. 746) connects the transverse sinus with the external jugular vein. (10) A vein may pass through the foramen caecum, which, however, is patent in only a little over 1 per cent of adult skulls; it connects veins in the nose with the superior sagittal sinus. (11) An *occipital emissary vein* connects the confluence of sinuses with the occipital vein through the occipital protuberance. It also receives the occipital diploic vein. This emissary vein may be absent. (12) The occipital sinus usually communicates with variably developed venous channels around the rim of the foramen magnum (the so-called *marginal sinuses*) and through these with vertebral venous plexuses, providing an alternative escape for venous drainage when the jugular vein is blocked or deliberately tied. (13) The ophthalmic veins must be regarded as potential emissaries; they do connect intracranial to extracranial venous channels. On the other hand, the parietal emissary veins, included here, are usually very small and do not appear to connect with veins of the scalp in corrosion cast preparations.

These arrangements are of importance in the possible spread of inflammatory processes from foci outside the cranium to the venous sinuses within. Moreover, surgical ligature of the internal jugular vein, as a measure to limit oral and pharyngeal malignant disease, is necessarily dependent upon the adequacy of collateral drainage.

6.127D Diagram showing left lateral view of the left internal carotid artery and surrounding venous channels. The limits of the cavernous venous system are shown by the encircling double black line. Note the *plexiform* nature of this system, as described by some authorities. This is an artist's impression founded upon numerous dissections and corrosion casts by Dr. Dwight Parkinson (University of Manitoba) to whom we are indebted. See text for further details.

6.128 The veins of the right orbit. Lateral aspect.

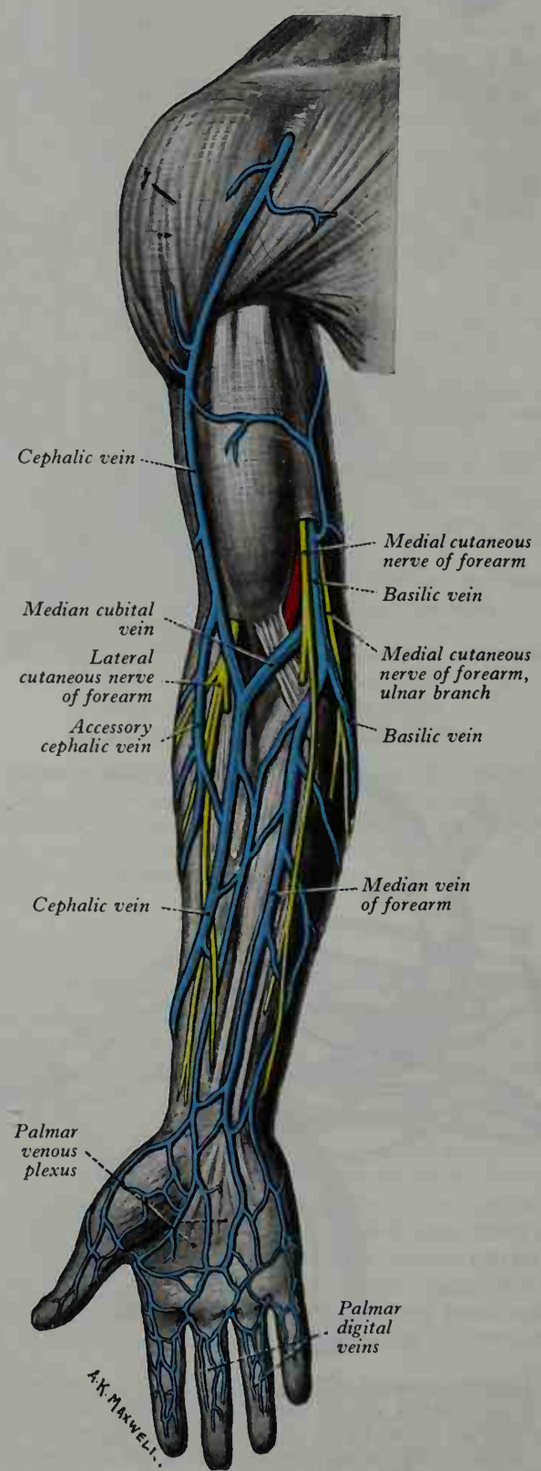


THE VEINS OF THE UPPER LIMBS

The veins of the upper limb can be divided into two sets, *superficial* and *deep*, which anastomose freely with each other. The superficial veins are immediately under the skin, in the superficial fascia; the deep veins accompany the arteries. Both sets are provided with valves, which are more numerous in the deep than in the superficial veins.

The Superficial Veins of the Upper Limb (6.129, 130)

The superficial veins of the upper limb are the cephalic, basilic, and median cubital and antebrachial veins, and their tributaries.



The *dorsal digital veins* pass along the sides of the fingers, joined by oblique communicating branches. Those from adjacent sides of the fingers unite into three *dorsal metacarpal veins* (**6**.129), which end in a *dorsal venous network* opposite the middle of the metacarpus. Laterally the network is joined by the dorsal digital vein from the radial side of the index finger and both dorsal digital veins of the thumb, and is prolonged proximally as the cephalic vein. Medially the network receives the dorsal digital vein of the ulnar side of the little finger, and is continued upwards as the basilic vein. A communicating vein frequently connects the central part of the dorsal venous network with the cephalic about the middle of the forearm (see also accessory cephalic vein, below).

6.129 The veins of the dorsum of the hand.

The *palmar* digital veins are connected to the *dorsal* by oblique *intercapitular veins*, which pass back between the metacarpal heads. They also drain into a venous plexus superficial to the palmar aponeurosis and extending over the thenar and hypothenar eminences.

The cephalic vein (**6**.130) winds upwards from the dorsal venous network round the radial border of the forearm to its anterior surface, receiving tributaries from both surfaces. Below the front of the elbow it gives off the *median cubital vein*, which receives a communicating branch from the deep veins of the forearm and passes medially to join the basilic vein. The cephalic vein then ascends subcutaneously in front of the elbow superficial to the groove between the brachioradialis and the biceps. It crosses superficial to the lateral cutaneous nerve of the forearm and runs upwards lateral to biceps. In the upper one-third of the arm it lies in the interval between pectoralis major and deltoid, where it is accompanied by the deltoid branch of the thoraco-acromial artery. Entering the infraclavicular fossa, it passes behind the clavicular head of pectoralis major. It then pierces the clavipectoral fascia, crosses the axillary artery, and ends in the

6.130 The superficial veins of the right upper extremity. Anterior aspect.

axillary vein just below the level of the clavicle. Sometimes it communicates with the external jugular vein by a branch ascending anterior to the clavicle.

Sometimes the median cubital vein is large and carries all or most of the blood from the cephalic into the basilic vein, the proximal half of the cephalic vein being either absent or proportionately diminished.

The *accessory cephalic vein* arises from a small tributary plexus on the back of the forearm or from the ulnar side of the dorsal venous network; it joins the cephalic below the elbow. In some cases it springs from the cephalic vein above the wrist and joins it again higher up. A large oblique branch frequently connects the basilic and cephalic veins on the back of the forearm.

The basilic vein (**6**.130) begins in the ulnar part of the dorsal venous network of the hand. It ascends for some distance on the posterior surface of the ulnar side of the forearm, but inclines forward to the anterior surface below the elbow. It is joined by the median cubital vein and ascends obliquely and superficially, in the groove between the biceps and pronator teres; filaments of the medial cutaneous nerve of the forearm pass in front of and behind this section of the vein. It then runs upwards medial to biceps, perforates the deep fascia a little below the middle of the arm, and ascends medial to the brachial artery to the lower border of teres major, continuing as the axillary vein.

The median vein of the forearm (**6**.130) drains the superficial palmar venous plexus. It ascends on the front of the forearm and ends in the basilic or median cubital vein; occasionally it divides below the elbow into two branches, one to the basilic, the other to the cephalic vein.

Surface Anatomy. All the superficial veins can be seen, especially in spare individuals, until they pierce the deep fascia. They become more obvious when the limb is dependent and its muscles are contracted to drive blood from deep to superficial veins. This is most effective with a light encircling pressure in the upper arm.

Applied Anatomy. Blood sampling and transfusion, and intravenous injections in general, are often performed at the bend of the elbow, and the largest vein, usually the median cubital, is commonly selected. The cubital veins are also the site for the introduction of cardiac catheters to secure blood samples from the chambers of the heart and great vessels, to assess pressure profiles, and for cardio-angiography. Equally useful for sampling and transfusions, is the cephalic vein overlying the 'anatomical snuffbox'.

The Deep Veins of the Upper Limb

These veins follow the arteries as their companions. They are generally in pairs, flanking the corresponding artery (venae comitantes), and connected at intervals by short transverse branches. Since most of the blood draining the upper limb is *returned* by the the *superficial veins*, the deep veins are relatively small.

The deep veins of the hand. The superficial and deep palmar arterial arches are each accompanied by venae comitantes, respectively the *superficial* and *deep palmar venous arches*, receiving veins corresponding to the branches of the arterial arches. Thus the *common palmar digital veins* open into the superficial, and the *palmar metacarpal veins* into the deep, palmar venous arches. The deep veins accompanying the dorsal metacarpal arteries receive perforating branches from the palmar metacarpal veins, and end in the radial veins and the dorsal venous network.

The deep veins of the forearm are companion vessels of the radial and ulnar arteries and constitute respectively the upward drainage of the deep and superficial palmar venous arches; they unite in front of the elbow as the brachial veins. The radial veins are smaller than the ulnar, and receive the deep veins of the dorsum of the hand. The ulnar veins receive tributaries from the deep palmar venous arch and communicate with the superficial veins at the wrist; near the elbow they receive the anterior and posterior interosseous companion veins and send a large branch to the median cubital vein.

The brachial veins are on each side of the brachial artery, and receive tributaries corresponding with its branches; near the lower margin of subscapularis, they join the axillary vein; the medial one frequently joins the basilic vein before becoming the axillary.

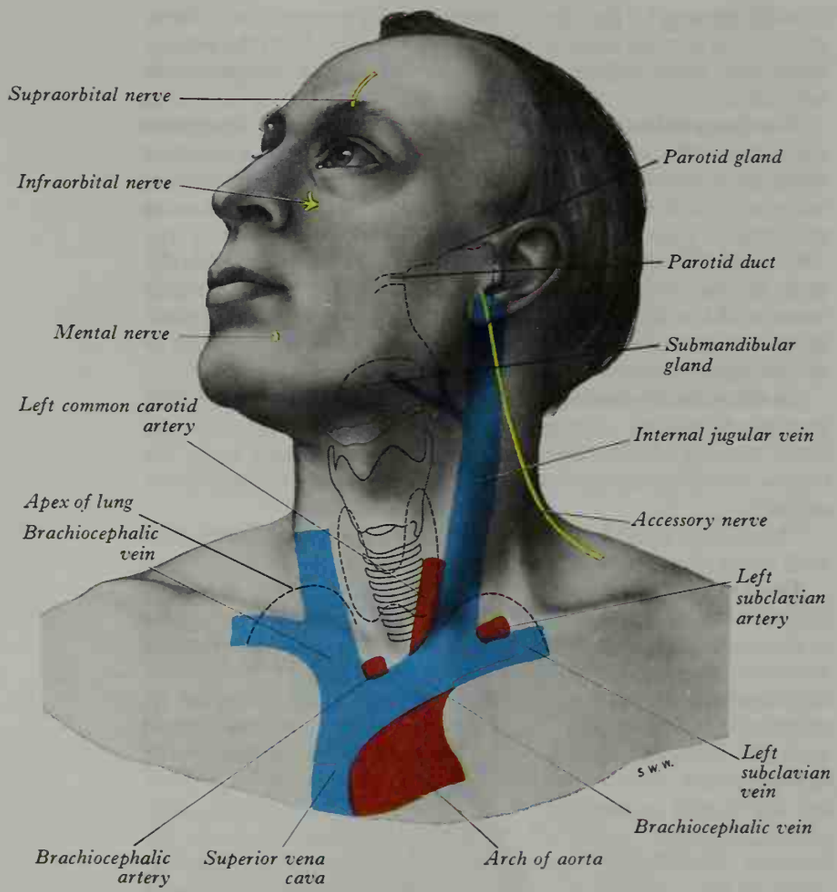
These deep veins have numerous anastomoses, not only with each other, but also with the superficial veins.

The axillary vein begins, by definition, at the lower border of the teres major, as the continuation of the basilic, increases in size as it ascends, and ends at the outer border of the first rib, where it becomes the subclavian vein. Near the lower border of subscapularis it receives the brachial veins and, close to its termination, the cephalic vein; its other tributaries correspond with the branches of the axillary artery. It lies medial to the axillary artery, which it partly overlaps; between the two vessels are the medial pectoral nerve, the medial cord of the brachial plexus, the ulnar nerve and the medial cutaneous nerve of the forearm. Medially it is accompanied by the medial cutaneous nerve of the arm, and both on its medial and posterior aspects it is intimately related to the lateral group of the axillary lymph nodes. It is provided with a pair of valves opposite the lower border of subscapularis; valves are also found in the ends of the cephalic and subscapular veins.

The subclavian vein (**6**.64), continuing the axillary, extends from the outer border of the first rib to the medial border of scalenus anterior, where it unites with the internal jugular to form the brachiocephalic vein. It is in relation, in front, with the clavicle and subclavius, behind and above, with the subclavian artery, separated from it by scalenus anterior and the phrenic nerve. Below, it rests in a shallow groove on the first rib and upon the pleura. It usually has a pair of valves, situated about 2 cm from its termination.

Its tributaries are the external jugular, the dorsal scapular and sometimes the anterior jugular veins, and occasionally a small branch, which ascends in front of the clavicle, from the cephalic. At its angle of junction with the internal jugular, the left subclavian vein receives the thoracic duct and the right subclavian the right lymphatic duct.

Surface Anatomy. The subclavian vein can be represented by a broad band convex upwards, from a point just medial to the mid-clavicular point to the medial edge of the clavicular attachment of sternocleidomastoid.



THE VEINS OF THE THORAX

The brachiocephalic (innominate) veins are two large trunks in the root of the neck and the uppermost part of the thorax; each is formed by union of the internal jugular and subclavian veins of its side, and both are devoid of valves.

The right brachiocephalic vein (**6**.131), about 2·5 cm long, begins behind the sternal end of the right clavicle, and passes almost vertically downwards to join the left brachiocephalic vein and form the superior vena cava, behind the lower border of the first right costal cartilage, close to the right border of the sternum. It lies anterolateral to the brachiocephalic artery and the right vagus nerve. The right pleura, phrenic nerve, and internal thoracic artery are posterior to its upper part, and become lateral below this.

Its tributaries are the right vertebral, internal thoracic and inferior thyroid veins, and sometimes the first right posterior intercostal vein.

The left brachiocephalic vein (**6**.131), about 6 cm long, begins behind the sternal end of the left clavicle, in front of the cervical pleura. It runs obliquely downwards to the right behind the upper half of the manubrium sterni to the sternal end of the first right costal cartilage, where it unites with the right brachiocephalic vein to form the superior vena cava. It is separated from the left sternoclavicular joint and the manubrium sterni by sternohyoid and sternothyroid, the thymus or its remains, and some areolar tissue; at its termination it is overlapped by the right pleura. In its course it crosses in front of

6.131 The surface projections of some of the important structures in the face, neck and upper part of thorax. The apices of the lungs, the thyroid, submandibular and parotid glands, and the parotid duct are indicated in interrupted dotted outline: the hyoid bone, the thyroid and cricoid cartilages and the rings of the trachea are shown in continuous outline.

the left internal thoracic, subclavian and common carotid arteries, the left phrenic and vagus nerves, the trachea and the brachiocephalic artery. The arch of the aorta lies inferior to it.

Its tributaries are the left vertebral, internal thoracic, inferior thyroid, and superior intercostal veins, sometimes the first left posterior intercostal vein and some thymic and pericardial veins.

Surface Anatomy. The brachiocephalic veins can be projected on to the surface as broad bands 1·5 cm wide from the sternal end of the clavicle on each side to the formation of the superior vena cava at the lower border of the first right costal cartilage.

Variations. Sometimes the brachiocephalic veins open separately into the right atrium: when this is so the right vein takes the ordinary course of the superior vena cava; the left vein—*left superior vena cava*, as it is then termed—may communicate by a small branch with the right one, and crosses the left side of the arch of the aorta, passes in front of the left pulmonary hilum, and, turning to the back of the heart, enters the right atrium. It replaces the oblique vein of the left atrium and the coronary sinus and receives all the tributaries of the latter. This abnormality is due to the persistence of the early fetal condition (p. 193), and is normal in birds and some mammals.

The left brachiocephalic vein sometimes projects above the level of the manubrium sterni (more frequently in childhood), crossing the suprasternal fossa, in front of the trachea.

The internal thoracic (mammary) veins (**6**.43, 67) are venae comitantes to the lower half of the internal thoracic artery, and are provided with a number of valves. About the level of the third costal cartilage the companion veins unite into a single trunk, which runs up medial to the artery and ends in the corresponding brachiocephalic vein. Veins accompanying branches of the artery (p. 697), and the pericardiacophrenic vein, are tributaries.

The inferior thyroid veins (**6**.43) arise in the thyroid gland in a venous network which also communicates with the middle and superior thyroid veins. They form a plexus in front of the trachea. From this plexus the left vein descends and joins the left brachiocephalic vein, and the right passes obliquely downwards to the right across the brachiocephalic artery to open into the right brachiocephalic vein, at its junction with the superior vena cava; frequently the two veins open by a common trunk either in the vena cava or the left brachiocephalic vein. They drain oesophageal, tracheal and inferior laryngeal veins, and have valves at their terminations.

The left superior intercostal vein (**6**.132) receives the second and third (and sometimes the fourth) left posterior intercostal veins; it runs obliquely upwards and forwards on the left side of the aortic arch, passing lateral to the left vagus and medial to the left phrenic nerve, and opens into the left brachiocephalic vein. It usually receives the left bronchial veins, and sometimes the left pericardiacophrenic vein; it communicates below with the accessory hemiazygos vein.

The superior vena cava (**6**.38, 40, 41r, 42, 132) collects blood from the upper half of the body. It measures about 7 cm in length, is formed by the junction of the two brachiocephalic veins, and has no valves. It begins behind the lower border of the first right costal cartilage close to the sternum, descends vertically behind the first and second intercostal spaces, ends in the upper part of the right atrium opposite the third right costal cartilage; the lower half of the vessel is within the fibrous pericardium, which it pierces at the level of the second costal cartilage. It is covered in front and on each side with the serous pericardium. In its course it describes a slight convexity to the right.

Relations. In *front*, the superior vena cava is related to the anterior margins of the right lung and its pleura, with the pericardium intervening below; these structures separate it from the internal thoracic artery and the first and second intercostal spaces, and from the second and third costal cartilages; the trachea and the right vagus nerve are *posteromedial* and the right lung and pleura *posterolateral* to its upper part, while the root of the right lung is a direct posterior relation below. On its *right* it is related to the right phrenic nerve and right pleura; on its *left* to the commencement of the brachiocephalic artery and the ascending aorta, the latter overlapping it.

Surface Anatomy. The superior vena cava is 2 cm wide and partly behind the right margin of the sternum. It extends from the lower border of the first to the lower border of the third right costal cartilage. The shadow of its lateral border is visible in anteroposterior radiographs of the chest.

Tributaries. These include the azygos vein and several small veins from the pericardium and other structures in the mediastinum.

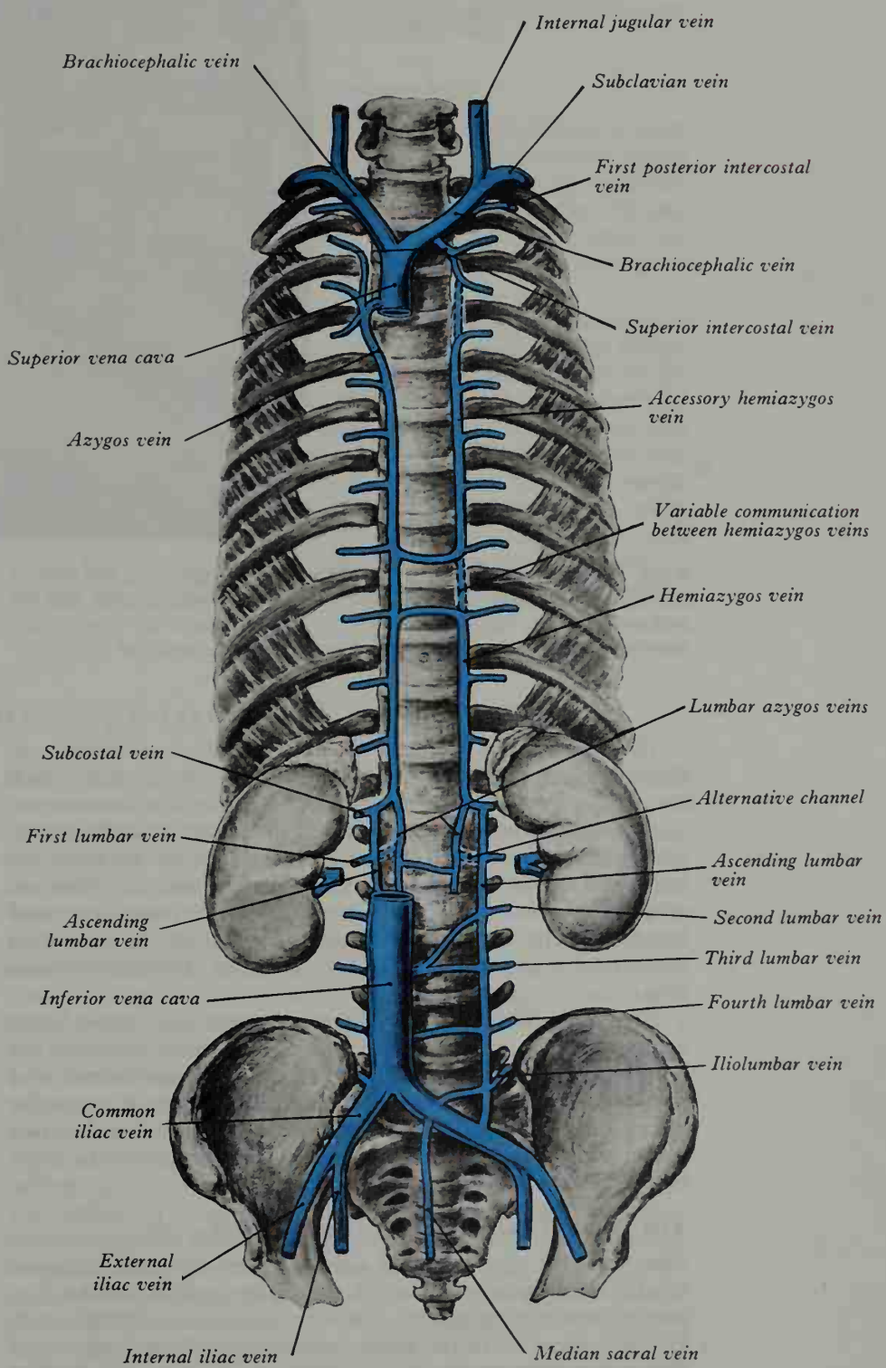
The azygos vein (**6**.132, 133) is inconstant in origin (as is the hemiazygos vein—*see* Gladstone 1929). On developmental grounds it may be expected to arise from the posterior aspect of the inferior vena cava, at or below the level of the renal veins. Such a vein (*lumbar azygos*) is indeed frequently present, and ascends in front of the upper lumbar vertebrae. The azygos vein may pass behind the lateral border of the right crus of the diaphragm, or it may pierce the crus. Occasionally it may pass through the aortic opening of the diaphragm, on the right side of the cisterna chyli. In front of the body of the twelfth thoracic vertebra, it is joined by a large vessel which, formed by the union of the right ascending lumbar with the right subcostal vein, passes forwards on the right side of the body of the twelfth thoracic vertebra behind the right crus of the diaphragm. This common trunk may, in the absence of a lumbar azygos vein, form the azygos itself. Whatever its mode of origin, the azygos vein ascends in the posterior mediastinum to the level of the fourth thoracic vertebra, where it arches forward above the root of the right lung, and ends in the superior vena cava, just before it pierces the pericardium. In its course it lies anterior to the bodies of the lower eight thoracic vertebrae (*see* comments below), the anterior longitudinal ligament, and the right posterior intercostal arteries. On its right are the right greater splanchnic nerve, lung and pleura; on its left, throughout the greater part of its course, are the thoracic duct and aorta, and higher up, where it arches forward above the root of the right lung, the oesophagus, trachea and right vagus. In the lower part of the thorax it is covered anteriorly by a recess of the right pleural sac and by the oesophagus, but it emerges from behind the right

edge of the latter and ascends behind the root of the right lung (**6**.133). For a variable extent in the lower thorax, the azygos vein is quite *closely applied* to the right posterolateral aspect of the descending thoracic aorta (Hutchinson, personal communication), and thus often reaches and sometimes crosses to the left of the midline of the vertebral bodies. It seems probable that aortic pulsations will, by intermittent compression, assist venous return in both the azygos and hemiazyos veins (cf. comments on venous return in venae comitantes in general on p. 630).

Tributaries. The azygos vein collects from the posterior intercostal veins of the right side, with the exception of the first; the veins from the second, third and fourth intercostal spaces usually open by a common stem called the right superior intercostal vein. It receives also the hemiazygos and accessory hemiazygos veins, several oesophageal, mediastinal, and pericardial veins, and, near its termination, the right bronchial veins. When it begins as a lumbar azygos vein, the common trunk formed by the union of the right ascending lumbar and subcostal veins is its largest tributary. A few imperfect valves are found in the azygos vein, but its tributaries are provided with complete valves.

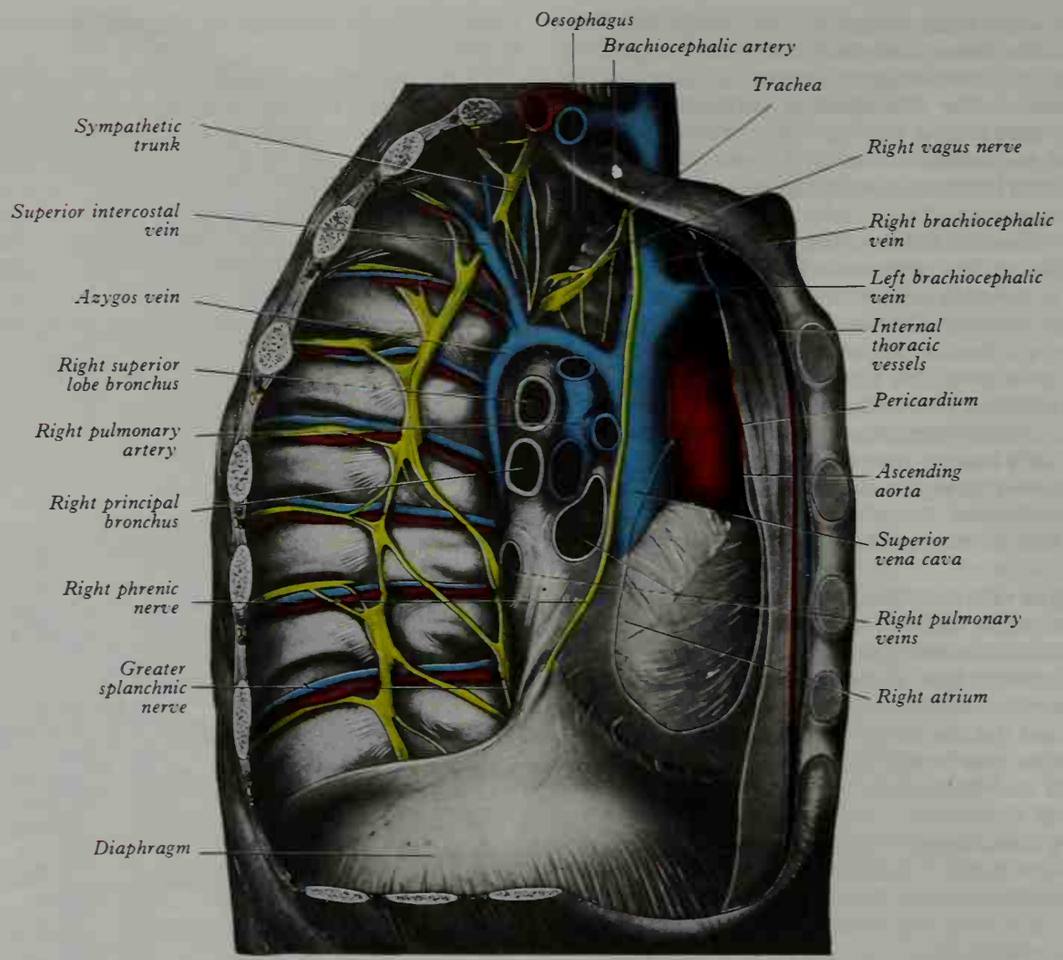
The hemiazygos vein starts on the left like the azygos vein on the right side. Ascending on the front of the vertebral column as high as the eighth thoracic vertebra, it passes across the column, behind the aorta, oesophagus, and thoracic duct, to end in the azygos vein. Its tributaries are the lower three posterior intercostal veins and the common trunk formed by the union of the ascending lumbar and the subcostal veins of the left side, and some oesophageal and mediastinal veins. Its lower end often communicates with the left renal vein.

The accessory hemiazygos vein (**6**.132) descends on the left side of the vertebral column. It receives the veins from the fourth (or fifth) to the eighth intercostal spaces inclusive of the left side, and sometimes the left bronchial veins. It crosses the body of the seventh thoracic vertebra and joins the azygos vein. The accessory hemiazygos vein sometimes joins the hemiazygos vein, and the common trunk thus formed opens into the azygos vein.



The azygos veins exhibit much variation, not only in their mode of origin, but also in their course, tributaries, anastomoses and termination. For a recent survey of the literature consult Grzybiak *et al.* (1975). According to this study the accessory hemiazygos is the most variable; it may drain into the left brachiocephalic, directly into the azygos vein, or into the hemiazygos. The arrangement illustrated in **6**.132 represents in its general features the commonest pattern (except for the position and calibre of the azygos vein). In a few instances (about 1 or 2 per cent according to Anson, 1963) there are two completely independent azygos veins (left and right), which is the early embryonic form, and in an equally small group of instances a single azygos vein, without any hemiazygos tributaries, which occupies an approximately midline position. In more than 95 per cent of cases there is a main 'right-sided' azygos vein and at least some representative of the hemiazygos veins. The latter, however, show much variation, one or other being absent or poorly developed. The number of retro-aortic trans-vertebral connexions from the hemiazygos and accessory hemiazygos veins, connecting them to the azygos vein, is also extremely variable; they may number from one to five, or more; when either hemiazygos vein is absent, the intercostal veins which would have drained into it themselves cross their vertebral bodies to end in the azygos vein. These trans-vertebral routes are, however, frequently extremely short, since the azygos vein is, as noted above, more commonly situated anterior to the vertebral column rather than on its right lateral aspect (Anson 1963, and Dr. M. C. E. Hutchinson, personal communication), and quite often passes to the *left* of the midline in a variable part of its vertical extent.

The posterior intercostal veins (**6**.83, 132, 133) run with the posterior intercostal arteries and are eleven in number on each side. As they approach the vertebral column each vein receives a tributary which accompanies the posterior branch of the corresponding artery returning blood from the muscles and skin of the back and from the vertebral venous plexuses.



On both sides of the thorax the first posterior intercostal vein ascends in front of the neck of the first rib. It arches forwards above the pleura to end in the corresponding brachiocephalic or vertebral vein.

On the right the second, third and, often, the fourth posterior intercostal veins unite to form the *right superior intercostal vein*, which joins the terminal part of the azygos vein. The veins from the intercostal spaces below the fourth open separately into the vena azygos.

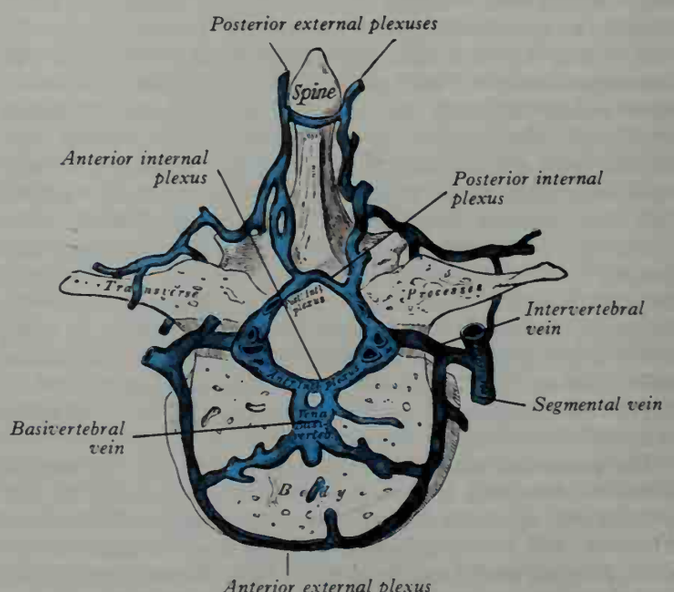
On the left the second and third and sometimes the fourth posterior intercostal veins unite to form the left superior intercostal vein (p. 754). The veins from the fourth (or fifth) to the eighth intercostal spaces inclusive end in the accessory hemiazygos vein, and the veins from the lower three spaces in the hemiazygos vein.

6.132 A highly schematic diagram of the azygos, hemiazygos and ascending lumbar veins, their tributaries and connexions. On both sides the first lumbar vein is terminated in the ascending lumbar, its occasional termination in the lumbar azygos vein is also shown. The hemiazygos and accessory hemiazygos veins both cross the midline one vertebra lower than usual. It should be noted that the azygos vein is usually much greater in calibre than the hemiazygos veins, and seldom follows a vertical course on the right anterolateral aspect of the vertebral bodies as diagrammed here. *See* text for more detailed comments on course and variations.

6.133 The right aspect of the mediastinum. The right lung and most of the right pleura have been removed and a large opening made into the pericardial sac to expose the heart. In this specimen the fourth right posterior intercostal vein did not join the superior intercostal vein.

The posterior intercostal veins are called 'posterior' to distinguish them from the small *anterior intercostal veins*, which are tributaries of the internal thoracic and musculophrenic veins.

Applied Anatomy. In obstruction of the venae cavae, the azygos and hemiazygos veins and the vertebral venous plexuses are important means by which the venous circulation is carried on, connecting, as they do, the superior and inferior venae cavae, and communicating with the common iliac veins by the ascending lumbar veins, and with many of the tributaries of the inferior vena cava.



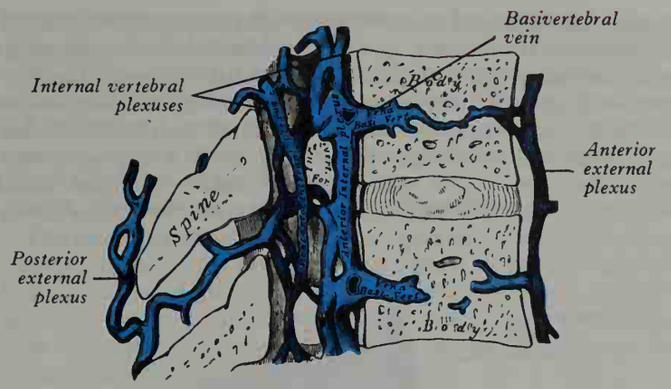
The bronchial veins, usually two on each side, return blood from the larger bronchi, and from the structures at the roots of the lungs. The bronchial veins of the right side open into the terminal part of the azygos vein, those of the left side, into the left superior intercostal vein or the hemiazygos vein. Some of the blood carried to the lungs through the bronchial arteries returns to the heart through the pulmonary veins (*see* p. 1266).

The Veins of the Vertebral Column (6.134, 135)

The veins of the vertebral column form intricate plexuses extending along its entire length; these plexuses are divisible into external and internal groups, outside or inside the vertebral canal. Both are devoid of valves, anastomose freely with each other, and end in the intervertebral veins. Interconnexions are established on a wide scale between the plexuses and longitudinal veins very early in fetal life (Loginova 1972).

The external vertebral venous plexuses, most developed in the cervical region, consist of anterior and posterior plexuses, which anastomose freely. The *anterior external plexuses* lie in front of the bodies of the vertebrae, communicate with the basivertebral and intervertebral veins, and receive tributaries from the vertebral bodies. The *posterior external plexuses* are on the posterior surfaces of the laminae and around the spines and the transverse and articular processes. They anastomose with the internal vertebral venous plexuses, and end in the vertebral, posterior intercostal and lumbar veins.

The internal vertebral venous plexuses lie within the vertebral canal between the dura mater and vertebrae, and receive



6.134 A transverse section through the body of a thoracic vertebra, showing the vertebral venous plexuses and basivertebral veins.

tributaries from the bones and from the spinal cord. They form a closer network than the external plexuses, and are arranged vertically as four longitudinal veins, two in front and two behind; therefore they may be divided into anterior and posterior groups. The *anterior internal plexuses* consist of large veins which lie on the posterior surfaces of the vertebral bodies and intervertebral discs, on each side of the posterior longitudinal ligament; under cover of this ligament they are connected by transverse branches into which the basivertebral veins open. The *posterior internal plexuses* are on each side of the median plane in front of the vertebral arches and ligamenta flava, and anastomose, by veins passing through and between those ligaments, with the posterior external plexuses.

The anterior and posterior internal plexuses communicate freely with one another by a series of venous rings, one opposite each vertebra. Around the foramen magnum they form an intricate network, which connects with the vertebral veins, occipital and sigmoid sinuses, the basilar plexus, the venous plexus of the hypoglossal canal and the condylar emissary veins.

The basivertebral veins emerge from foramina on the posterior surfaces of the vertebral bodies. They are large, tortuous channels in the substance of the bones, similar in every respect to those found in the diploë of the cranial bones. It is to be noted that the cancellous bone in the bodies of the vertebrae contains much red haemopoietic bone marrow. They also drain into the anterior external vertebral plexuses through small openings on the front and sides of the bodies of the vertebrae, and converge behind to form single (sometimes double) veins, which open into the transverse branches uniting the anterior internal vertebral plexuses. The basivertebral veins become enlarged in advanced age.

The intervertebral veins accompany the spinal nerves through the intervertebral foramina; they drain veins from the spinal cord, the internal and external vertebral plexuses and end in the vertebral, posterior intercostal, lumbar and lateral sacral veins. There is some difference of opinion as to whether the basivertebral or intervertebral veins contain effective valves; but

6.135 A median sagittal section through two thoracic vertebrae showing the vertebral venous plexuses and basivertebral veins.

experimental studies strongly suggest that the blood flow in them may be reversed (Batson 1957). This may explain how pelvic neoplasms in particular may lead to metastases in vertebral bodies, tumour cells spreading into the internal vertebral venous plexuses through connexions with the pelvic veins when the direction of blood flow is temporarily reversed by raised intra-abdominal pressure.

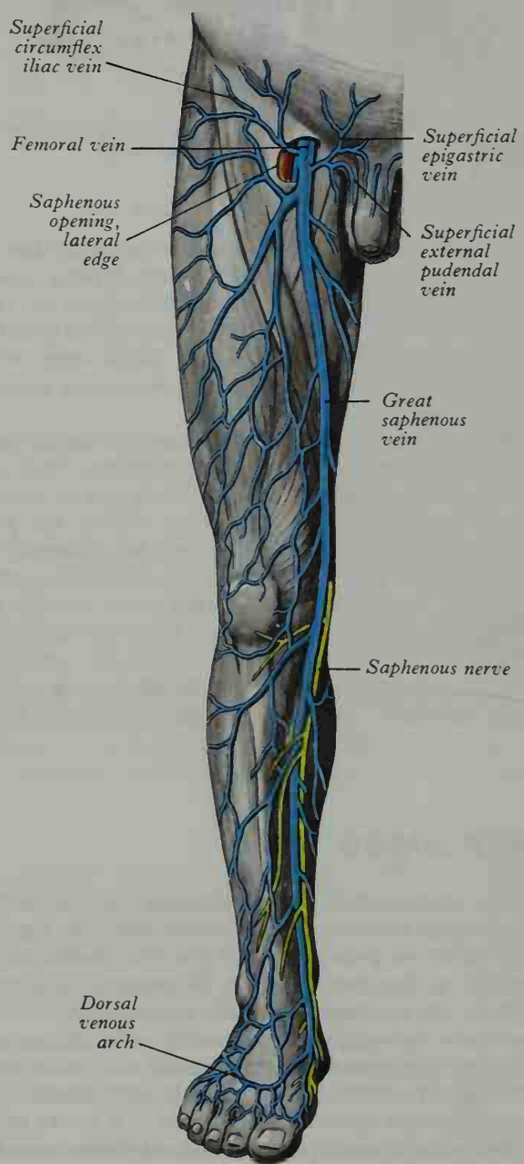
The veins of the spinal cord are situated in the pia mater and form a tortuous venous plexus in this membrane. In this plexus there are: (*a*) two *median longitudinal veins*, one in front of the anterior median fissure, and the other behind the posterior median septum of the spinal cord; (*b*) two *anterolateral* and two *posterolateral longitudinal veins*, which run behind the ventral and the dorsal nerve roots respectively. They drain into the internal vertebral venous plexuses, and thence the intervertebral veins. Near the base of the skull they unite to form two or three small trunks which communicate with the vertebral veins, and end in the inferior cerebellar veins, or in the inferior petrosal sinuses.

THE VEINS OF THE LOWER LIMBS

The veins of the lower limbs can be subdivided, like those of the upper limbs, into two sets, *superficial* and *deep*; the superficial veins are immediately under the skin in the superficial fascia; the deep veins accompany the arteries. Both sets are provided with valves, which are more numerous in the deep than in the superficial veins. Valves are also more plentiful in the veins of the lower than in those of the upper limbs.

The Superficial Veins of the Lower Limb (6.136, 137)

The principal named superficial veins are the great and small saphenous veins. Most of their tributaries are unnamed. (For variations in the superficial veins consult Kosinski 1926.)



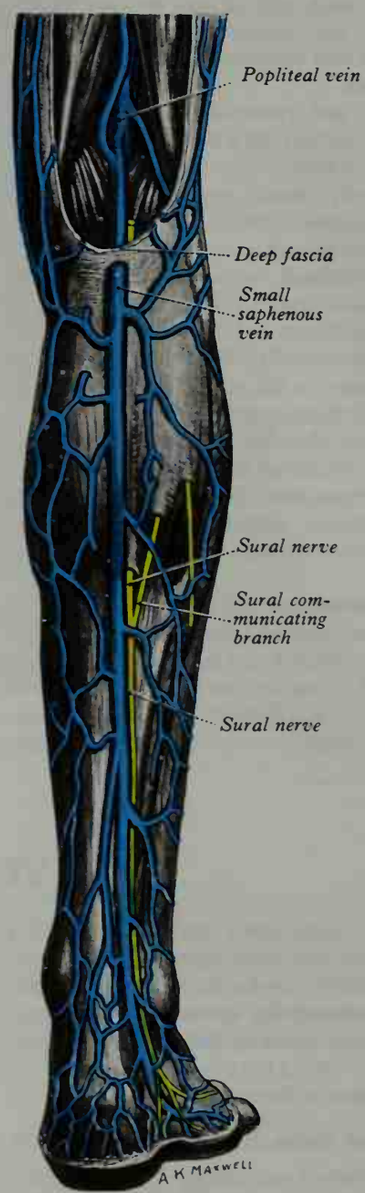
The *dorsal digital veins* receive, in the clefts between the toes, communications from the plantar digital veins, and then join to form *dorsal metatarsal veins*, which unite across the proximal parts of the metatarsal bones in a *dorsal venous arch*. Proximal to this arch there is an irregular dorsal venous network, which receives tributaries from the deep veins and is continuous with the venous network on the front of the leg. At the sides of the foot this network communicates with a *medial* and a *lateral marginal vein*, both of which are formed mainly by the union of veins from the superficial parts of the sole of the foot.

In the sole of the foot the superficial veins form a *plantar cutaneous arch*, which extends across the roots of the toes and opens at the sides of the foot into the medial and lateral marginal veins. Proximal to this arch there is a *plantar cutaneous venous network*, which is especially dense in the fat beneath the heel; this network communicates with the plantar cutaneous venous arch and with the deep veins, but is chiefly drained into the medial and lateral marginal veins.

The great (long) saphenous vein (6.136), the longest in the body, begins in the medial marginal vein of the foot, and ends in the femoral vein about 3 cm below the inguinal ligament. It ascends about 2·5 to 3 cm in front of the tibial malleolus, crosses the lower part of the medial surface of the tibia obliquely to its medial border, about a finger's breadth behind which it ascends to the knee. It runs upwards postero-medial to the medial condyles of the tibia and femur and along the medial side of the thigh and passes through the saphenous opening (p. 595), into the femoral vein. The saphenous opening is about 2·5 to 3·25 cm below and lateral to the pubic tubercle, and the vein may be represented by a line from here to the adductor tubercle of the femur. In the thigh it is accompanied by some branches of the medial femoral cutaneous nerve, at the knee by the saphenous branch of the descending genicular artery, and in the leg and foot by the saphenous nerve, which is in front of the vein. The great saphenous vein is often duplicated, especially below the knee. The valves in it number from ten to twenty and are more numerous in the leg than in the thigh. One valve lies just before the vein pierces the cribriform fascia and another at its junction with the femoral vein. In practically its entire extent the vein is in the superficial fascia, but it has many communications with the deep veins, especially in the leg (*vide infra*).

Tributaries. At the ankle it drains the sole of the foot through the medial marginal veins. In the leg it communicates freely with the small saphenous vein and deep veins. Just below the knee it usually has three large tributaries, one from the front of the leg, one from the region of the tibial malleolus which communicates with the 'perforating' veins and a third from the calf which communicates with the small saphenous vein. The second of these tributaries, ascending on the medial aspect of the calf, was called the '*posterior arch vein*' by Dodd and Cockett (1956), and the

clinical importance of its connexions with the venae comitantes of the posterior tibial artery by 3 to 6 perforating (communicating) veins has been emphasized by Platz and Adelmann (1976), who proposed the term '*vena arcuata cruris posterior*' for this vessel. In the thigh it receives numerous tributaries; those from the medial and posterior parts frequently unite to form a large *accessory saphenous vein*, which communicates below with the small saphenous vein and joins the main vein at a variable level. A fairly



6.136 The great saphenous vein and its tributaries.

constant large vessel, sometimes called the *anterior femoral cutaneous vein*, commences from a network of veins on the lower part of the front of the thigh and crosses the apex of the femoral triangle to enter the great saphenous vein in the upper part of the thigh. Just before it pierces the saphenous opening (**6**.136) it is joined by three veins, the superficial epigastric, superficial circumflex iliac and superficial external pudendal. Their precise mode of union with the great saphenous varies. The superficial epigastric and superficial circumflex iliac veins drain the lower part of the abdominal wall, the latter veins also receiving tributaries from the upper and lateral parts of the thigh; the superficial external pudendal veins drain part of the scrotum and one is joined by the superficial dorsal vein of the penis. The deep external pudendal vein joins the great saphenous vein at its termination in the saphenous opening.

A vein, named *thoraco-epigastric*, runs along the anterolateral wall of the trunk, connecting the superficial epigastric vein, or the femoral vein, with the lateral thoracic veins and establishing a communication between the femoral and axillary veins. This communication is an important connecting channel between the superior and the inferior vena caval fields of drainage. It is held by some to reflect the line of the primitive mammary ('milk') ridge which extends from axilla to pubic region (p. 156).

The small (short) saphenous vein (**6**.137) begins behind the

6.137 The small saphenous vein and its tributaries.

lateral malleolus as a continuation of the lateral marginal vein of the foot; it first ascends lateral to the tendo calcaneus, and then along the middle of the back of the leg. It perforates the deep fascia and passes between the two heads of gastrocnemius in the lower part of the popliteal fossa, and ends in the popliteal vein from 3 to 7·5 cm above the level of the knee joint. It communicates with the deep veins on the dorsum of the foot, receives numerous cutaneous tributaries from the back of the leg, and sends several branches upwards and medially to join the great saphenous vein. Sometimes a communicating branch from the small saphenous vein just before it pierces the deep fascia passes upwards and medially to join the accessory saphenous vein. This communication may occasionally be the main continuation of the small saphenous. In the leg it is close to the sural nerve. The small saphenous vein possesses from seven to thirteen valves, one near its termination in the popliteal vein.

The mode of ending of the small saphenous vein is variable. It may join the great saphenous vein in the upper third of the thigh, or may bifurcate, one branch joining the great saphenous vein, the other the popliteal or the deep posterior veins of the thigh; occasionally it ends, below the knee joint, in the great saphenous vein or in the deep muscular veins of the calf.

Applied Anatomy. In the upright position, the venous return from the lower limb depends almost entirely on muscular activity (*see* p. 630), especially the contraction of the calf muscles, known as the 'calf pump', whose efficiency is aided by the tight sleeve of deep fascia. A number of '*perforating*' *veins* connect the great saphenous vein with the deep veins, particularly near the ankle and in the lower medial part of the leg. In these perforating veins the valves are arranged so that normally they prevent the flow of blood from the deep to the superficial veins. At rest, the pressure in a superficial vein of the leg is equal to the height of the column of blood extending therefrom to the heart. When the calf muscles contract, the blood is pumped upwards in the deep veins; it is normally prevented from flowing outwards into the superficial veins by the valves in the perforating veins; and during relaxation of the calf muscles blood is actually aspirated from the superficial into the deep veins. If the valves in the perforating veins become incompetent, these veins become 'high pressure leaks' during muscular contraction, and this transmission of the high pressure in the deep veins to the superficial veins results in dilatation and venous stagnation in the superficial veins, producing varicosities, devitalization of the tissues, and in some cases, varicose ulceration. In the operative treatment of severe varicose veins and ulcers it is essential that these perforating veins be ligatured. Similar perforating venous connexions occur on the anterolateral aspect of the leg and varicosities of the superficial veins may occur in this region (Cockett 1956; Green *et al.* 1958). Veins connecting the great saphenous vein to the femoral vein, as the latter lies in the adductor canal, may also become varicose (Dodd and Cockett 1956; Dodd 1959).

The Deep Veins of the Lower Limb

These accompany the arteries and their branches; they possess numerous valves.

The *plantar digital veins* arise from plexuses on the plantar surfaces of the digits. They communicate with the dorsal digital veins and unite to form four *plantar metatarsal veins*; which run back in the metatarsal spaces, communicate, by means of perforating veins, with the veins on the dorsum of the foot, and unite to form the *deep plantar venous arch*, accompanying the plantar arterial arch. From the deep plantar venous arch the *medial* and *lateral plantar veins* run backwards close to the corresponding arteries and, after communicating with the great and small saphenous veins, unite behind the medial malleolus to form the posterior tibial veins.

The posterior tibial veins accompany the posterior tibial artery. They receive veins from the calf muscles, especially from the venous plexus in soleus, communicating vessels from the superficial veins of the leg and the *peroneal veins*. The latter, which accompany the peroneal artery, also receive veins from soleus and communications from the superficial veins.

The anterior tibial veins are the upward continuations of the venous companions of the dorsal artery of the foot. They leave the front of the leg by passing between the tibia and fibula, through the upper part of the interosseous membrane of the leg, and unite with the posterior tibial veins to form the *popliteal vein* at the lower border of popliteus.

The popliteal vein ascends through the popliteal fossa to the aperture in the adductor magnus, where it becomes the femoral vein. In the lower part of its course it is medial to the popliteal artery; between the heads of the gastrocnemius it is superficial to it; above the knee joint it is posterolateral to it. Its tributaries are the small saphenous vein, the veins corresponding to the branches of the popliteal artery and muscular veins, including a prominent vessel from each head of the gastrocnemius. There are usually four valves in the popliteal vein.

The femoral vein accompanies the femoral artery, beginning at the opening in adductor magnus as the continuation of the popliteal vein, and ending at the level of the inguinal ligament, by becoming the external iliac. In the lower part of the adductor canal it is posterolateral to the femoral artery; in the upper part of the canal, and in the lower part of the femoral triangle, it is behind the artery. At the base of the femoral triangle it is medial to the artery (**6**.100, 103); here it occupies the middle compartment of the femoral sheath, between the femoral artery and the femoral canal, the fatty tissue in the latter allowing considerable expansion of the vein. It receives numerous muscular tributaries, and about 4 to 12 cm below the inguinal ligament is joined posteriorly by the vena profunda femoris, and a little higher by the great saphenous vein, which enters its anterior aspect. In addition, the lateral and medial circumflex femoral veins are usually tributaries. There are usually four or five valves in the femoral vein, the most constant being just below the entry of the profunda femoris vein; there is also commonly a valve below the inguinal ligament.

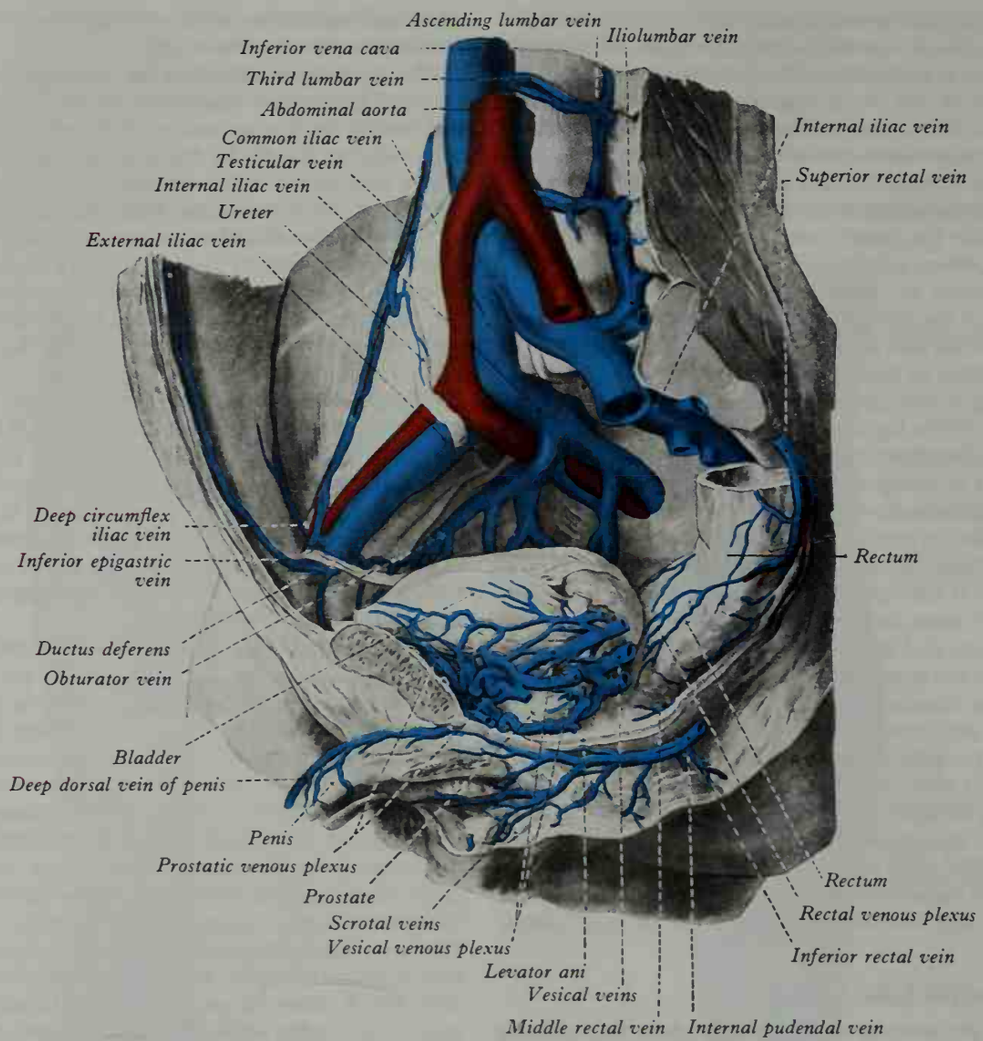
The *vena profunda femoris* is anterior to the arteria profunda femoris; it receives tributaries corresponding to the muscular and perforating branches of that artery, and through these establishes communications with the popliteal vein below and the inferior gluteal vein above. It sometimes drains the medial and lateral circumflex femoral veins. It has a pair of valves just below its termination.

THE VEINS OF THE ABDOMEN AND PELVIS

The External Iliac Vein

The upward continuation of the femoral vein constitutes the external iliac vein: it begins behind the inguinal ligament, and ascends along the brim of the lesser pelvis, to end in front of the sacro-iliac joint, by joining the internal iliac vein to form the common iliac vein. On the right, it lies at first medial to the external iliac artery; but, as it passes upwards, gradually inclines behind it. On the left, it lies altogether on the medial side of the artery. On its medial aspect, it is crossed by the ureter and the internal iliac artery; elsewhere it is covered with parietal peritoneum. In the male it is crossed by the ductus deferens and in the female by the round ligament of the uterus and the ovarian vessels. Laterally it is related to the psoas major, except where the external iliac artery intervenes. It is usually valveless but may contain one valve.

Tributaries. These are the inferior epigastric, deep circumflex iliac, and pubic veins.



The inferior epigastric vein is formed by union of the venae comitantes of the inferior epigastric artery, which communicate above with the superior epigastric vein; it joins the external iliac about 1 cm above the inguinal ligament.

The deep circumflex iliac vein is derived from the venae comitantes of the deep circumflex iliac artery, and joins the external iliac vein about 2 cm above the inguinal ligament after crossing in front of the external iliac artery.

The pubic vein, which connects the external iliac with the obturator vein in the obturator foramen, ascends on the pelvic surface of the pubis alongside the pubic branch of the inferior epigastric artery. It is sometimes enlarged and replaces the normal obturator vein.

The Internal Iliac Vein

A confluence of veins occurs near the upper part of the great sciatic foramen and constitutes the internal iliac vein. It ascends behind and slightly medial to the internal iliac artery, and joins with the external iliac vein to form the common iliac vein at the brim of the lesser pelvis, in front of the lower part of the sacro-iliac joint and is covered with parietal peritoneum on its anteromedial aspect.

6.138 The veins of the right half of the male pelvis (after Spalteholz).

Tributaries. With the exception of the iliolumbar vein, which usually joins the common iliac, the tributaries of the internal iliac vein correspond with the branches of the internal iliac artery. These are (*a*) the gluteal, internal pudendal, and obturator veins, which have their origins outside the pelvis; (*b*) the lateral sacral veins, which lie in front of the sacrum; (*c*) the middle rectal, the vesical, uterine, and vaginal veins, which originate in venous plexuses connected with the pelvic viscera.

The superior gluteal veins are the venae comitantes of the superior gluteal artery; their tributaries from the buttock correspond to the branches of the artery; entering the pelvis through the greater sciatic foramen, above piriformis, they end in the internal iliac vein, frequently uniting to form a single trunk before this.

The inferior gluteal veins are the venae comitantes of the inferior gluteal artery; they begin in the upper part of the back of the thigh, where they anastomose with the medial circumflex femoral and first perforating veins; they enter the pelvis through the lower part of the greater sciatic foramen and join to form a stem which opens into the lower part of the internal iliac vein.

The gluteal veins communicate with the superficial veins of the buttock by a considerable number of perforating veins (Doyle 1970), as in the calf (p. 759). These *gluteal perforating veins* are, indeed, more numerous. In addition to their possible venous 'pumping' role, in association with the activities of the gluteal musculature, these venous connexious provide collaterals between the femoral and internal iliac veins.

The internal pudendal veins are the venae comitantes of the internal pudendal artery. They begin in the prostatic venous plexus (p. 761), accompany the internal pudendal artery, and unite to form a single vessel, which ends in the internal iliac vein. They receive the veins from the bulb of the penis, and the scrotal (or labial) and inferior rectal veins. The deep dorsal vein of the penis communicates with the internal pudendal veins, but ends mainly in the prostatic plexus.

The obturator vein begins high in the adductor region of the thigh, and enters the pelvis through the upper part of the obturator foramen. It runs back and upwards on the lateral wall of the pelvis below the obturator artery covered by peritoneum; it passes between the ureter and the internal iliac artery, and ends in the internal iliac vein. Sometimes it is replaced by an enlarged pubic vein, which joins the external iliac vein (p. 759).

The lateral sacral veins accompany the lateral sacral arteries. The veins are interconnected by the *sacral venous plexus.*

The middle rectal vein varies in size; it begins in the rectal venous plexus, with tributaries from the bladder, prostate and seminal vesicle; it runs laterally on the pelvic surface of levator ani and ends in the internal iliac vein.

The rectal venous plexus surrounds the rectum, and communicates in front with the vesical plexus in the male, and the uterovaginal plexus in the female. It consists of two parts, an *internal* beneath the epithelium of the rectum and anal canal, and an *external* outside their muscular coats. In the anal canal the internal plexus presents a series of longitudinal dilatations, connected by transverse branches, which are arranged in circles around the tube, immediately above the anal valves. These dilatations are more obvious in the left lateral, right anterolateral, and right posterolateral sectors of the tube. The plexus drains mainly into the superior rectal vein but communicates freely with the external plexus. The lower part of the external plexus is drained by the inferior rectal veins into the internal pudendal, the middle part by the middle rectal vein into the internal iliac vein, and the upper part by the superior rectal vein, which is the commencement of the inferior mesenteric, a tributary of the

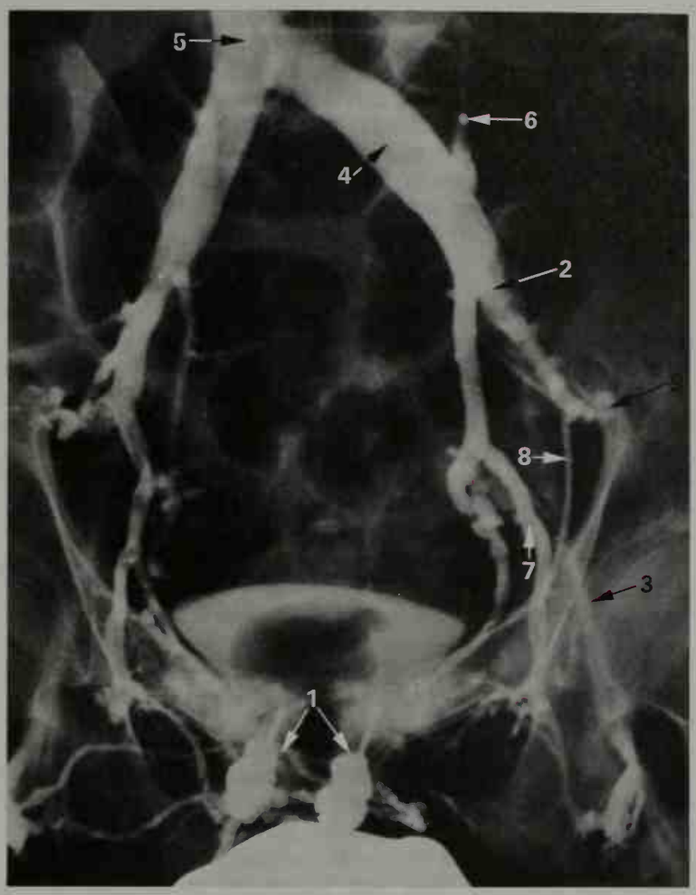
portal vein. A free communication between the portal and systemic venous systems is thus established through the rectal plexus.

Applied Anatomy. The veins of the internal rectal plexus are apt to become further dilated and varicose, and form *internal* haemorrhoids (piles), most commonly at one or more of the three sites of concentration mentioned above. This is due to several factors: the vessels are contained in very loose connective tissue, so that they get less support from surrounding structures than most other veins, and are less capable of resisting increased blood pressure; the condition is favoured by the fact that the superior rectal and portal veins have no valves; the veins pass through muscular tissue and are liable to be compressed by its contraction, especially during the act of defaecation; finally they are affected by every form of portal obstruction.

The veins of the subcutaneous part of the external plexus may suffer thrombosis, the basis of one type of *external* haemorrhoid; alternatively, rupture of these vessels leads, on occasion, to an acute perianal haematoma.

The prostatic venous plexus lies behind the arcuate pubic ligament and the lower part of the symphysis pubis and in front of the bladder and prostate (**6**.138). Its chief tributary is the deep dorsal vein of the penis, but it also receives tributaries from the front of the bladder and prostate. It communicates with the vesical plexus and the internal pudendal vein, and drains into the vesical and internal iliac veins. The veins of the plexus are embedded in the lateral part of the fascial sheath of the prostate (*see* p. 1422).

The vesical plexus envelops the lower part of the bladder and, in the male, the base of the prostate. It communicates with the prostatic plexus in the male, and with the vaginal plexus in the female. It is drained by means of several vesical veins which usually form a single trunk before entering the internal iliac vein.



The dorsal veins of the penis are superficial and deep: The *superficial dorsal vein* drains the prepuce and skin of the penis, and, running backwards in the subcutaneous tissue, inclines to the right or left, and opens into the corresponding external pudendal vein, a tributary of the great saphenous. The *deep dorsal vein* lies within the fibrous envelope of the penis; it receives blood from the glans penis and corpora cavernosa penis, and courses backwards in the median plane between the dorsal arteries; near the root of the penis it passes deep to the suspensory ligament and then through an aperture between the arcuate pubic ligament and the anterior margin of the perineal membrane, and divides into two branches (right and left), which enter the prostatic plexus after communicating below the symphysis pubis with the internal pudendal veins. The *dorsal vein of the clitoris*, after a similar course, ends in the vesical plexus.

The uterine plexuses extend along the lateral side of the uterus within the broad ligament, and communicate with the ovarian and vaginal plexuses. They are drained by two uterine veins on each side; these arise from the lower parts of the plexuses, opposite the external opening of the cervix of the uterus, and open into the corresponding internal iliac vein.

The vaginal plexuses flank the vagina; they communicate with the uterine, vesical and rectal plexuses, and are drained by the vaginal veins, one each side, into the internal iliac veins.

The common iliac veins (**6**.138) result from the union of the external and internal iliac veins, in front of the sacro-iliac joint; passing obliquely upwards, they end on the right side of the fifth lumbar vertebra by uniting at an acute angle to form the inferior vena cava. The *right common iliac vein*, shorter than the left, is nearly vertical, and ascends behind, and then lateral to its artery. The right obturator nerve passes behind it obliquely, as it runs downwards and forwards to the obturator foramen. The *left common iliac vein*, longer and more oblique than the right, is at first medial to its artery, and then behind the right common iliac artery. It is crossed anteriorly by the root of the sigmoid mesocolon and the superior rectal vessels. In the rest of its course it is covered only with peritoneum. Each common iliac vein receives the iliolumbar, and sometimes the lateral sacral veins; the left common iliac drains the median sacral vein. There are no valves in these veins.

The median sacral veins accompany the corresponding artery along the front of the sacrum, and join to form a single vein, which usually ends in the left common iliac, but sometimes in the junction of the two common iliac veins.

6.139 Venogram showing the veins of the pelvis and groin. The contrast medium has been injected into the bodies of the pubic bones. 1. Injected contrast medium in pubic bones. 2. Internal iliac vein. 3. External iliac vein (faintly outlined). 4. Common iliac vein. 5. Inferior vena cava. 6. Ascending lumbar vein. 7. Obturator vein. 8. Internal pudendal vein. 9. Gluteal vein. (Radiograph kindly supplied by Dr. M. Lea Thomas.)

Variations. The left common iliac vein, instead of joining the right in its usual position, occasionally ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses in front of the aorta to join the inferior vena cava. This anomalous vessel represents the persistent caudal half of the left postcardinal or supracardinal vein (p. 194).

The Inferior Vena Cava (**6**.84, 183)

This conveys blood to the right atrium of the heart from all the body below the diaphragm. It is formed by junction of the two common iliac veins, anterior to the body of the fifth lumbar vertebra, a little to the right. It ascends in front of the vertebral column, on the right of the aorta. Reaching the liver it is contained in a deep groove on its posterior surface—a groove which is occasionally converted into a tunnel by a band of liver substance. It then perforates the tendinous part of the diaphragm between the median and right portions of its tendinous centre, inclining slightly forwards and medially. After passing through the fibrous pericardium, it passes behind the serous pericardium to open into the lower posterior part of the right atrium. In front and to the left of its atrial orifice there is a semilunar valve, the *valve of the inferior vena cava*; this is rudimentary in the adult, but large and functionally important in the fetus (p. 665). The inferior vena cava is devoid of valves.

Relations of the abdominal part:

Anteriorly the inferior vena cava is overlapped at its commencement by the right common iliac artery and is covered, below the horizontal part of the duodenum, with the posterior

parietal peritoneum. It is crossed obliquely by the root of the mesentery and its contained vessels, and by the right testicular (or ovarian) artery. Passing behind the horizontal part of the duodenum, it loses its peritoneal covering and ascends behind the head of the pancreas and then behind the superior part of the duodenum, from which it is separated by the bile duct and the portal vein. Above the duodenum it is again covered for a short distance with peritoneum in the posterior wall of the epiploic foramen (aditus to the lesser sac) (**8**.99, 100), by which it is separated from the right free border of the lesser omentum and its contents. Above this level the liver is anterior to it.

Posterior to the lower part of the inferior vena cava are the bodies of the lower three lumbar vertebrae and the anterior longitudinal ligament, the right psoas major and the right sympathetic trunk, while the third and fourth right lumbar arteries pass behind to its medial border. In its upper part, it is anterior to the right crus of the diaphragm, from which it is partially separated by the medial part of the right suprarenal gland and the right coeliac ganglion; the right renal, suprarenal and inferior phrenic arteries cross behind it.

On its *right side* the inferior vena cava is related to the right ureter, though not in immediate contact, to the descending part of the duodenum, the medial border of the right kidney and the right lobe of the liver.

On its *left side* it is related to the aorta, below, and to the right crus of the diaphragm and the caudate lobe of the liver above.

Relations of the thoracic part:

This part of the inferior vena cava is very short, and is partly inside and partly outside the pericardial sac. The *extrapericardial part* is separated from the right pleura and lung by the right phrenic nerve. The *intrapericardial part* is covered on the front and sides by the serous layer of the pericardium.

Surface Anatomy. The vein begins in, or just below, the transtubercular plane, its centre 2·5 cm from the midline; about 2·5 cm wide, it ends above behind the sternal end of the sixth right costal cartilage. A line, slightly convex laterally, from its lower end to a point 1 cm medial to the mid-inguinal point, indicates the course of the *common* and *external iliac veins* on each side.

Variations. Numerous anomalies of the inferior vena cava have been recorded and are attributable to arrests or errors in the complicated series of developmental changes which result in its formation. The vessel is sometimes represented, below the level of the renal veins, by two more or less symmetrical vessels. This is often associated with failure of the cross anastomosis connecting the two common iliac veins, and is due to persistence on the left of one of the longitudinal channels (usually supra- or subcardinal) which normally disappear in early fetal life (p. 194). In complete transposition of the viscera, the inferior vena cava lies to the left side of the aorta.

Applied Anatomy. Thrombosis of the inferior vena cava leads to oedema of the legs and back, without ascites. An extensive collateral venous circulation is soon established by enlargement of either the superficial or deep veins, or both. In the first case, the epigastric, the circumflex iliac, the lateral thoracic, the thoracoepigastric (p. 758), the internal thoracic, the posterior intercostals, the external pudendal and the lumbovertebral anastomotic veins effect the communication with the superior vena cava; in the second, the deep anastomosis is made by the azygos, hemiazygos and lumbar veins. It has also been suggested that the vertebral venous plexuses may provide effective collateral circulation between the venae cavae (Batson 1957).

Tributaries. These include in addition to the two common iliac veins the following: lumbar, right testicular or ovarian, renal, right suprarenal, inferior phrenic, and hepatic veins.

The lumbar veins, four on each side, collect the blood by dorsal tributaries from the muscle and skin of the loins, and by abdominal tributaries from the walls of the abdomen, where they communicate with the epigastric veins. Near the vertebral column they drain veins from the vertebral plexuses, and they are here connected with one another by the *ascending lumbar vein*—a longitudinal vessel in front of the roots of the transverse processes of the lumbar vertebrae. The *third* and *fourth lumbar veins* pass forwards on the sides of the bodies of the corresponding vertebrae and enter the posterior aspect of the inferior vena cava. Those of the left side pass behind the abdominal aorta and are longer than the right. The *first* and *second lumbar veins* may end in the inferior vena cava, the ascending lumbar, or lumbar azygos veins. Mostly, the first lumbar vein does not pass directly into the inferior vena cava. It may turn downwards to join the second and so open into it indirectly, but more frequently it ends in the ascending lumbar vein or passes forwards over the side of the body of the first lumbar vertebra and terminates in the lumbar azygos vein (p. 754). The second lumbar vein may join the inferior vena cava at or below the level of the renal veins. Sometimes it joins the third lumbar vein or it may terminate in the ascending lumbar vein. The first and second lumbar veins are frequently connnected to each other, to the vessels of the opposite side, and to the right and left lumbar azygos veins by a plexiform network which lies on the bodies of the upper lumbar vertebrae.

The *ascending lumbar vein* connects the common iliac, iliolumbar and lumbar veins. It is behind psoas major and in front of the roots of the transverse processes of the lumbar vertebrae. At its upper end it joins the subcostal vein, and the trunk so formed turns forwards over the side of the body of the twelfth thoracic vertebra and, passing deep to the crus of the diaphragm, ascends in the thorax as the azygos vein on the right, and as the hemiazygos vein on the left. There is an angled bend on the vessel as it turns upwards, and it is usually joined at this point by a small vessel from the back of the inferior vena cava (or from the left renal vein, on the left side). This little vessel represents the azygos line (p. 193), and has already been described as the *lumbar azygos vein* (p. 754). Not infrequently the ascending lumbar vein ends in the first lumbar vein, which then turns forwards round the first lumbar vertebra in company with the first lumbar artery and joins the lumbar azygos vein. In this case the subcostal vein joins the azygos vein on the right and the hemiazygos vein on the left.

The testicular veins (**6**.84) emerge from the back of the testis, and receive tributaries from the epididymis; they unite and form a convoluted mass, the *pampiniform plexus*, the chief constituent of the spermatic cord, which ascends in the cord, in front of the ductus deferens. Below the superficial inguinal ring the veins of the plexus are drained by three or four veins which pass along the inguinal canal, enter the abdomen through the deep inguinal ring and coalesce into two veins, which run upwards in front of psoas major and the ureter, behind the peritoneum, one on each side of the testicular artery. These two veins become a single vessel, which on the right side opens into the inferior vena cava at an acute angle a little below the level of the renal veins; on the left side it opens into the left renal vein at a right angle. The testicular veins contain valves. The left vein passes behind the lower part of the descending colon and the lower margin of the pancreas and is crossed by the left colic vessels; the right passes behind the terminal part of the ileum and the horizontal part of the duodenum and is crossed by the root of the mesentery, the ileocolic and right colic vessels.

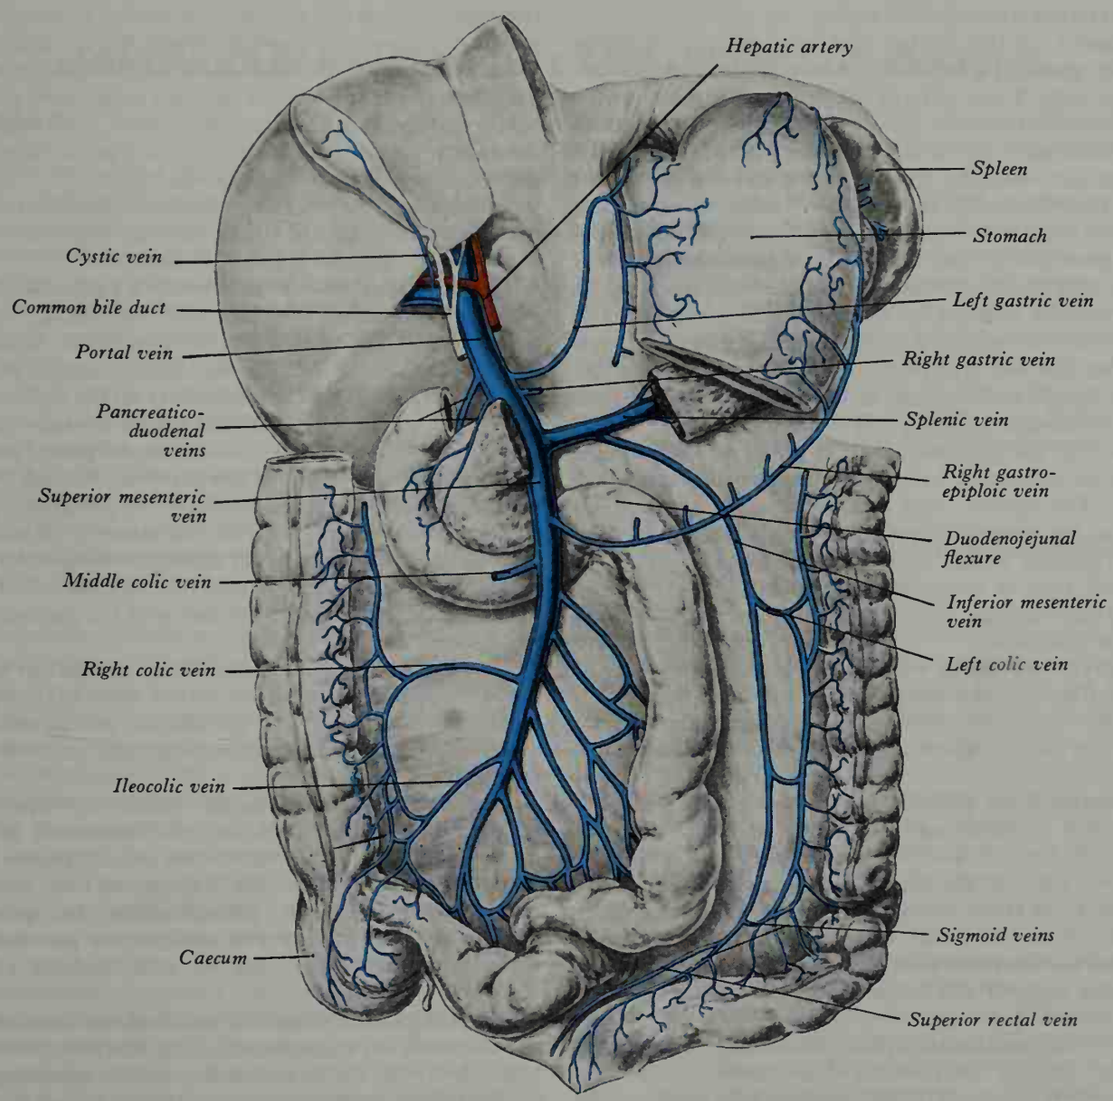
Applied Anatomy. The testicular veins are frequently varicose, a condition known as *varicocele*. Varicocele almost invariably occurs on the left, and this has been accounted for by the fact that the left testicular vein joins the left renal at a right angle; also it is overlaid by the lower part of the descending colon, and when this portion of the gut is full of faecal matter, in cases of constipation, its weight impedes the venous return. After the removal of a varicocele the venous return is carried out by the small veins of the ductus deferens, the cremaster, and the scrotal tissues.

The ovarian veins correspond with the testicular veins; each forms a plexus in the broad ligament near the ovary and uterine tube, and communicates with the uterine plexus. Two veins issue from this plexus and ascend across the external iliac artery, on each side of the ovarian artery. Their further course and mode of termination are like those of the testicular veins. Valves are occasionally found in the ovarian veins. Like the uterine veins, they are much enlarged during pregnancy.

The renal veins, of large size, are anterior to the renal arteries, and open into the inferior vena cava almost at right angles. The *left* is thrice the length of the right (7·5 cm to 2·5 cm), and crosses the posterior abdominal wall, behind the splenic vein and the body of the pancreas. Near its termination it passes in front of the aorta, just below the origin of the superior mesenteric artery. The

left testicular (or ovarian) vein enters it from below, and the left suprarenal vein, which generally receives one of the left inferior phrenic veins, enters it above a little nearer the median plane. The left renal vein opens into the inferior vena cava at a slightly higher level than the right. The *right renal vein* is behind the descending part of the duodenum and sometimes the lateral part of the head of the pancreas.

Variations. Occasionally the left renal vein may be double, then one vein passes behind and one in front of the aorta to join the inferior vena cava—persistence of the renal collar (p. 194)—or the anterior vessel may be entirely absent. The latter condition represents persistence of the posterior limb of the renal collar combined with absence of the intersubcardinal anastomosis.



The suprarenal veins issue from the hilum of each suprarenal gland. The right is very short and passes directly into the posterior aspect of the inferior vena cava; the left runs downwards and medially, in front of or just lateral to the left coeliac ganglion, and passes behind the body of the pancreas to the left renal vein.

The inferior phrenic veins follow the course of the corresponding arteries on the inferior surface of the diaphragm; the right ends in the inferior vena cava; the left is often represented by two branches, one of which ends in the left renal or suprarenal vein, while the other passes in front of the oesophageal opening in the diaphragm and joins the inferior vena cava.

The hepatic veins drain the liver, and commence in the *intralobular veins*, which collect blood from the sinusoids of the liver lobules (*see* p. 1381). The intralobular veins open into *sublobular veins*, and these in turn unite to form the hepatic veins, which emerge from the posterior surface of the liver and open *immediately* into the inferior vena cava as it lies in the groove on the posterior surface of the liver. The hepatic veins are arranged in two groups, upper and lower. The *upper group* usually consists of three large veins, right, left and middle, the last emerging from the caudate lobe; those of the *lower group* vary in number; they are of small size and come from the right and caudate lobes. The hepatic veins are in direct contact with hepatic tissue and are destitute of valves. The occurence of large *'accessory' hepatic veins* belonging to the lower group, and draining a variable volume of the intermediate to inferior part of the right lobe has been studied in 93 adult livers using corrosion cast techniques. Such veins are usually single, occasionally double and have an incidence of 15 per cent (*see* Sledziński and Tyszkiewicz 1975).

The Hepatic Portal System

The portal system (**6**.140, 141) includes all veins collecting blood from the abdominal part of the digestive tube (with the exception of the lower part of the anal canal) and from the spleen, pancreas, and gall bladder. From these viscera blood is conveyed into the liver by the *portal vein*. In the liver this vein ramifies like an artery and ends in capillary-like vessels termed sinusoids, from which blood is conveyed to the inferior vena cava by the hepatic veins. The blood of the portal system therefore passes through two sets of 'exchange' vessels, (*a*) the capillaries of the digestive tube, spleen, pancreas, and gall bladder, (*b*) the sinusoids of the liver. In

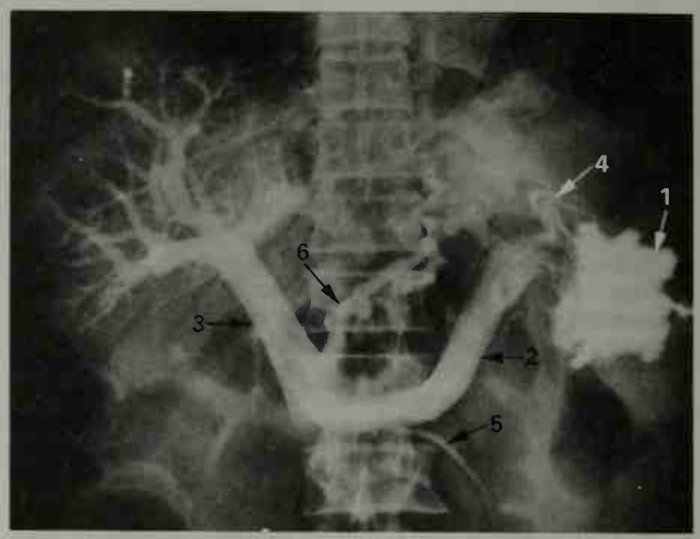
6.140 The portal vein and its tributaries. Semi-diagrammatic. Portions of the stomach, pancreas and left lobe of the liver, and the transverse colon have been removed.

the adult the portal vein and its tributaries have no valves; in the fetus and for a short time after birth valves can be demonstrated in its tributaries; as a rule they atrophy and disappear, but some may persist in a degenerate form.

The portal vein (**6**.87, 140) is about 8 cm long, and starts at the level of the second lumbar vertebra from the junction of the superior mesenteric and splenic veins, in front of the inferior vena cava and behind the neck of the pancreas. The vein inclines slightly to the right as it passes upwards behind the superior part of the duodenum, the bile duct and the gastroduodenal artery, and in front of the inferior vena cava; it then ascends in the right border of the lesser omentum in front of the epiploic foramen to reach the right end of the porta hepatis, where it divides into right and left stems, which accompany the corresponding branches of the hepatic artery into the substance of the liver. In the lesser omentum it is behind the bile duct and the hepatic artery, the former to the right of the latter; it is surrounded by the hepatic plexus of nerves, and is accompanied by numerous lymph vessels and some lymph nodes. The *right branch* of the portal vein enters the right lobe of the liver, but before doing so generally receives the cystic vein. The *left branch*, longer but of smaller calibre than the right, gives branches to the caudate and quadrate lobes and then enters the left lobe of the liver. As it does so, it is joined in front by the para-umbilical veins (p. 765) and by a fibrous cord, the *ligamentum teres*, the remains of the obliterated left umbilical vein. It is connected to the inferior vena cava by a second fibrous cord, the *ligamentum venosum*, a vestige of the obliterated ductus venosus, and ascends in a fissure on the posterior aspect of the liver. The small extrahepatic portion of the left branch, from which the vessels to the quadrate and left lobes arise, is a persistent part of the left umbilical vein.

The tributaries of the portal vein are: splenic, superior mesenteric, left gastric, right gastric, para-umbilical, and cystic.

The splenic vein (**6**.140) of large size, but not tortuous like the artery, commences from five or six tributaries issuing from the spleen. These unite into a single vessel, which traverses the lienorenal ligament with the splenic artery and the tail of the pancreas. It then descends to the right across the posterior abdominal wall, lying at a lower level than the splenic artery and immediately posterior to the body of the pancreas (which it grooves), receiving numerous short tributaries from the gland. In its course it crosses anterior to the left kidney and its hilar structures (or the lower pole of the left suprarenal gland), and it is separated from the left sympathetic trunk and crus of the diaphragm by the left renal vessels, and from the abdominal aorta by the superior mesenteric artery and the left renal vein. It ends behind the neck of the pancreas where it unites at a right angle with the superior mesenteric vein, to form the portal vein.



Tributaries. The splenic vein drains the short gastric, left gastro-epiploic, the pancreatic, and the inferior mesenteric veins.

The short gastric veins, four or five in number, drain the fundus and left part of the greater curvature of the stomach, traversing the gastrosplenic ligament to reach the splenic vein or one of its large tributaries.

The left gastro-epiploic vein drains both surfaces of the stomach and adjacent greater omentum; it runs from right to left along the greater curvature of the stomach, between the anterior two layers of the greater omentum, and ends in the commencement of the splenic vein.

The pancreatic veins drain the body and tail of the pancreas. These veins may be small and numerous or larger and less numerous. In the former case they empty more or less directly into the splenic vein; in the latter case, superior and inferior arcades receive these larger veins, their ultimate drainage being into the splenic vessel (Sow *et al.* 1976; see also p. 1372).

The inferior mesenteric vein (**6**.140) returns blood from the rectum, and the sigmoid and descending parts of the colon. It begins in the rectum as the *superior rectal vein*, which starts in the rectal plexus (p. 760), and through this plexus communicates with the middle and inferior rectal veins. The superior rectal vein leaves the lesser pelvis, crosses the left common iliac vessels on the medial side of the left ureter together with the superior rectal artery, and is continued upwards as the inferior mesenteric vein. This lies to the left of its artery and ascends behind the peritoneum and in front of the left psoas major; it may cross the testicular (or ovarian) vessels or lie medial to them; it then passes above, or behind, the duodenojejunal flexure and opens into the splenic vein behind the body of the pancreas; sometimes it ends at the union of the splenic and superior mesenteric veins.

6.141 Portal venogram. A contrast medium has been injected percutaneously into the spleen. There has been some retrograde filling of some of the gastric veins and of the inferior mesenteric vein. The ramifications of the portal vein in the liver are especially prominent in the right lobe. 1. Injection mass in spleen. 2. Splenic vein. 3. Portal vein. 4. Short gastric vein. 5. Inferior mesenteric vein. 6. Left gastric vein. (Radiograph kindly supplied by Dr. M. Lea Thomas.)

If a duodenal or a paraduodenal fossa is present, the inferior mesenteric vein usually lies in the fold of peritoneum which forms the anterior wall of the fossa (*see* p. 1331).

Tributaries. The inferior mesenteric vein receives the *sigmoid veins* from the sigmoid colon, and the *left colic vein* from the descending colon and left colic flexure.

The superior mesenteric vein (**6**.140) collects blood from the small intestine, caecum, and ascending and transverse portions of the colon. It begins in the right iliac fossa by the union of tributaries from the terminal ileum, caecum and vermiform appendix. It ascends in the mesentery on the right of the superior mesenteric artery; in its upward course it passes in front of the right ureter, inferior vena cava, horizontal part of the duodenum, and the uncinate process of the pancreas. Behind the neck of the pancreas it joins the splenic to form the portal vein (**6**.141).

Tributaries. The superior mesenteric vein's tributaries correspond to the branches of the superior mesenteric artery, viz. jejunal, ileal, ileocolic, right colic, and middle colic veins; it is also joined by the right gastro-epiploic and the pancreaticoduodenal veins.

The right gastro-epiploic vein drains the greater omentum and the lower part of the stomach; it runs from left to right along the greater curvature, between the anterior two layers of the greater omentum and joins the superior mesenteric vein below the neck of the pancreas.

The pancreaticoduodenal veins accompany their corresponding arteries; the lower one frequently joins the right gastro-epiploic vein; the upper one usually passes up to the left behind the bile duct and ends in the portal vein. Sow *et al.* (1975) have described anterior, intraglandular, and posterior *venous arcades* between the superior and inferior pancreaticoduodenal veins in about 70 per cent (in each case) of 157 pancreatic corrosion preparations.

The left gastric vein derives tributaries from both surfaces of the stomach; it runs upwards along the lesser curvature of the stomach in the lesser omentum, to the oesophageal opening, where it receives some oesophageal veins. It then turns backwards and passes downwards and to the right behind the omental bursa (lesser sac), and ends in the portal vein at the upper border of the superior part of the duodenum.

The right gastric vein, of small size, runs from left to right along the pyloric portion of the lesser curvature of the stomach in the lesser omentum, and ends in the portal vein. It is joined by the *prepyloric vein* which ascends in front of the pylorus and usually marks the site of the pyloric opening.

The para-umbilical veins, which establish an anastomosis between the veins of the anterior abdominal wall and the portal vein, extend along the ligamentum teres of the liver and the median umbilical ligament (p. 1405). The best marked of these small veins is one which begins at the umbilicus and runs backwards and upwards in, or on the surface of, the ligamentum teres in the falciform ligament, to end in the left branch of the portal vein.

The cystic veins. The veins draining the gall bladder vary considerably. Those from its upper surface lie in the areolar tissue between the gall bladder and liver and usually run directly into the liver through the fossa for the gall bladder to join the hepatic veins. Those from the rest of the gall bladder join to form one or two cystic veins on its neck, and these commonly enter the liver, either directly or after joining with veins draining the hepatic ducts and the upper part of the bile duct. Only rarely does a single or double cystic vein drain directly into the right branch of the portal vein.

Applied Anatomy. Obstruction to the portal vein may produce ascites, whether the site of the obstruction is intra- or extra-hepatic. In cirrhosis of the liver, the radicles of the portal vein are compressed by the contraction of the fibrous tissue in the portal canals. In valvular disease of the heart backward pressure on the hepatic veins, and so on the whole circulation through the liver, exerts a similar effect. In addition the portal vein may be compressed by tumours of the liver, or by enlarged lymph nodes in the lesser omentum or carcinoma of the head of the pancreas. Thrombosis of the portal vein may accompany a variety of conditions. In cases of obstruction of the portal vein, the *anastomoses between the portal and systemic circulations*, which may collectively offer an effective collateral circulation, are as follows. (1) In the abdominal part of the oesophagus tributaries of the left gastric vein (portal drainage) anastomose with the oesophageal tributaries of the azygos and accessory hemiazygos (systemic) veins. Enlargement of the anastomoses may result in varicosity of these veins, leading even to a fatal haematemesis. (2) In the wall of the anal canal the opening up of communications between the inferior and middle rectal (systemic) and superior rectal (portal) veins may result in varicosity of these venous connexions. (3) At the umbilicus the veins running with the ligamentum teres of the liver to the left branch of the portal vein (p. 764) anastomose with the epigastric veins (systemic); enlargement of these connexions may produce a varicose condition of veins radiating from the umbilicus, known clinically as the *caput Medusae*. (4) Retroperitoneal veins of the abdominal wall communicate with venous radicles of the colon and bare area of the liver. (5) Very rarely the ductus venosus remains patent and connects the left branch of the portal vein directly to the inferior vena cava.

Some success has been achieved in case of portal obstruction by anastomosis of the portal vein to the inferior vena cava, or of the splenic vein to the left renal vein, after removal of the spleen.

MONONUCLEAR PHAGOCYTE AND LYMPHATIC SYSTEMS

Introduction

Scattered widely throughout the body are systems of tissues, or fluids and their cellular contents, which are concerned with a variety of interrelated functions. The latter include the circulation and modification of some of the tissue fluid formed in the blood capillary beds; phagocytosis of foreign matter and cell débris; long-term specific immune responses of the body, both humoral and cellular and, finally, the production and maintenance of the circulating cell populations in the blood, lymph and tissue fluid. Since these activities are interdependent, often having a common cellular basis, precise definition of various so-called 'systems' presents difficulties of terminology and may obscure rather than clarify important concepts. However, certain terms, widely used, will be retained in this account, even though they may reflect historical stages in the scientific analysis of the phenomena, or a preoccupation with a particular functional attribute, rather than any exclusive basis for their separate classification.

The term *reticulo-endothelial system* included all those cells and tissues with well-marked phagocytic properties and whilst the term is adequately descriptive for certain tissues, in others, the cells are neither reticular nor endothelial. Accordingly, this term has been generally replaced by the designation *mononuclear phagocyte* (or *macrophage*) *system* to include all major phagocytic cell types, except haemal polymorphonuclear leucocytes.

Most of the tissue fluid formed at the arterial end of the capillary bed returns to the blood circulation via the venous ends of the capillaries and the post-capillary venules. Some 10–20 per cent, however, is transported through a system of fine lymphatic capillaries, traverses one or more groups of lymph nodes, and finally larger lymph vessels, before returning to the venous system. These channels and nodes together with other masses of lymphoid tissue in the walls of the alimentary tract, spleen, thymus and bone marrow are often grouped as the *lymphatic system*. However, in addition to transporting and modifying lymph, parts of the lymphatic system are essentially involved in phagocytosis, effecting immune responses and contributing to the cell populations of the blood and lymph, and are accordingly often classed as *lympho-reticular organs*.

The term *haemopoietic system* is used when the origins of circulating blood cells are being considered; this topic has been discussed earlier (p. 63).

Finally, the term *immunocyte system* or *complex* is often used when considering the origins, transformations and activities of the cell types directly or indirectly concerned in mounting an immune response (e.g. certain phagocytes, plasma cells, varieties of lymphocyte, their precursors, and transformed progeny).

In this section an account of the mononuclear phagocyte system and an outline of the immune response is followed by general consideration of a lymph node and its vessels, the spleen, alimentary lymphoid tissue, thymus, and finally, a review of the topographical distribution of lymphatic vessels and nodes.

Mononuclear Phagocyte or Macrophage System

The macrophage, mononuclear phagocyte or reticulo-endothelial system (Aschoff 1924) is a collective term for a widespread system of highly phagocytic cells (*see* p. 45). Its cells are numerous and are characteristically present in large numbers in certain situations in the body. In postnatal life they are believed to arise primarily in the bone marrow, where they are formed as monocytes which migrate into connective and peripheral lymphoid tissues, and the liver, where they may form a relatively fixed or 'resting' component. In some cases, e.g. the liver, the cells are frequently highly branched, the ends of the branches coming into close apposition (but not syncytial fusion) to form a three-dimensional meshwork or *reticulum*, often supported by a complementary meshwork of fine reticulin fibres, a product of the cells themselves. Under appropriate stimulation they are capable of detaching themselves from the tissues, which, when they are static, they help to form, and of acquiring mobility which is amoeboid in character. In ordinary stained histological preparations they display few characteristics by which they can be distinguished with certainty. They can be identified by their marked affinity for inert particles and certain colloidal dyes, when these are injected into the living animal. Particulates such as India

ink, when injected into the bloodstream of the living animal, are taken up by the intravascular components of the macrophage system as well as by the granulocytes in the blood. Diffusible colloidal dyes, such as trypan blue, when injected into the vascular system, are taken up by both the intravascular and extravascular components of the mononuclear phagocyte system; for electron microscopic identification, cells may be visualized in the same manner by injecting electron-dense tracers such as ferritin or thorium dioxide, or enzymic markers (e.g. horseradish peroxidase) into the circulation. The basis for the inclusion of particular cells in the mononuclear phagocyte system is rather arbitrary and depends upon the readiness of uptake of particulate matter. Thus, the general endothelial cells lining most of the blood-vascular and lymphatic systems, fibroblasts and most leucocytes take up only small amounts of a test injection and are excluded from the system by most workers in the field.

Cells of the mononuclear phagocyte type occur in considerable number and varying morphology in the following situations: (1) Connective tissues, where they have already been described as macrophages. In nervous tissue the microglial cells are considered to belong to this system. In the subserous connective tissue of the pleura and peritoneum the macrophages are frequently aggregated and appear as white streaks, known as *milky spots*, close to the small lymphatic trunks where they adhere; many also wander freely in the fluid of the pleural or peritoneal cavities (*pleural* or *peritoneal macrophages*). (2) Blood, where they are represented by monocytes. There is much evidence that these migrate into the tissues from the bloodstream, to become tissue macrophages, and are distinct from other circulating white blood cells. (3) Lining the blood sinuses of the liver where they are termed Kupffer's cells. (4) The *reticular tissue* of the spleen, lymph nodes, solitary and aggregated lymph follicles, tonsils and bone marrow where they adhere to the fibres or migrate within the cavities which permeate the reticulum. (5) The meninges, where they are known as *meningocytes*. (6) The alveoli of the lung, which are constantly patrolled by *alveolar macrophages* migrating from the interalveolar connective tissue through the intercellular junctions between the epithelial cells. These cells engulf inhaled particles and bacteria, and in the case of congestive heart failure, extravasated red blood corpuscles; they are accordingly sometimes termed *dust cells* or *heart failure cells*, and may be found in the sputum bearing their ingested material. (7) In certain infections of the tissues, where macrophages may fuse together to form multinucleate *foreign body giant cells* around foci of bacterial, viral, or other types of damage. (8) In resorbing bone, where some authorities consider the *osteoclast* to be a cell similar in origin and function to the foreign body giant cell, although others view the osteoclast as a distinctive cell type (p. 261); the same considerations apply to the *chondroclast*.

Because of their amoeboid and phagocytic properties the cells of the macrophage system form one of the most important short-term defences of the body against micro-organisms and under appropriate stimulation, the cells proliferate freely. Repeated injections of particulate matter into an animal can 'block' the normal function of the macrophages, so that subsequent destruction of micro-organisms is hindered. These cells are involved in the initial phagocytosis and destruction of aged red blood cells in the spleen and liver, although it is not certain whether such erythrocytes may be, to some extent, lysed prior to their uptake by macrophages and Kupffer cells. The haemoglobin is split into globin and an iron-porphyrin ring compound, which is opened and the iron removed. The released iron is re-used for haemoglobin synthesis and the remaining group degraded to bilirubin which is excreted by the liver. There is evidence also that the macrophage system is concerned in the metabolism of lipids; it is extensively involved in certain disorders of lipid metabolism.

In addition to providing a first-line defence system against invading micro-organisms, the macrophages present in lymphoid tissue are now considered to be intimately concerned with the establishment of specific immune responses by neighbouring cells (*see* p. 45).

Many of the prominent reticulo-endothelial tissues are also important sites of haemopoiesis, both during mid-fetal life (spleen, liver and some connective tissues), and later fetal and postnatal life (lymphoid tissues and bone marrow).

The Lymphoid System

The other major defensive arm, which operates in close association with the system of phagocytes, is provided by the lymphocytes which are constantly present in the bloodstream, lymph, and other body fluids, as well as in the connective tissues and in their major areas of lymphocyte proliferation, the specialized lymphoid tissues and organs. The lymphocytes constitute several populations of cells which have in common their ability to produce chemicals such as antibodies which can inactivate foreign substances, microbes and neoplastic cells when these arise in the body, or are introduced to the tissues (*see* p. 61).

Lymphocytes undergo their initial differentiation in the **central lymphoid tissues**, i.e. the bone marrow, where B-lymphocytes capable of synthesizing antibodies are initially produced, and the thymus, where the T-lymphocytes able to kill virus-infected cells, fungi and neoplastic cells, etc., are first formed. The progeny from these central tissues then pass in the circulation to the **peripheral lymphoid organs**—the *lymph nodes*, *epithelio-lymphoid tissue* ('lymphoid nodules' in Peyer's patches, vermiform appendix, bronchial tree, etc.) and similar tissues in the bone marrow and spleen; in these peripheral sites lymphocytes may proliferate, mature, and migrate into the surrounding tissues, or they may return to the circulation. This system of tissues is quite labile, and a given component may become extremely active in lymphocyte production and maturation when subjected to effective antigenic stimulation. The lymphocytes produced within them can travel freely in the haemal and lymphatic circulation, populating lymphoid tissue temporarily, and providing a circulating pool which can be called upon during antigenic emergencies (*see* Roitt 1977).

DIFFERENTIATION OF LYMPHOCYTES

As in all cell lineages, the cells of the lymphoid series undergo a succession of stages in their development from 'pluripotent' lymphoid stem cells before they finally emerge as fully competent defensive elements of the immune system. (However, *see* discussion on cell 'potentiality' on pp. 83–85). During early fetal life this process occurs in the liver, but in later fetal and postnatal life the site is transferred to the bone marrow, where the stem cells proliferate giving rise to uncommitted lymphocytes which must then pass through another process of differentiation before they are established as either B- or T-lymphocytes. This step occurs in the thymus in the case of T-lymphocytes, whilst the B-lymphocytes apparently undergo this stage within the bone marrow itself, although in birds the wall of the bursa of Fabricius, a hind-gut diverticulum, is the site of B-cell commitment.

B-lymphocytes are able to produce an enormous range of antibodies, each able to recognize and inactive a narrow range of antigens, and it is generally established that each B-lymphocyte is able to synthesize antibody with only one type of specificity.

According to the selective hypothesis, only those cells capable of reacting by cell division and the synthesis and secretion of an appropriate antibody are activated when a particular antigen is introduced into the body, so there must be a large 'resting' population of cells each with a distinctive capacity to produce antibodies of different types. The manner in which this variability is initially achieved has been the subject of much debate. It is known that the ability to produce antibodies of different kinds is under genetic control, and therefore it seems likely that antibodies are coded for on the chromosomes in the normal manner. However, as there may be many thousands of antibodies formed within an individual, it has been argued that the amount of genetic material devoted to antibody production would be a major proportion of the whole genome, and that instead it may be possible that the genes in the lymphocyte precursors could undergo somatic mutation, thus generating a wide diversity of genes in the lymphoid series.

Recent evidence, although not decisive, favours the more

usual genetic view that mutation does not take place and that the genes of the germ line are all that is necessary for antibody diversity. Further, since antibody molecules are composite structures of two light and two heavy chains, with variable regions in each, it is feasible that genes code for small parts of antibody molecules, which could thereafter be assembled in different ways to create the observed diversity of the final antibody molecules. (For further discussion consult Williamson 1976; Cunningham 1976; Roitt 1977.)

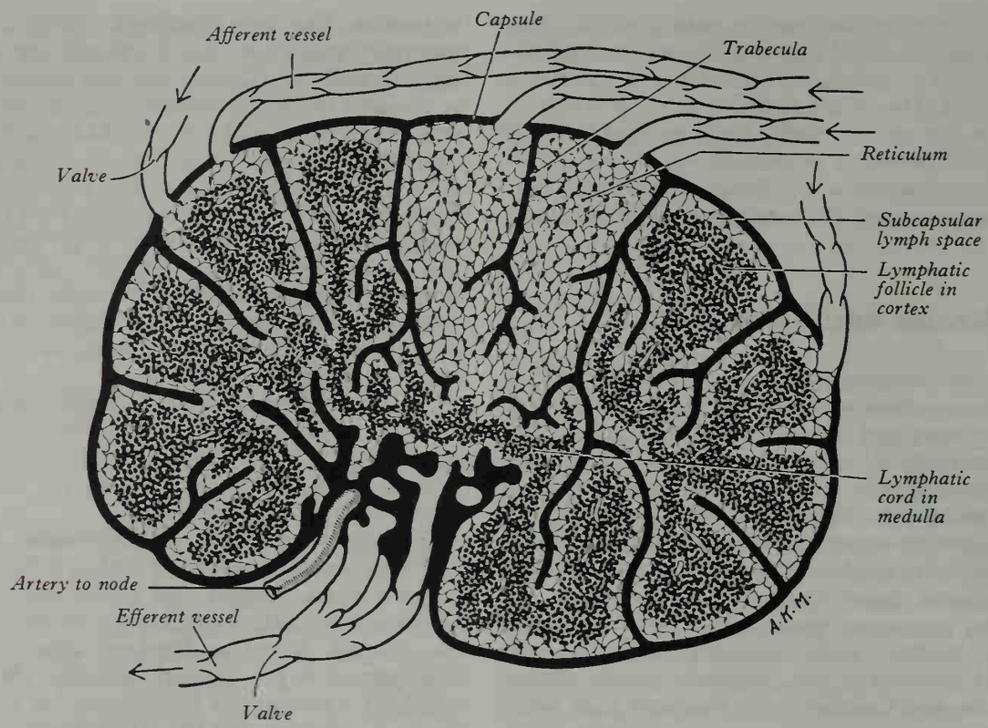
The Lymph Nodes and Vessels

The lymphatic system comprises (*a*) plexuses of minute vessels (*lymph capillaries*) that commence blindly in the tissue spaces in many tissues of the body and ultimately empty their contents (*lymph*) into certain veins; (*b*) *lymph nodes*, consisting of small solid masses of lymphoid tissue, into which the lymph vessels at some part of their course pour their lymph, so that generally the lymph from any tissue or organ traverses one or more lymph nodes before it eventually reaches the venous bloodstream; (*c*) collections of lymphoid tissue situated in the walls of the alimentary canal and respiratory tract (*epitheliolymphoid tissue*), and in the spleen and thymus; (*d*) the circulating *lymphocytes* (*vide infra*). (For general accounts of the lymphatic system consult Rouviére 1932; Yoffey and Courtice 1956; Rusznyák *et al.* 1960; Allen 1967.)

LYMPH VESSELS

The lymph capillaries form networks in the tissue spaces, the meshes of which are larger than those of the neighbouring blood capillaries. They often commence with a dilated, bulb-like, blind extremity and their calibre is greater and less regular than that of capillaries. An important feature of the endothelial wall of the lymph capillaries is that it is permeable to substances of much greater molecular size than those which can pass through the endothelial wall of blood capillaries (Allen 1967). The lymph capillaries form the pathway for absorption of colloidal material (and particular matter including cell débris and micro-organisms) from the tissue spaces, whereas the blood capillaries are more concerned with the absorption of soluble crystalloid substances. Thus, if the lymph vessels become obstructed, the tissues drained by them become oedematous and distended with a fluid containing much protein. Experimental evidence suggests that the absorption of macromolecular and particulate substances takes place through intercellular fenestrations between the endothelial cells or by micropinocytosis across the cells. Whereas the lymph draining from most tissues is a clear colourless fluid, that draining from the small intestine is milk-white in appearance, due to the absorption of fat, as chylomicra, from the gut; the fluid is called *chyle* and the lymph vessels are known as *lacteals*. Lymph capillaries are present in many tissues of the body, but are absent from avascular structures (epidermis, hair, nails, cornea, and articular and some other cartilages), the brain and spinal cord, the splenic pulp and bone marrow.

The lymph capillaries join to form larger trunks that pass to neighbouring, or sometimes remote, lymph nodes. The lymph nodes are for the most part arranged in *regional groups*, as described later. Most of these groups are sufficiently regular to receive names. Each group has a characteristic region of drainage, but the immediately local group is often by-passed. The nodes in a particular group are also frequently interconnected by short trunks (*see* Kubik 1974, for literature). In general, most of the lymph appears to traverse a series of nodes before reaching the major collecting ducts. There are, however, exceptions to the general rule that lymph traverses one or more lymph nodes before reaching the bloodstream. These are some of the lymph vessels of the thyroid gland, oesophagus, and the lymph vessels running in the coronary and triangular ligaments of the liver, all of which enter directly into the thoracic duct (Rusznyák *et al.* 1960). The larger superficial lymph vessels of the skin lie near the deep fascia and tend to accompany the superficial veins, though some run independently; they have very few connexions with the deep lymphatics. The deep lymphatic trunks in most cases closely accompany arteries or veins. Eventually, practically all the lymph from the body is collected into two channels, the *thoracic duct* (p. 784 and the *right lymphatic duct* (p. 785), which pour their lymph into the left and right brachiocephalic veins respectively. Most lymphatic vessels anastomose freely and those of the two sides of the body are in communication *across the midline*. The larger lymph vessels are supplied with their own vasa vasorum and are accompanied by a plexus of fine blood vessels. If the walls of the lymph vessels are acutely infected (lymphangitis) this plexus becomes congested and the paths of superficial lymph vessels are often marked by painful red lines visible through the skin. Nerve networks are described both within and around the walls of the larger lymph vessels.



Lymph vessels have a great capacity for repair and for the formation of new vessels after damage. The new vessels are formed first as solid cellular sprouts produced by the mitotic division of the endothelial cells of the persisting vessels, the sprouts later becoming canalized.

The structure of the lymph vessels. The wall of a lymph capillary consists of a single layer of endothelial cells. It resembles that of a blood capillary, but the basement membrane is often lacking and specialized attachments between endothelial cells are few, though fenestrae between adjacent cells have been demonstrated in subserous lymphatics. The latter are absent in well-fixed subcutaneous lymphatics, but are very evident after trauma to neighbouring tissue. Filopodia are more frequent on their luminal surfaces. In the lacteals similar projections may also occur on the outer surfaces of the cell and pericytes are absent (Fraley and Weiss 1961). Thus, as with blood capillaries, there may exist considerable structural variation between lymph capillaries in different tissues (Allen 1967; Leak and Burke 1968). As the capillaries unite to form larger vessels, a thin connective tissue coat is added outside the endothelium. The larger collecting lymph trunks have three tunics, comparable with those of small veins. The tunica intima consists of endothelial cells and a thin layer of fibrous tissue; the tunica media contains some smooth muscle cells, most disposed circularly, and the tunica adventitia is composed mainly of fibrous tissue with a slight admixture of smooth muscle.

An optical and electron microscopic study of human lymphatic trunks by Boggon and Palfrey (1973) confirmed this trilaminar structure, though these authors did not observe muscle fibres in the adventitia. Elastic fibres were sparsely distributed in the subendothelial connective tissue, but were numerous enough to constitute an external elastic lamina in the tunica adventitia. The lymph channels differ from small veins in that they possess many more valves. These are semilunar and are generally arranged in pairs; they are formed by a reduplication of the endothelium with a delicate fibrous tissue core. Their free edges are directed along the course of the lymph current, and the wall of the lymph vessel immediately proximal to the attached edges of the valves is expanded into a sinus or pouch which gives the vessel, when distended, a knotted or beaded appearance. The valves are of considerable importance in connexion with the mechanism of the flow of lymph. The thoracic duct is similar in structure to a medium-sized vein, though the non-striated muscle in its tunica media is more prominent.

Satiukova and Rassokhina-Volkova (1972) have studied the regeneration of lymph capillaries in dogs after auto-transplantations of hind legs and lungs; they observed an early formation of buds from severed lymph channels in the junctional scar tissue, and they considered that lymph flow was largely restored by such new collateral routes.

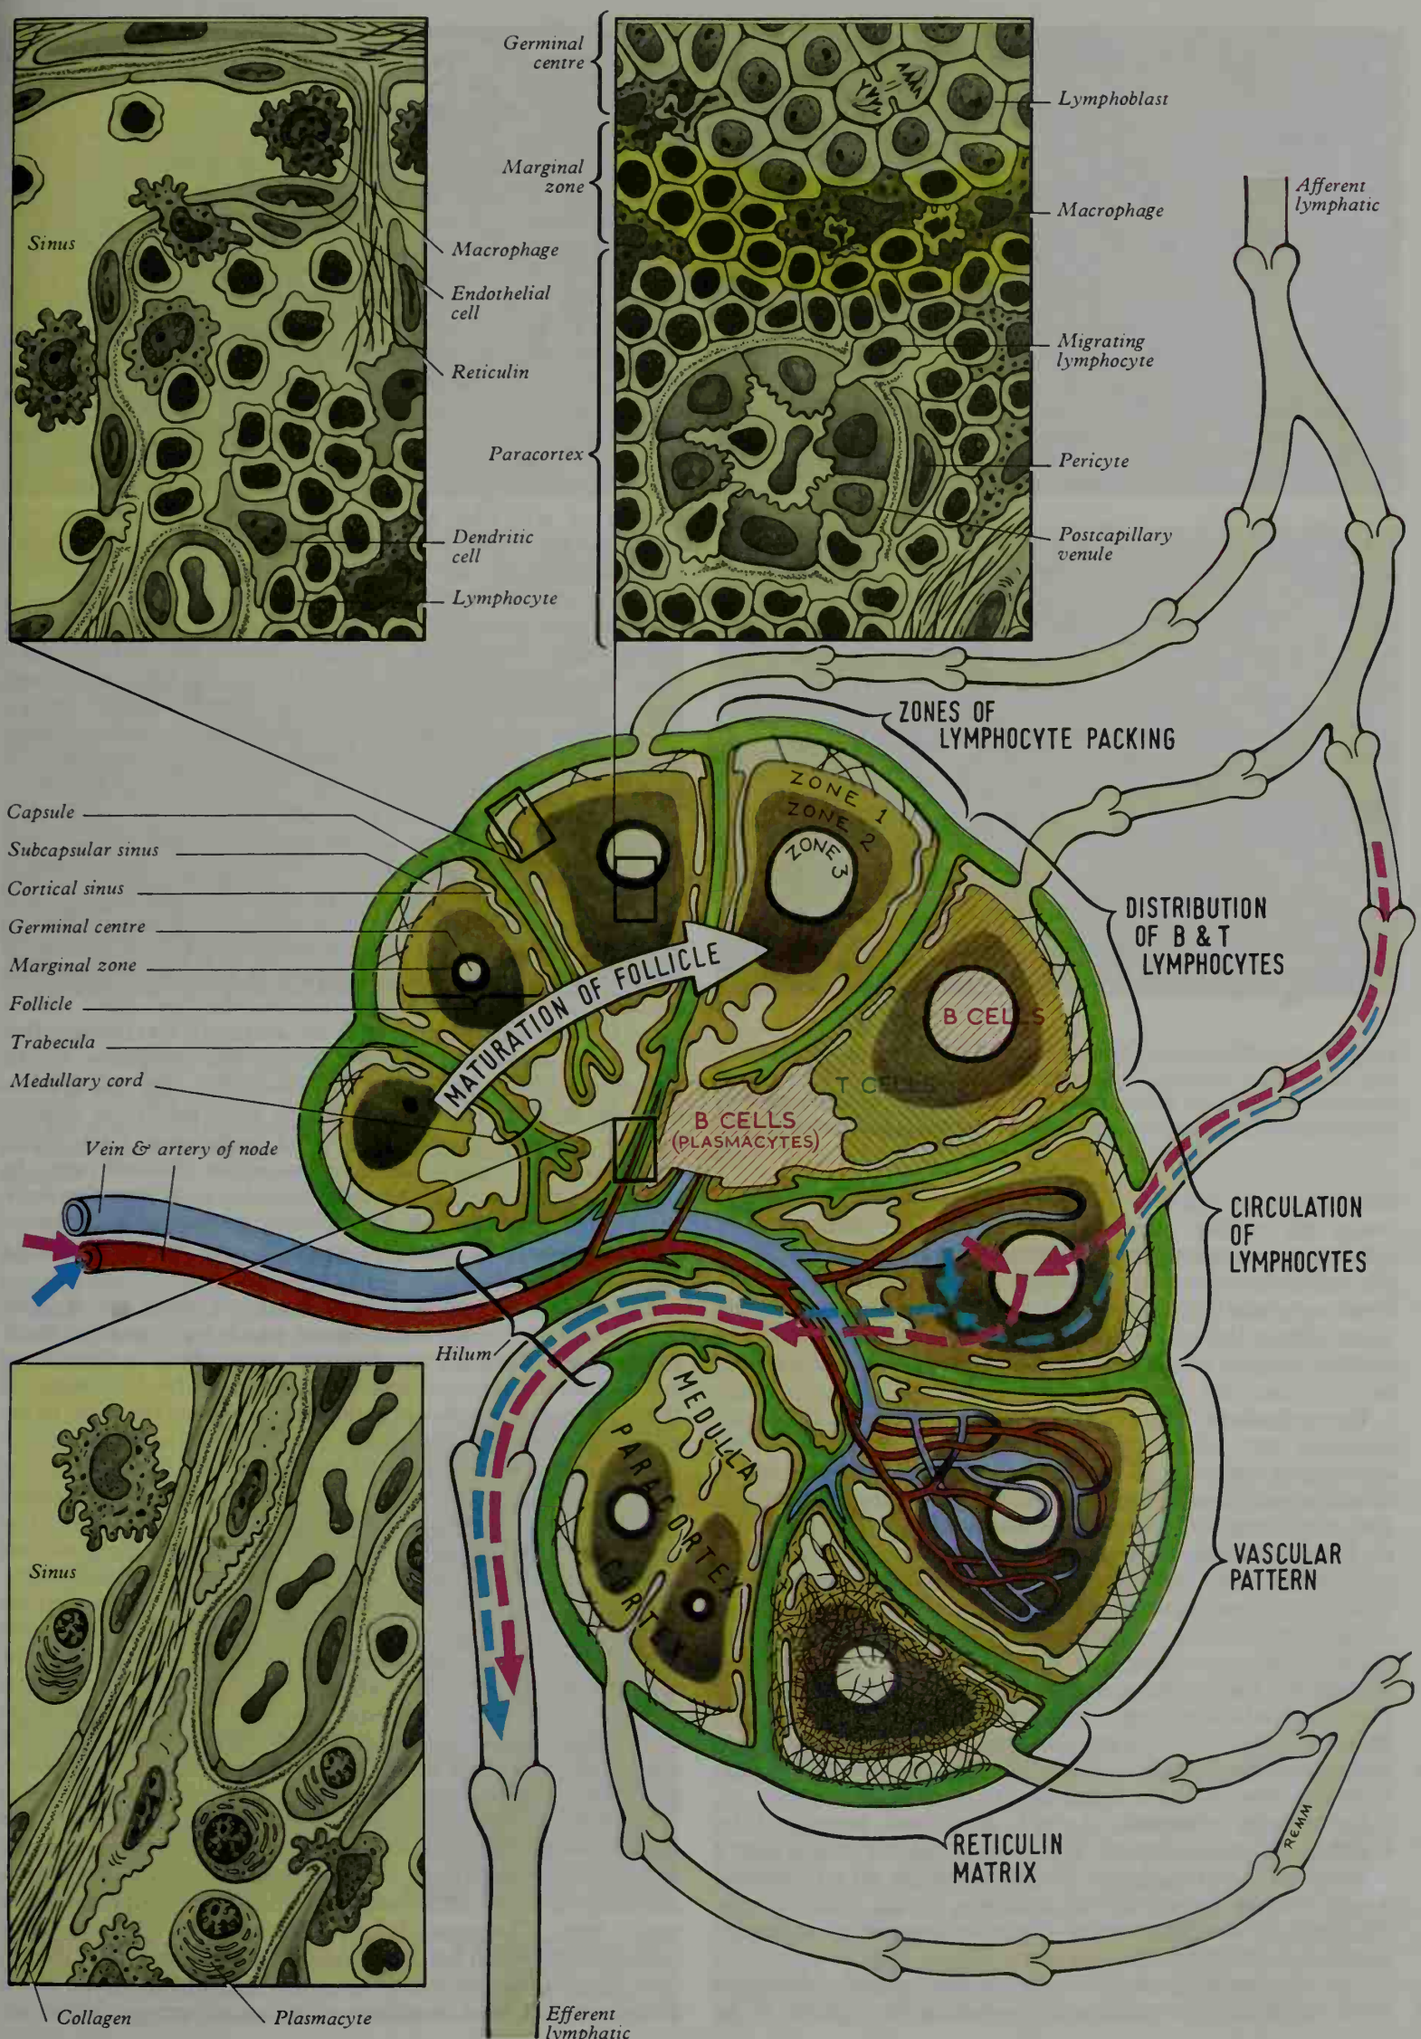
Movement of lymph. Several factors are concerned in propelling lymph from the tissue spaces towards lymph nodes and the venous bloodstream. (*a*) The 'filtration pressure' in the tissue spaces, generated by the filtration of fluid from the blood capillaries. (*b*) Contraction of surrounding muscles compresses the lymph vessels and the lymph moves in the direction determined by the valves; that this is an important factor is shown by the fact that extremely little lymph flows along the lymphatics of a limb that has been rendered immobile, whereas the flow is considerably increased when the limb is moved (actively or

6.142A Diagram of a lymph node. (Modified from Maximow and Bloom.) In part of the diagram, lymphocytes have been omitted to show the reticulum. This diagram from an earlier source has been retained for historical interest. Greater detail and modern concepts have been displayed in **6.142B**.

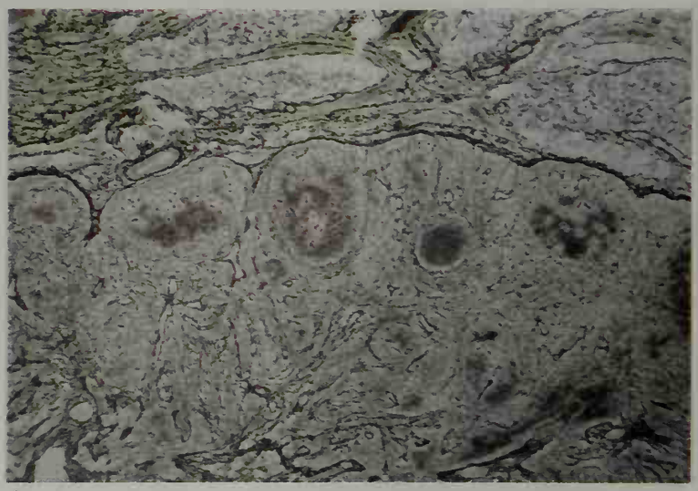
passively). Clinically, immobilization of a limb is used to diminish or prevent dissemination of toxic material from infected tissues. Massage or movement of a part in which there is excess of fluid (oedema) in the tissue spaces promotes the flow of lymph from the affected regions. (*c*) Where a lymph trunk is close to an artery, pulsation of the artery probably compresses the lymphatic vessel and thus assists the lymph flow. (*d*) Respiratory movements and the negative pressure in the brachiocephalic veins are also factors promoting lymph flow. (*e*) The smooth muscle in the walls of the lymphatic trunks is most marked just proximal to the valves; stimulation of sympathetic nerves accompanying the trunks results in contraction of the vessels; the intrinsic muscle of the vessels thus probably aids the flow of lymph. What form of muscle contraction occurs naturally has, however, not been determined. The valves are of considerable importance in determining the direction of the flow of lymph. If, however, the lymph vessels become markedly dilated, the valves may become incompetent and a retrograde flow may occur. This may explain some instances of the retrograde spread of malignant tumours.

Methods of study of lymph vessels. Infected material and malignant growths may be spread from an affected site by the lymph vessels. It is therefore of considerable clinical importance to know the precise lymph pathways from the various regions and organs of the body. Ordinary dissection methods are not suitable for investigating these pathways because, apart from the large terminal collecting lymph ducts, the vessels are very slender and difficult to see. Knowledge of these pathways has been obtained by the following methods. (1) *Experimental.* Injection of substances into the organs or tissues of living or dead animals, including man. In successful experiments, the substances pass into the lymph vessels draining the site and render visible the vessels and the lymph nodes into which they drain. The substances most commonly used are suspensions of India ink, Neoprene latex or Prussian blue. The latter was used by Jamieson and Dobson (1907–20), for their extensive studies of the lymph pathways in man. In living animals methylene blue and radio-opaque substances, such as ultrafluid lipiodol, have been injected; with the latter the lymph vessels are visualized by radiography. Lymphangiography in the human subject after cannulation of appropriate peripheral lymphatic channels and the injection of lipiodol, is now adding considerably to our knowledge of lymphatic channels and is being increasingly used as a diagnostic aid (Kinmonth 1964; Kinmonth and Taylor 1964). (2) *Clinical.* By noting the lymph nodes involved by the spread of inflammatory or malignant disease of an organ or tissue, the lymph path from that site is inferred. However, the phenomenon of retrograde spread of tumour cells after blockage of a lymphatic channel limits the usefulness of such observations when attempting to determine *normal* directions of lymph flow.

LYMPH NODES

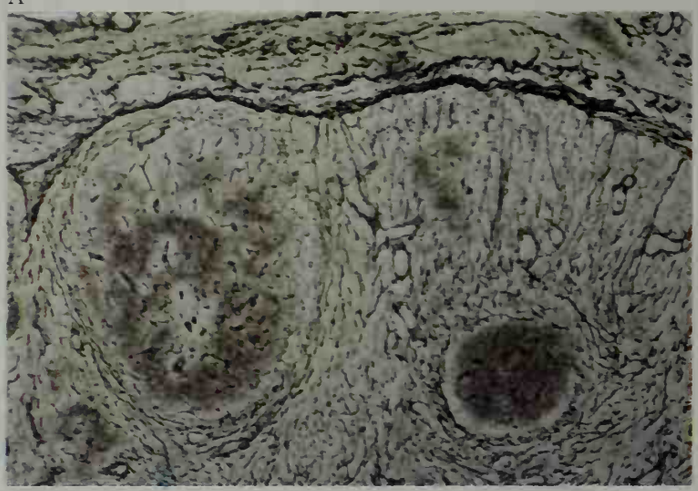


These are small, oval or reniform bodies (0·1–2·5 cm long), situated in the course of lymph vessels so that the lymph passes through them on its way to the blood. Generally each presents on one side a slight depression, termed the *hilum* through which *blood* vessels enter and leave the node. The *efferent lymph vessel* (usually single) also emerges from the node at this spot, while the *afferent vessels* enter it at different parts of the periphery. A lymph node has a highly cellular *cortex* and a darker *medulla* containing numerous cavities, with an indefinite line of demarcation between the two. The cortex does not form a complete investment but is deficient at the hilum, where the medulla reaches the surface of the node; thus the efferent lymph vessel is derived directly from the medulla, while the afferent vessels empty themselves into the cortex. Lymph nodes are most numerous in the thoracic mediastinum, on the posterior abdominal wall, in the abdominal mesenteries, and in the pelvis, neck and proximal ends of the limbs.



STRUCTURE OF LYMPH NODES

A lymph node consists essentially of a continuous framework which includes a capsule, trabecula and reticular fibres, and the cells entangled in this framework (**6.142–144**).



The capsule and trabeculae. The capsule is composed mainly of collagen fibres, a few fibroblasts and some elastin fibres, especially in its deeper layers. In some animals many smooth

muscle cells are found but these are few in man. The capsule covers the outside of the node and from its deep surface, trabeculae of a similar structure extend radially into the interior of the node, where they are continuous with the fine *reticulum* that forms a supporting framework for the lymphoid tissue. At the hilum, dense fibrous tissue may extend some distance into the medulla and the efferent lymphatic vessel is embedded in this before it leaves the node.

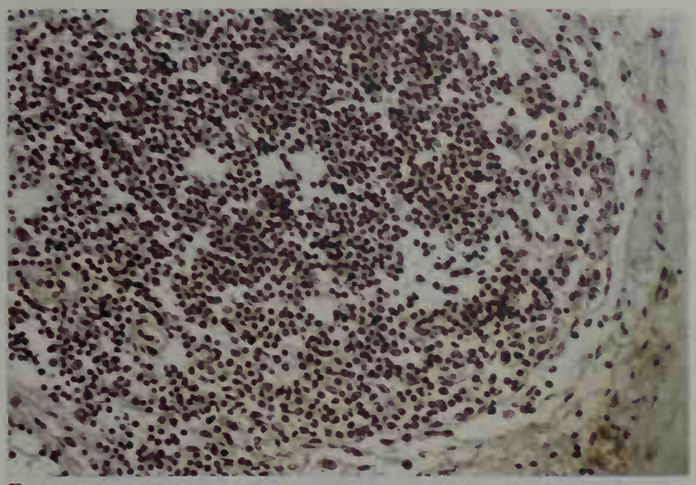
The reticulum. This is a meshwork of fine reticulin fibres and attendant cells which permeates the spaces outlined by the capsule and trabeculae (**6**.142) providing mechanical support for the cell masses lying in their vicinity. The fibres are histologically demonstrable with special reticulin stains (**6**.143) which show that the bundles of fibres branch and interconnect freely, forming a particularly dense network in the cortex, although the germinal centres have fewer fibres than the areas surrounding them. Fibres of this type, clothed with endothelial cells, criss-cross the sinuses of the node, providing attachment sites for various cells, particularly macrophages and lymphocytes, entangled in their mesh. The reticulin fibres together with the glycoprotein matrix associated with them appear to be laid down by cells indistinguishable from fibroblasts, although various names (e.g. 'reticular cells') have been appended to them in the past.

Lymphatic channels. Lymph nodes are permeated by lymphatic channels through which the lymph percolates after it has entered from the afferent lymphatic vessels, an arrangement which ensures the maximum exposure of the lymph to the macrophages and lymphocytes which line them or are entangled between the fibres which cross them.

The afferent vessels enter at different points on the periphery of the node, and after branching and forming a dense plexus in the substance of the capsule, open into the *subcapsular sinus*, a cavity running around the periphery of the cortex except in the region of the hilum (**6**.142). From this space numerous radial *cortical sinuses* lead towards the medulla, eventually coalescing to form the larger *medullary sinuses* which are confluent at the hilum with the efferent lymphatic vessel or vessels draining the node. These spaces are everywhere lined by endothelial cells, although there is a constant passage of lymphocytes, macrophages and other cells, through the sinus walls, in both directions. Numerous trabeculae (*vide supra*) cross the sinuses, converting their lumina into an almost labyrinthine system, and providing widespread attachment areas for the various cell types present in the spaces (Nopajaroonsri *et al.* 1971; Luk *et al.* 1973).

Lymphatic blood system. Arteries and veins serving the interior of lymph nodes enter through the hilum and give off straight branches which traverse the medulla in company with the connective tissue trabeculae, giving off a few minor vessels *en route*. On reaching the cortex, the arteries break up into dense arcades of arterioles and capillaries which form numerous anastomosing loops, eventually to pass back into the highly branched venules and veins. The capillaries are particularly profuse around the periphery of the follicles, with fewer vessels in the germinal centres (Herman *et al.* 1973; Blau 1976); the postcapillary venules are abundant in the paracortical zones where they are an important route of lymphocyte migration (*vide infra*). This pattern of vascularization is considerably altered when nodes undergo antigenic stimulation to produce large numbers of lymphocytes, with consequent alterations in general architecture, and the density of the capillary beds greatly increases (Herman *et al.* 1972).

The structure of these various blood vessels is not unusual except in the case of the *postcapillary venules*, which are lined by tall cuboidal endothelial cells, between which colloidal materials pass quite readily into the perivascular space (Mikata and Niki 1970) and which allow extensive movements of lymphocytes from the bloodstream into the paracortex of the lymph node, and probably also in the reverse direction (Marchesi and Gowans 1964; Gowans and Knight 1964). At one time it was thought that these cells actually migrated through the cytoplasm of the endothelial cells, but in view of subsequent data this appears unlikely, and the lymphocytes would seem merely to migrate through the rather easily dislocated endothelial intercellular junctions—in the usual manner of leucocytes (Schoefl 1972). In addition to the vessels of the nodal medulla, some may also leave the lymph node through its principal trabeculae and general capsule, supplying those structures, and the surrounding connective tissue.



The entangled cells. The majority of these are *B*- and *T-lymphocytes*, though *macrophages* which have become freed from the reticulum are also frequent, particularly in the sinuses and around the germinal centres (*vide infra*). The distribution of the lymphocytes is different in the various parts of the node. In the lymph sinuses are found some free cells which have been swept into the lymph as it circulates through the node. In the cortex the cells are very densely packed and may form more or less isolated masses called *lymphatic follicles* (nodules) (**6**.142–144). The number and the degree of isolation of the follicles vary from time to time according to the prevailing level of antigenic stimulation. The central part of each follicle is composed of cells which are larger, less deeply staining and dividing more rapidly, than those at the periphery. The central areas are called *germinal centres*; the cells are mainly *lymphoblasts* which by their prolific mitotic divisions produce small lymphocytes accumulating initially in the *marginal zones* around the germinal centres. These leave the peripheral parts of the follicles to enter the lymph sinuses, which convey them through the medulla to the efferent lymph vessel at the hilum of the node. In the medulla of the node the lymphocytes are much more loosely packed than they are in the cortex. They constitute irregular branching *medullary cords* between which the reticulum of the medullary lymph sinuses is easily seen. The entangled cells include, in addition, some macrophages which are more numerous in the medulla, plasma cells which often surround individual macrophages, and a few granulocytes. Under conditions of intense antigenic stimulation,

e.g. when the node drains a focus of infection or an immunization site, the whole node increases in size and vascularity and becomes a *reactive node*. The number and size of its germinal centres increases, with a raised rate of lymphopoiesis, the proliferation of macrophages, and the differentiation of numerous plasma cells within the sinuses. (The experimental methods employed, and the theories concerning the cellular origins of lymphocytes, the distinction between B- and T-lymphocytes, and the views concerning their respective roles in the cellular functioning of the lymphocytic system is discussed in some detail on pp. 59–63, in addition to the following pages.)

Cell Zones in Lymph Nodes

Although for many years it was useful to divide the lymph node into medullary and cortical areas, recent studies have indicated the value of further subdivisions. As already mentioned, the cortex is divided into a number of rather indistinct lobules by connective tissue trabeculae passing inwards from the capsule, and within each of these territories lie several *lymphoid follicles* or rounded masses of cells, continuous centrally with the medullary cords. Variations occur in the cell packing and cell types in these divisions (**6.142B**). Nopajaroonsri *et al.* (1971) have suggested that these populations can be divided into three zones. *Zone 1* is a region of loosely packed cells consisting predominantly of small lymphocytes, macrophages and occasional plasma cells, found around the extreme periphery of each follicle and extending into the medullary cords. *Zone 2* is a more densely packed region within zone 1, limited to the cortical and paracortical areas of the node, consisting mainly of small lymphocytes and macrophages. *Zone 3* comprises the germinal centres forming the core of the lymphoid follicles, and they are prominent in antigenically stimulated lymph nodes; cells within these include large lymphoblasts, some undergoing mitosis, together with macrophages. Fibroblasts, reticulin fibres, and other associated cells

A

B

C

of the node, mentioned below, are scattered throughout all zones. It seems likely that these three zones represent, in part at least, a maturational sequence, and that lymphocytes formed by division of cells within the germinal centres (zone 3) pass to the densely packed zone 2, becoming smaller in this process, and finally migrating to the loosely packed zone 1, from which they may pass on through the endothelium into the sinuses. However, this sequence is complicated by the immigration of other cells from the lymphatic and haemal vascular systems, and the precise relation between the cellular architecture and maturational processes are not altogether clear. In any case, although helpful for purposes of description, such purely structural schemes are incomplete without a consideration of the sub-classes of lymphocytes occurring within these zones.

Another type of subdivision is concerned with the distribution of B- and T-lymphocytes in the node, and immunofluorescent staining techniques have demonstrated that these two types of cell occupy quite distinct territories. Immature B-cells have been detected in the outermost parts of the follicles (**6**.142B) whereas T-cells are sited in the region between the germinal centres and the medulla, i.e. the *paracortex* or *thymus-dependent zone*. Mature B-cells (plasma cells) are present mainly in the medullary cords, some also being found at the edges of the follicular masses. This distribution of T-lymphocytes is demonstrated clearly in animals with congenital absence of a thymus; these fail to develop a paracortex. Whether the germinal centres contain T- or B-cells, or both, is arguable as there is some conflicting evidence, and it is also possible that the cytological markers allowing detection of these cells only become effective after the lymphocytes have left the germinal centres.

Non-lymphocytic Cell Types in Lymph Nodes

The nature of the varieties of non-lymphocytic cells, like the names given to them by the many investigators of nodal histology, is a most confused and confusing subject, and it is only quite recently that attempts have been made to characterize these cells using adequate techniques. Following Steinman *et al.* (1974) we can distinguish the following cell varieties: (1) endothelial cells, (2) fibroblasts, (3) macrophages, (4) perivascular cells including pericytes, and (5) 'dendritic cells'. The endothelial cells of the nodal sinuses appear to be similar both in structure and properties to those elsewhere, and, contrary to the older suggestions, do not show any particular phagocytic ability which had prompted such terms as 'endothelial macrophages', 'reticuloendothelial cells', 'reticular cells', or 'littoral cells' by various authors (*see* Nopajaroonsri *et al.* 1971). Fibroblasts (corresponding to the 'reticular cells' of some authors) lay down reticulin and collagen, forming the framework of the node, including its capsule and trabeculae. Macrophages are identifiable as typical of that genre in both structure and behaviour (*see* p. 45). Perivascular cells (pericytes and smooth muscle cells), as elsewhere, surround the larger blood vessels. Another class of cell has recently been identified as a distinct entity, named the 'dendritic' cell because of its irregular outline (Steinman *et al.* 1974); it possesses few organelles, and may possibly represent a precursor for some other cell type. Whether it is similar to the presumed 'reticulum' cell of the earlier literature is uncertain, although the concept of a multipotent stem cell for the various defensive cell lines present in lymph nodes now seems unlikely, since it appears that the various cells are derived separately from stocks differentiating in other ('central') lymphoid tissues.

Circulation of the Lymphocytes

The lymph node, being a peripheral lymphoid organ, is constantly receiving lymphocytes from the vascular system and from the afferent lymphatic supply, and in turn, continually provides lymphocytes to its efferent lymphatic drainage which eventually leads back to the haemal circulation. In fetal life, and to a decreasing extent through postnatal life, these lymphocytes arise from the central lymphoid organs of the bone marrow and thymus where the initial differentiation of B- and T-lymphocytes takes place respectively. The cells then pass in the bloodstream to the lymph nodes and other peripheral lymphoid organs where they may proliferate when suitably stimulated, providing new lymphocytes which may rejoin the circulatory system and move to other peripheral organs, sites of inflammation, and other tissues.

As already mentioned, the lymphocytes migrate from the bloodstream into the lymph node through the postcapillary venules, and may then move to the germinal centres, in the case of B-lymphocytes, or into other regions of the cortex and medulla. Some cells appear to be quite transient visitors, whereas others may remain for considerable periods. Antigenically stimulated B-lymphocytes transform into *plasma cells*, migrating as they do so to the medullary cords and sinuses where they may remain, secreting antibodies into the lymph as it flows by, although some may also pass into the lymphatic channels, and ultimately the haemal circulation.

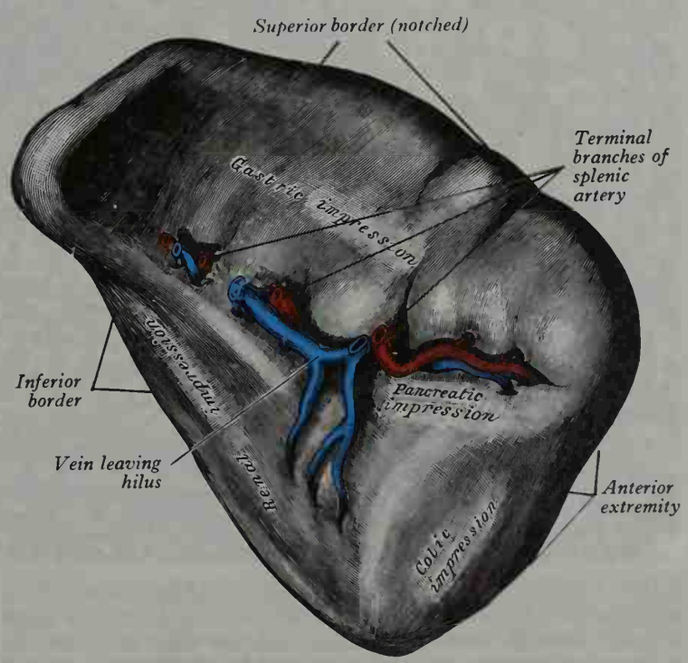
FUNCTIONS OF THE LYMPHOID SYSTEM

Lymph capillaries are primarily concerned with absorption from the tissue spaces. The absorbed material is conveyed to lymph nodes and in its passage through these, particulate matter (e.g. dust material inhaled into the lungs) is to a large extent filtered off by the phagocytic activity of cells in the nodes and prevented from entering the bloodstream. The same applies to bacteria and other micro-organisms in lymph draining from an affected area. Lymph nodes thus have a *protective function* in preventing to a considerable extent the entrance of noxious material from tissues into the bloodstream. Some observers, however, have stressed that the lymphatic system, under certain conditions, operates adversely, providing a pathway along which the *spread* of infection or malignant disease from tissues may occur.

The essential significance of the lymph node includes, therefore: (1) The provision of an intricate network of spaces, of large volume and surface area, through which the lymph percolates slowly. (2) The exposure of any contained foreign material to the phagocytic action of macrophages in the sinuses. (3) The trapping of antigen by the phagocytes. (4) The provision of centres for lymphocyte production and a pool of stem cells potentially capable of transforming into antibody-producing B-lymphocytes and mature T-lymphocytes. (5) The interaction between antigen-laden phagocytes and the lymphoid tissues with the mounting of an immune response both cellular and humoral. (6) A portal of entry of blood-borne lymphocytes back into the lymphatic channels. (7) Humoral antibody production.

As indicated above further details concerning the origins, varieties, and functional roles of lymphocytes are found on pp. 59–63.

Connexions of the lymphatic system with the bloodstream. It is generally believed that the main, if not the only, direct connexions between the lymph vessels and the venous bloodstream are by means of the thoracic duct and the right lymphatic duct with the veins at the root of the neck. Various observers have, however, reported additional connexions with the inferior vena cava, the renal, azygos, suprarenal and iliac veins. As the lymph vessels are very closely associated with veins in their development (**2**.124), such additional connexions would not be surprising, though they may be very variable. In this context, the importance of the post-capillary venules of the lymph nodes should again be stressed (p. 770).



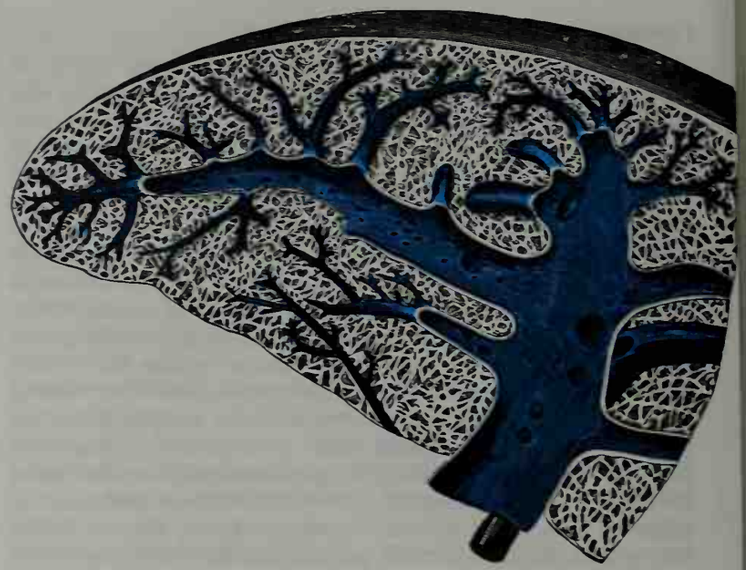
Haemal nodes. In typical lymph nodes, some red blood cells may sometimes be found in the lymph sinuses. In some animals a variable number of small bodies are found, mainly related to the abdominal and thoracic viscera, which are called haemal nodes. In structure they resemble lymph nodes but the sinuses are filled with blood, which gives them a red colour, and they have no afferent or efferent lymph vessels. They appear to be more closely related to the blood-vascular system than to the lymphatic system. Investigations on the haemal nodes of the rat (Turner 1969) show that they possess no afferent, but one large efferent lymphatic vessel. Fast and slow components of the blood circulation are claimed, the former through arterioles, capillaries and venules and the latter through a tortuous sinusoidal system. Specialized post-capillary venules are present as in true lymph nodes. It is suggested that haemal nodes may represent an intermediate stage between a lymph node and the spleen, and phylogenetically, may be a basis from which these have evolved. However, their existence, structure and distribution in man is still uncertain. In some animals, *haemolymph nodes* have been described, with a structure intermediate between lymph nodes and haemal nodes, possessing lymphatic as well as vascular connexions. Some observers maintain that they are stages in the transformation of lymph nodes into haemal nodes, but others are strongly of the opinion that no such intermediary structures exist.

Applied Anatomy. The lymph vessels and lymph nodes draining any infected area of the body are very liable to become inflamed, resulting in acute or chronic lymphangitis and lymphadenitis. Chronic lymphangitis, together with the blocking of numerous lymphatic vessels by the escaped ova of the minute parasitic worm, *Microfilaris nocturna*, is the cause of elephantiasis, a condition common in the tropics and subtropics, and characterized by enormous enlargement and thickening of the skin of some parts of the body, most frequently of the leg and scrotum. Blockage of lymphatic vessels may also occur as a result of extensive spread of malignant disease or widespread removal of lymphatic glands.

The present view is that cancer spreads both by minute emboli and by permeating the lymph vessels as a solid cell growth. Operations for the removal of cancer are therefore planned to take away *in one mass* the cancer, the intervening lymph vessels, and the lymph nodes. In this connexion it is important to note that the lymph vessels from a given region may drain *directly*, not to neighbouring lymph nodes, but to nodes quite far removed, thus rendering operative removal of the primary site, the intervening vessels and the nodes extremely difficult, if not impracticable.

The Spleen

The spleen (**6**.145–149) is situated for the most part in the left hypochondriac region of the abdomen, but its posterior edge extends into the epigastric region; it lies between the fundus of the



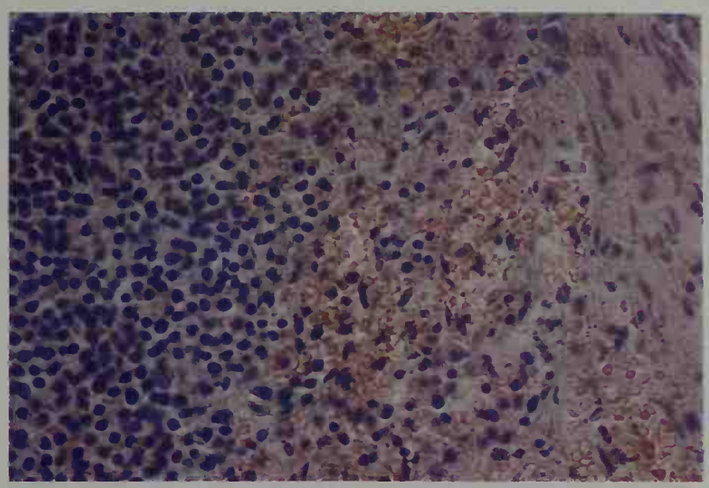
6.145 The visceral surface of the spleen.

stomach and the diaphragm. It varies in shape, according to the size of the colic impression, from that of a slightly curved wedge (if the colic impression is small) to a tetrahedron (if the colic impression is large). Its long axis lies in the line of the tenth rib, its posterior extremity being about 3·5 to 4·0 cm from the mid-dorsal line opposite the spine of the tenth thoracic vertebra, and its anterior extremity reaching as far as the mid-axillary line. It is soft, of very friable consistence, highly vascular, and of a dark purplish colour.

Relations. It presents diaphragmatic and visceral surfaces, upper and lower borders, anterior and posterior extremities. The *diaphragmatic surface* is convex, smooth and faces upwards, backwards and to the left, except at its posterior edge, where it faces slightly medially. It is in relation with the abdominal surface of the diaphragm, which separates it from the lowest parts of the left lung and pleura and the ninth, tenth and eleventh ribs of the left side. The costodiaphragmatic recess of the pleura extends down as far as the inferior border of the spleen.

The *visceral surface* (**6**.145) is directed towards the abdominal cavity, and presents gastric, renal, pancreatic and colic impressions.

The *gastric impression*, directed forwards, upwards and medially, is broad and concave. It is in contact with the posterior



6.146 A transverse section through the spleen, showing the trabecular tissue and the splenic vein and its tributaries. From the first edition of *Gray's Anatomy* (1858).

6.147 A scheme of the main features of splenic structure—the various elements are not drawn to scale, to enable representation on a single diagram. Note the capsule, trabeculae, reticular fibres and cells, the perivascular lymphatic aggregations (white pulp), the ellipsoids, and cell cords and venous sinusoids of the red pulp. The 'open' and 'closed' theories of splenic circulation are illustrated. The venous sinusoids are shown in two states (*a*) with their lining of 'stave' cells (bright blue) in close apposition, and (*b*) with intercellular gaps—these have been over-emphasized for clarity. Consult text for further details.

wall of the stomach, from which it is separated by a recess of the greater sac of the peritoneum. It presents near its lower limit a long fissure, termed the *hilum*. This is pierced by several irregular apertures for the entrance and exit of vessels and nerves.

The *renal impression*, which is very slightly concave, is placed on the lower part of the visceral surface and is separated from the gastric impression above by a raised margin. It is directed medially, downwards and a little backwards, and is related to the upper and lateral part of the anterior surface of the left kidney and, sometimes, to the upper pole of the left suprarenal gland.

The *colic impression* is placed at the lateral extremity of the spleen and is usually flattened. It is related to the left colic flexure and phrenicocolic ligament (**8**.111).

The *pancreatic impression*, when present, is small and is placed between the colic impression and the lateral part of the hilum. It is directly related to the tail of the pancreas which lies in the lienorenal ligament (**8**.111).

The *superior border* separates the diaphragmatic surface from the gastric impression. It is usually convex upwards and is marked, near its lateral end, by one or two notches of variable depth. The notches indicate the lobulated character of the spleen in early fetal life (p. 207). The *inferior border* separates the renal impression from the diaphragmatic surface and lies between the diaphragm and the upper part of the lateral border of the left kidney. It is blunter and more rounded than the superior border and corresponds to the lower margin of the eleventh rib.

The *posterior extremity* of the spleen is blunt and rounded in most cases. It is directed towards the vertebral column. The *anterior extremity* is more expanded, and commonly takes the form of a margin connecting the lateral ends of the upper and lower borders. It is related to the left colic flexure and to the phrenicocolic ligament.

The spleen is almost entirely surrounded by peritoneum, which is firmly adherent to its capsule. Recesses of the greater sac intervene between the spleen and the stomach, and between the spleen and the left kidney. It develops in the upper part of the dorsal mesogastrium (p. 205) and remains connected with the stomach and the posterior abdominal wall by two folds of peritoneum. One, termed the *lienorenal ligament*, is derived from the peritoneum where the wall of the general peritoneal cavity comes into contact with the omental bursa between the left kidney and spleen; the splenic vessels pass between its two layers (**8**.99A). The other fold, termed the *gastrosplenic ligament*, also consists of two layers, and is formed by the meeting of the walls of the greater sac and omental bursa between the spleen and stomach (**8**.99A); the short gastric and left gastro-epiploic branches of the splenic artery run between its two layers. The lateral part of the lateral end of the spleen is in contact with the phrenicocolic ligament.

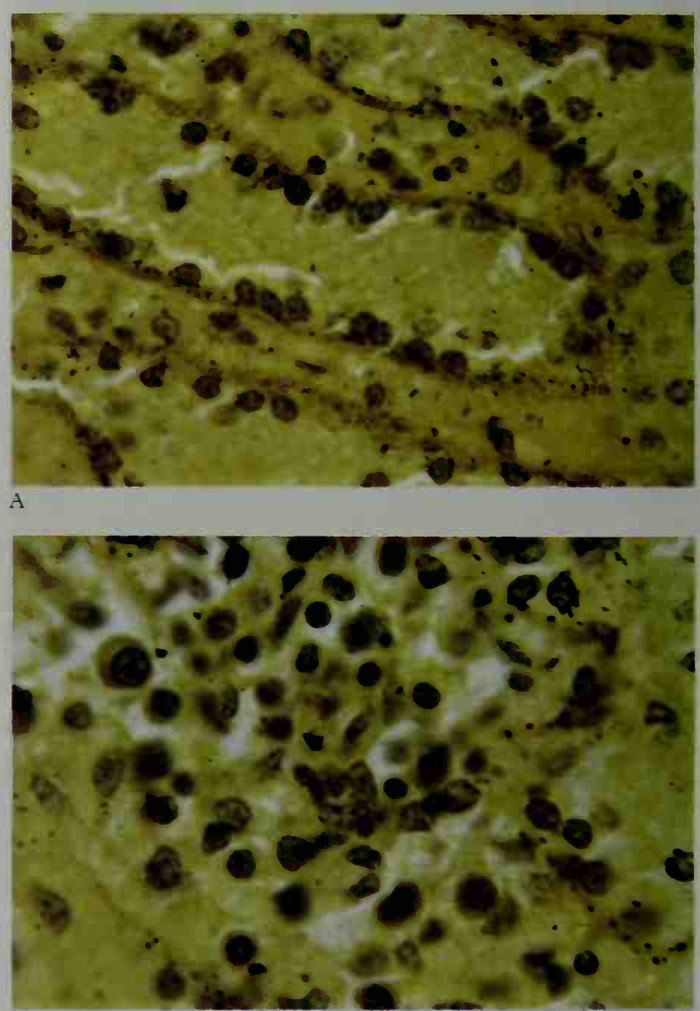
The *size and weight* of the spleen vary at different periods of life, in different individuals, and in the same individual under different conditions. *In the adult* it is usually about 12 cm in length, 7 cm in breadth, and 3 or 4 cm in thickness, but it tends to diminish in size and weight with advancing age. Its average weight in the adult is about 150 gm, though it may range between 80 and 300 gm, largely according to the amount of blood it contains.

The size of the spleen slowly increases during digestion, and

varies according to the state of nutrition of the body, being large in highly fed, and small in starved animals.

Frequently in the neighbourhood of the spleen, and especially in the gastrosplenic ligament and greater omentum, small encapsulated nodules of splenic tissue may be found, either isolated or connected to the spleen by thin bands of splenic tissue. They are known as *accessory spleens* or *spleniculi*, and they may be very numerous and widely scattered in the abdomen. The spleen may retain its fetal lobulated form, or there may be deep notches on the diaphragmatic surface and inferior border, in addition to those usually present on the superior border.

Surface Anatomy. The position of the spleen in the living can be determined by percussion. The dull area extends over the ninth, tenth and eleventh ribs in vertical extent and should not extend forwards further than the mid-axillary line. The normal spleen is not palpable.

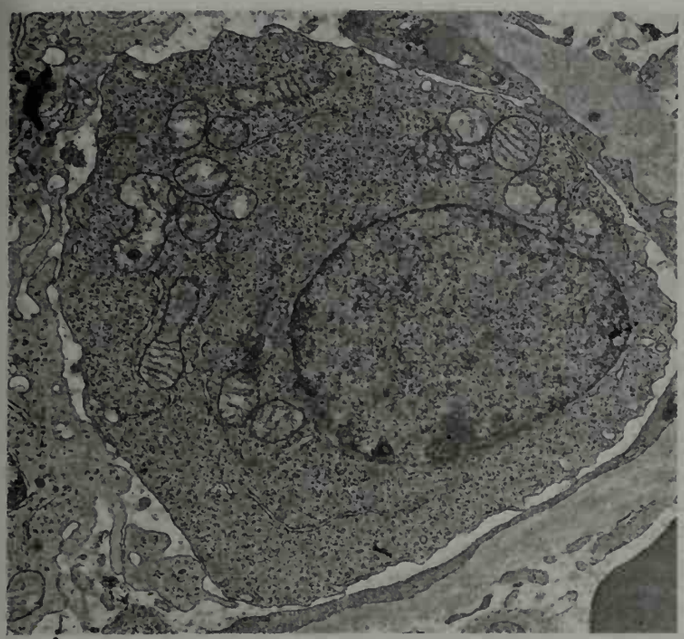


Structure (**6**.146–149). The spleen is invested by two coats: an external serous and an internal fibro-elastic coat.

The *external*, or *serous*, *coat* is formed by the peritoneum; it is thin, smooth, and in the human subject intimately adherent to the fibro-elastic coat. It invests the entire organ, except at the hilum and along the lines of reflection of the lienorenal and gastrosplenic ligaments.

The *fibro-elastic coat*, or *capsule*, invests the organ and from it *trabeculae* pass into the spleen and branch to form a network which constitutes the framework of the spleen (**6**.146). The largest trabeculae pass in from the hilum and ensheath the splenic vessels, which divide into branches that run in the subdivisions of the trabeculae (**6**.147, 148). The capsule and trabeculae consist of collagenous white fibrous tissue and yellow elastic fibres, the latter being more numerous in the trabeculae. In many mammals the capsule and trabeculae contain many non-striated muscle cells and the rhythmical contraction of the spleen is attributed to these. In man, few muscle cells are present in the capsule and trabeculae, and contraction and distension of the spleen are attributed to constriction or relaxation of the blood vessels (**6**.147) with consequent alteration in the amount of blood in the organ. Increase in the blood content distends the spleen and stretches the elastic fibres in the capsule and trabeculae; contraction of the spleen is due to the recoil of these fibres.

The subdivisions of the trabeculae are continuous with a fine reticulum which pervades the remainder of the organ. Electron microscopy reveals that the reticulum consists of dense amorphous matrix, probably mainly proteoglycan in nature, with only occasional fine collagen fibres. Closely associated with the reticulum are reticular cells, or fibroblasts, into which strands of the matrix may be invaginated, and macrophages. The interstices of the reticulum are occupied by the *splenic pulp*, of which there are two kinds, *red pulp* and *white pulp*, which are both related to the blood vessels permeating the spleen. The reticulum is particularly dense around the borders of the white pulp where it constitutes a *marginal zone*.



Circulation of blood inside the spleen. (*See:* Knisely 1936; MacKenzie *et al.* 1941; Snook 1950; Peck and Hoerr 1951; Lewis 1957; Wennberg and Weiss 1969, and Li-Tsun Chen and Weiss 1972, 1973.) The large, tortuous splenic artery, before it reaches the spleen, divides in the lienorenal ligament into five or more branches which enter the hilum of the organ and ramify throughout its substance in the trabeculae. The splenic vein is formed in the lienorenal ligament by the junction of five or more tributaries which emerge from the hilum. Small arteriolar branches of the splenic arteries leave the trabeculae, and their adventitial coat becomes replaced by a *periarteriolar sheath* of lymphatic tissue which accompanies the vessels and their branches almost as far as their division into capillaries (**6**.147, 148). These lymphatic sheaths constitute the *white pulp* of the spleen, and here and there the sheaths are enlarged containing rounded masses of lymphocytes, the *splenic lymphatic follicles* (Malpighian bodies), which vary in diameter from 0·25 mm to 1 mm and are visible to the naked eye on the freshly cut surface of the organ as whitish semi-opaque dots contrasting with the dark red colour of the surrounding tissue, which constitutes the *red pulp* of the spleen. These lymphatic or lymphoid follicles are centres of lymphocyte production and when antigenically stimulated, show germinal centres similar to those of lymph node follicles. The follicles atrophy with increasing age and may be absent in old age. The arterioles usually occupy an eccentric position in the follicles and give off fine side branches to supply the follicles. Before the arterioles finally lose their sheaths of lymphatic tissue and enter the surrounding red pulp, they divide into a number of straight vessels termed *penicilli*. After running a course of about 0·5 mm, entering or penetrating through the marginal zone around the white pulp, each of these vessels develops a slight thickening of its coat known as an *ellipsoid* or *sheath of Schweigger-Seidel*, which is formed by an aggregation of macrophages and fibroblastic (reticular) cells, and the lumen of the vessel is considerably narrowed. The ellipsoids are well developed in some mammals, e.g. pig, cat and dog, but are only feebly developed in man. Beyond the ellipsoids each vessel continues as a capillary-like arteriole, or may divide into two vessels, but thereafter its precise course is somewhat uncertain, although it is known that the blood passes into the red pulp and eventually drains into the veins of the spleen. The red pulp, in man (as in rabbit) consists of numerous *venous sinusoids* which are large and complex cavities containing blood, separated by areas of tissue rich in macrophages attached to the reticulum of the spleen (reticulin fibres and fibroblasts), termed *splenic cords* or *cords of Billroth*.

The splenic venous sinusoids are lined by flattened, greatly elongated endothelial cells often called *stave cells* because of their shape, reminiscent of the planks of a barrel; when the sinusoids are inflated by a rise in internal pressure (as, for example, during perfusion in preparation for routine electron microscopy), numerous gaps appear between the stave cells which allow blood to pass in and out of the surrounding splenic cords. It should be noted, however, that the dimensions and dynamic state of such intercellular crevices in the *in vivo* condition remain conjectural. The luminal surfaces of the endothelial cells are uneven and beset with protrusions and the cells are moderately phagocytic; they are supported externally by strands of, in the main, circularly arranged reticulum. Further ultrastructural details of the red pulp of the human spleen (Chen and Weiss 1972), and experimental results after modification of rats' splenic vasculature with phenylhydrazine (Chen and Weiss 1973) have been added. The fine architecture of the predominantly circumferential ('ring') and occasional longitudinal fibrillary components of the surrounding basal lamina of the reticulum were analysed, together with details of the neighbouring stave cell cytoplasm. The endothelial (stave) cells of the venous sinusoids possessed three distinctive structural features. Numerous pinocytotic vesicles about 0·1 μm in diameter were present beneath the plasma membrane on both luminal and basal aspects of the cell. Loosely organized filaments some 7–8 nm in diameter coursed longitudinally through the cell, whilst bands of finer filaments about 3–5 nm in diameter arched through the basal cytoplasm. The latter filaments appeared to attach to the cell membrane at points adjacent to the fibrillary ring component of the reticular basal lamina, and were possibly in structural continuity with the rings. It was proposed that the filaments dynamically maintained the shape of the stave cells, stabilized the relation of the cells to their basal lamina, and controlled the dimensions of the intercellular crevices—thereby also controlling cellular passage through the crevices.

The splenic cords are areas of intense phagocytic activity because of their numerous macrophages, and also contain innumerable lymphocytes derived from the white pulp and elsewhere. The term 'cord' is perhaps misleading, since these areas of perivascular tissue form a continuous network throughout the spleen, and have numerous cavities between the indigenous cells through which blood can pass. In some animals, including mouse and cat, there do not appear to be any sinusoids, and so the majority of the red pulp is formed by splenic cord tissue.

The passage of blood from the penicillar arterioles to the veins of the trabeculae has been a subject of much controversy, stemming from the variations in techniques of observation and species of animal studied. According to the 'open' theory of splenic circulation, blood passes from the arterioles directly into the splenic cord tissue, eventually collecting in the venous sinusoids to enter the veins. In the 'closed' theory, the blood passes from the arterioles directly into the venous sinusoids and does not at any point enter the extravascular tissue of the cords. Electron microscope studies do not appear yet to have settled this issue unequivocally, but in observations of spleens in living animals, blood appears to flow directly from the arteries into the sinusoids, then to escape through their walls into the surrounding cordal tissue, where it can certainly be demonstrated by electron microscopic and other methods. It appears probable that the flow of blood through these routes depends on the local control of blood flow by the intermittent opening and closing of the blood vessels at either end by perivascular smooth muscle contraction, which allows the tidal flow of blood between sinusoids and the spaces outside them, but this has yet to be demonstrated unambiguously. However, in those animals which apparently lack sinusoids, there must be some other type of circulation, presumably of the 'open' type.

After entering the venous tributaries which pass along the trabeculae towards the hilum, the blood eventually flows into the main splenic vessels.

FUNCTIONS OF THE SPLEEN

These are essentially phagocytosis, cytopoiesis, erythrocyte storage, and the mounting of immune responses.

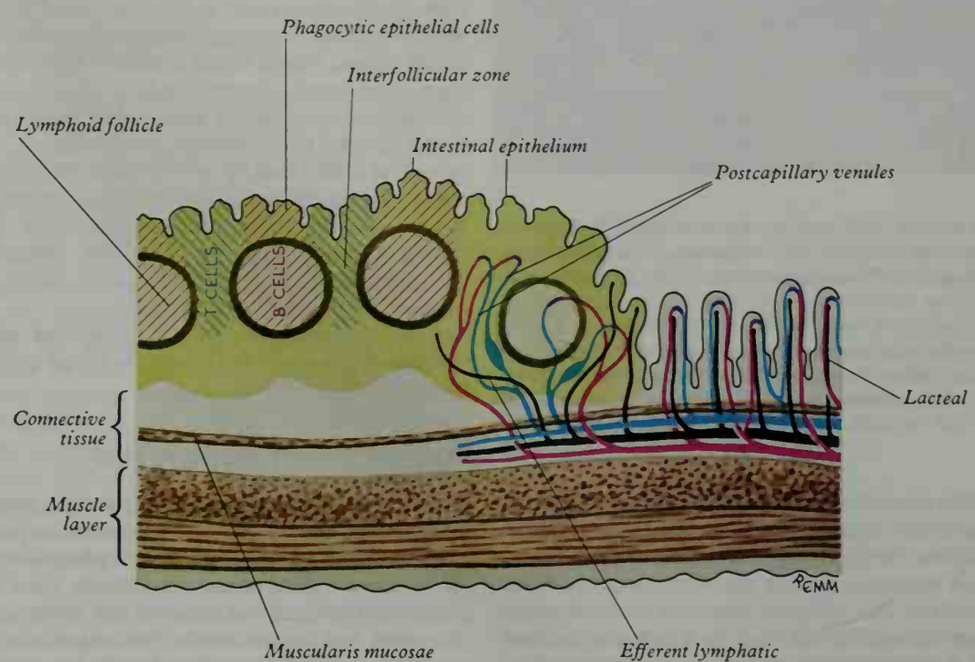
Phagocytosis. The splenic macrophages form an important part of the mononuclear phagocyte system. They consist of the macrophages of the marginal zones of the white pulp, and those of the ellipsoids and splenic cords. Particulate matter such as carbon is also taken up to some extent by the stave cells lining the venous sinusoids and some authorities have considered these cells to be part of the macrophage system. However, since all endothelial cells have a minor ability to phagocytose particles, the stave cells do not appear to warrant separate classification, and certainly

have various features which indicate that they are not true macrophages.

The phagocytes remove cell débris and the products of effete erythrocytes, leucocytes, platelets, and micro-organisms from the circulating blood. It is especially important in the processing of aging or damaged red cells, and all stages of erythrophagocytosis, from disintegrating erythrocytes to granules of haemosiderin, may occur in the cytoplasm of the splenic macrophages. Ultimately, bilirubin is produced, which is conveyed to the liver for excretion, and the iron is largely re-used by the bone marrow in the production of further erythrocytes. As in the other peripheral lymphoid organs, the spleen is important in the phagocytosis of circulating antigens and in the initiation of humoral and cellular immune responses.

Lymphocyte activities. Various studies have shown that T- and B-lymphocytes are sited in different parts of the white pulp, the periarteriolar layers of cells being mainly T-lymphocytes and the follicles, with their germinal centres, being B-lymphocytes. Cells from these regions can migrate into the splenic cord tissue and other areas of the spleen, to perform their various characteristic functions. Some of the B-lymphocytes transform into plasma cells which secrete antibodies into the fluid-filled cavities, when suitably stimulated, and the T-lymphocytes carry out cytotoxic killing of infected circulating cells, or cooperating with the B-cells in complex immune reactions. Lymphocytes are also provided for the general defence of the body, some passing into the haemal circulation via the venous sinusoids, but the great majority apparently moving into the lymphatic drainage to rejoin the blood system indirectly.

Cytopoiesis. In the human fetus, from the fourth month onwards, the spleen is an important *haemopoietic* organ and the red pulp contains groups of myelocytes, erythroblasts and megakaryocytes. In some anaemias and myeloid leukaemia in post-natal life, as yet unidentified cell types in the red pulp may revert to a haemopoietic function.



In the mature spleen, lymphopoiesis in the white pulp contributes to the circulating pool of immunologically competent lymphocytes and it also contributes to the large mononuclear cell population of the blood and connective tissue. (*See* p. 45.)

Immune response. Under conditions of adequate antigenic stimulation there is a proliferation of splenic macrophages, increased lymphopoiesis and an increased growth and differentiation of antibody-producing plasma cells. (See also pp. 59–63, and above.) In individuals who have suffered many episodes of a blood-borne infection, for example malaria, the splenic tissues may be permanently hypertrophied and the spleen greatly enlarged (*splenomegaly*).

Erythrocyte storage. The storage mechanism involves the separation of erythrocytes from plasma, but the site of separation and storage is uncertain; according to the 'closed' theory of splenic circulation it is in the venous sinusoids, the filling and emptying of which are controlled by sphincters at each end of the sinusoids, whereas according to the 'open' theory it is in the reticular meshes of the red pulp. In states of emergency, especially those associated with anoxia, the erythrocytes are discharged into the circulation, thus increasing the oxygen-carrying capacity of the blood. In most mammals, the discharge is due to contraction of the unstriped muscle in the capsule and trabeculae under the influence of the sympathetic nervous system and adrenalin; in man it is due to recoil of the stretched elastic fibres of the distended spleen, though the blood storage and discharge function of the human spleen is not nearly so marked as in other species.

Splenic Vascular Segmentation

There is evidence (Dreyer and Budtz-Olson 1952) that the spleen in man and other animals consists of separate 'segments' or 'compartments', each supplied by one of the hilar branches of the splenic artery and drained by one of the hilar tributaries of the splenic vein (Braithwaite and Adams 1957). Adjacent compartments, it has been claimed, are connected by an intersegmental vein so that if one compartment becomes congested with blood, excess blood can pass by these channels to adjacent compartments (but *vide infra*). It is suggested that the splenic segments may act in normal circumstances as separate units when the blood flow to them is not excessive. (For a review of the relevant literature on splenic vascular segmentation since its first proposal over a century ago by Kyber 1870, consult Gupta *et al.* 1976.) The latter authors studied corrosion casts of 50 adult human spleens. In 42 specimens (84 per cent), only two segments (superior and inferior) were present; in 8 specimens (16 per cent), three segments (superior, intermediate, and inferior) were demonstrated. There was no apparent anastomosis between adjacent segments. A comparable segmental arrangement of the splenic veins was claimed by Fuld and Irwin (1954). This finding of only two or three segments (arterial or venous) was supported

6.150 A diagram of the organization of an epitheliolymphoid complex in the wall of the small intestine (a Peyer's patch), showing the distribution of B-lymphocytes associated with the follicles and T-lymphocytes in the interfollicular zones; the arrangement of the vascular supply of the lymphoid tissue is also shown (right).

by a number of the investigators quoted by Gupta *et al.* However, it should be noted that this does not accord with the usual description of the splenic artery breaking up into five or more major branches in the lienorenal ligament before entering the splenic hilum: no explanation of this discrepancy is advanced by the authors. (Braithwaite and Adams described 5 to 7 vascular splenic segments in the rat.) Clearly, further investigations are necessary.

The effects of splenectomy. Partial removal of the spleen is followed by rapid regeneration of the lost tissue, but even total splenectomy has few serious effects, as its functions can be carried out fairly effectively by the remaining reticulo-endothelial organs. However, splenectomy, particularly in the early years of life, may be accompanied by a general reduction in the rate of mounting an immune response and consequently an increased susceptibility to infection. Splenectomy in later life is soon attended by a leucocytosis with increased lymphocyte, neutrophil, eosinophil and platelet counts in the peripheral blood. This has been interpreted as the result of removal of humoral factors produced by the spleen which oppose the formation and release of cells from the haemopoietic tissues. These effects gradually disappear over the course of a few weeks.

The *lymphatic vessels* of the spleen, once thought to be an insignificant component merely draining the capsule and thickest trabeculae, has recently been shown (in at least some species) to be an important feature of *all* parts of the tissue. Extensive blind-ending (efferent) lymphatic vessels are present in the white pulp, running in tortuous fashion alongside the arterioles and arteries, the flow of lymph being counter to that of the arterial blood. The lymphatic vessels eventually emerge at the hilum. No afferent lymphatic vessels are present. This lymphatic pathway is a drainage area for fluid infiltrating the white pulp, and also provides a major route for lymphocytes to pass from the spleen into the general circulation, in a manner similar to that of lymph nodes (*see* Weiss 1979).

The *nerves* are derived from the coeliac plexus and are chiefly nonmyelinated. In man their distribution is confined mainly to the branches of the splenic arteries; in other mammals they also supply the non-striated muscle in the capsule and trabeculae.

Applied Anatomy. Enlargement of the spleen, or *splenomegaly*, may accompany a variety of conditions, e.g. increased phagocytosis in certain generalized infections, either bacterial or viral; in conditions of increased erythrocyte breakdown, and in various lipoidoses. Any circumstance leading to a massive immune response may be accompanied by enlargement of the spleen, which is also a characteristic of many of the reticuloses. A full review of the causes of splenomegaly is outside the scope of this volume, but the general features of the enlarging spleen will be considered. It is the anterior extremity, the anterior part of the diaphragmatic surface and the notched superior border that become palpable below the left costal margin; the notches become exaggerated and may be easily palpable. The left part of the transverse colon and the left colic flexure are displaced downwards, so that there is no area of colonic resonance on percussion over the enlarged organ; this is in contrast to a retroperitoneal tumour (e.g. of the kidney) which does not displace the gut and in which, therefore, an area of colonic resonance may sometimes be elicited on percussion over the palpable tumour. There is no anastomosis between the smaller branches of the splenic arteries, so that obstruction leads to infarction of the spleen. In surgical removal of the spleen, damage to the tail of the pancreas must be avoided when ligating the splenic vessels near the hilum.

Gut-Associated Lymphoid Tissue

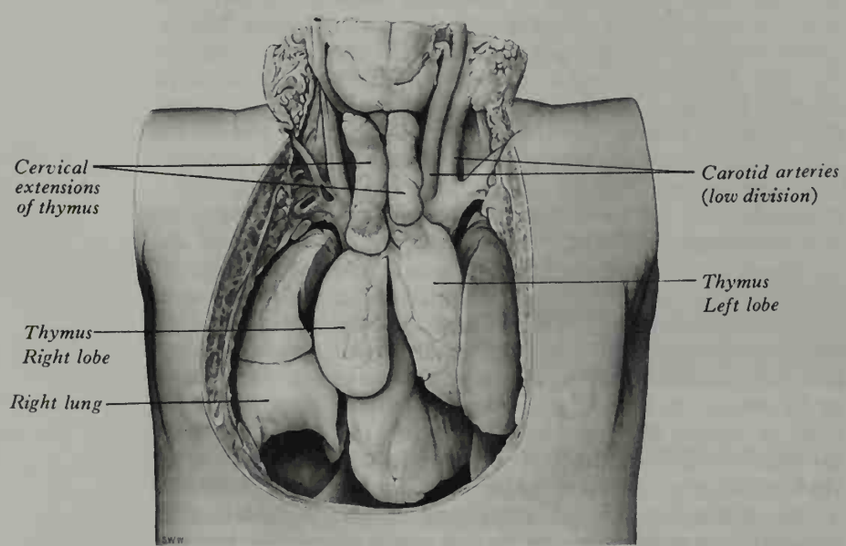
In addition to the encapsulated peripheral lymphoid organs of the lymph nodes and spleen, there are large amounts of unencapsulated lymphoid tissue, the *lymphoid nodules* in the walls of the alimentary and respiratory tracts, termed collectively the *epithelio-lymphoid* or *gut-associated lymphoid tissue*. These are located chiefly in the lamina propria just beneath the adjacent epithelium, although when active, they may extend into deeper layers, e.g. the submucosa of the intestine, and their cells may also be disseminated diffusely throughout the neighbouring tissues. Such nodules include the pharyngeal, tubal, palatine, and lingual tonsils, various nodules in the wall of the oesophagus, the large groups in the small intestine (Peyer's patches) and vermiform appendix, smaller aggregates in the colon and rectum, and nodules in the trachea and bronchial tree.

The precise form of the nodules depends on their location, but in all sites it is possible to distinguish numerous rounded follicles similar to those of lymph nodes, which develop noticeable germinal centres when antigenically stimulated (*see*, for example, Anderson 1977). Between the follicles (**6**.150) lie wedge-shaped masses of somewhat less closely packed (parafollicular) lymphocytes. The whole mass of cells, together with numerous macrophages, is supported by a fine meshwork of reticulin fibres with their associated fibroblasts, and occasional coarser connective tissue trabeculae in some of the larger nodules, such as those of the pharyngeal tonsil. The adjacent epithelium of the gut covers the luminal surface of the tissue and in most places gives off glandular or other diverticula which penetrate into the lymphocyte aggregate. In some areas (e.g. the palatine tonsils) such crypts may become loci of infection leading to a general inflammatory response of the whole surrounding area. In many sites, dome-like areas of specialized epithelium cover the lymphoid nodule (*vide infra*). The vascular pathways consist of blood vessels branching from the surrounding connective tissue to supply the follicles with a capillary plexus which drains into post-capillary venules possessing cuboidal endothelial cells similar to those of lymph nodes, and which allow the frequent migration of lymphocytes to and from the bloodstream into the nodules. The lymphatic vessels associated with lymph nodes are exclusively efferent, draining into the general network of lymphatic channels serving the organ in which they are embedded.

Immunofluorescence studies have shown that the B- and T-lymphocytes of lymphoid nodules are segregated, again in a manner resembling the lymph node, the follicles being composed of B-lymphocytes and the parafollicular areas of T-lymphocytes. These cells can migrate either into the lymphatic drainage and so rejoin the hemal circulation, or may migrate out into the adjacent tissues, including the intercellular spaces of the neighbouring epithelia. In the case of non-stratified epithelia, they may eventually pass into the lumen of the alimentary or respiratory tract. In the lamina propria of these tracts migrating B-lymphocytes are often seen to have transformed into plasma cells (**6**.150).

FUNCTIONS OF LYMPHOID NODULES

There has been much speculation about the precise role of these structures in the total lymphoid system of the body. This interest has, in part, stemmed from the condition in birds in which the B-lymphocytes differentiate in lymphoid tissue in the wall of a hind-gut diverticulum, the *bursa of Fabricius*, suggesting that the lymphoid tissues of the gut in mammals may have a similar function. However, various experiments have so far failed to support this idea, and it seems more likely that these regions provide areas in which B- and T-lymphocytes can proliferate and act as reservoirs of defensive cells which can infiltrate the surrounding tissues providing local defences. The B-lymphocytes are particularly important in the synthesis of secretory antibodies of the IgA class which are present in the secretions of the alimentary tract. These antibodies are secreted first by plasma cells in the lamina propria and intercellular spaces of the unicellular epithelia and sub-epithelial glands. The latter are of considerable importance where the general epithelial lining is of stratified squamous type. The antibodies appear to be taken up by certain varieties of glandular cell (although not by goblet cells, at least in the gut) and then modified by the addition of carbohydrate to form the final secretory IgA (sometimes termed sIgA) which is secreted into the lumen of the gut or bronchial tree. These antibodies are of great importance in eliminating pathogenic organisms in the various tracts in which they are found, although other types of antibody (IgM and IgG) secreted



by the plasma cells of the lamina propria are also vital to the destruction of pathogens which have already passed through the epithelial surface.

For this system to operate efficiently there must presumably be some way in which lymphocytes can detect antigens present on the luminal side of the epithelium covering them. Recently, specialized phagocytic cells have been demonstrated in the epithelium lying over lymphoid follicles, which are capable of passing particulate material to the lymphoid tissue beneath, thus providing a route for antigens to reach the immune system (Bockman and Cooper 1973; Chamberlain *et al.* 1973; Owen and Jones 1974).

The Thymus

The thymus (**6**.151A) varies in size with age. Until recent years the significance of the thymus was completely unknown, but evidence from intensive and elegant experimentation has now placed the thymus as a primary *central organ* of the lymphoid system. At birth it commonly weighs between 10 and 15 gm; it continues to grow up to the age of puberty, when its weight ranges between 30 and 40 gm. Thereafter it generally progressively diminishes in size, undergoing gradual atrophy and replacement by fat, so that after mid-adult life it may weigh only about 10 gm, though it may remain large and weigh between 28 and 50 gm (Young and Turnbull 1931; Keynes 1954). Certain disease processes greatly accelerate the involution and this may account for much of this variation.

In early life it is pinkish grey in colour, soft and finely lobulated on its surfaces, and consists of two unequally sized, pyramidal lobes connected together by areolar tissue. Although the thymus is customarily described as a single unpaired organ, each lobe is developed from the third pharyngeal pouch of its own side (p. 198), and strictly there are two separate thymic bodies, right and left. The thymus lies in the anterior and superior mediastina of the thorax, extending as far inferiorly as the fourth costal cartilages, and its upper tapering parts extend into the neck, sometimes as far as the lower part of the thyroid gland, or even higher. Its shape is largely determined by the structures related to it and upon which it is moulded. Anteriorly, it is covered by the sternum and the adjacent parts of the upper four costal cartilages, and the sternohyoids and sternothyroids. Posteriorly, it is moulded on the pericardium, the aortic arch and its branches, the left brachiocephalic vein, and the front and sides of the trachea. After mid-adult life it becomes yellowish in colour due to its gradual replacement by fat. Small accessory nodules of thymic tissue may occur in the neck as detached parts of the thymic diverticula in their developmental descent (p. 198), or the main thymus may be continued upwards as thin strands into the neck along this path, reaching the thyroid cartilage or even slightly higher. Sometimes the cervical part of the thymus is represented by strands of connective tissue which connect the thymus to the inferior parathyroid glands. The nodules may be closely associated with the parathyroids, those related to the superior parathyroids (parathyroids IV) being developed from the fourth pharyngeal pouch, and to the inferior parathyroids from the third.

780 **6**.151A A dissection to display the neonatal thymus.

Structure (**6**.151–154). Each lobe of the thymus is surrounded by a delicate fibrous capsule, from which septa penetrate for a short distance to divide the lobe into irregular lobules, each of 0·5–2·0 mm in diameter, which consist of an outer, darkly staining, densely cellular *cortex* and an inner, lightly staining, less dense *medulla*. The lobules are not completely separated from each other by these septa, and the medullary parts of the lobules are continuous with each other in the central parts of the lobe, running through which is a central parenchymatous cord derived from the embryonic thymic diverticulum. The lobules are connected to this cord through prolongations of their medullary substance, and if the interlobular connective tissue is dissected away (in the young child), the lobules are seen to have an irregular 'necklace' arrangement.

Essentially, throughout both the cortical and medullary parts of the thymus, there are two principal tissue components, which differ quantitatively in the two regions. These are: (1) a framework of irregularly branched epithelial 'reticular' cells, quite distinct from those found in the other lymphoid tissues; and (2) lymphocytic cells, macrophages and occasional other cells in the interstices of the epithelial framework.

The epithelial framework. The cells vary in their size and shape in the different regions of the thymus, but in all regions they retain epithelial characteristics, more immediately obvious in the fetal thymus or after the loss of thymic lymphocytes following X-irradiation or in early stages after thymic grafting. The cells form flattened, incomplete sheets which extend as a continuous layer on the surface of the thymus, beneath the connective tissue capsule (**6**.151B) and trabeculae of the lobules, and ensheathe the branches of the thymic blood vessels. The medullary framework is formed by a system of incomplete, fairly tightly packed, anastomosing sheets of similar, but larger, eosinophilic epithelial cells. The cortex is permeated by a more reticular arrangement of epithelial cells which are more highly branched with larger interstices, but the cells of this reticulum retain intercellular contacts, both with each other, and with the sheets of medullary cells and those lining the capsule and covering the blood vessels.

These epithelial cells are almost certainly derived from the original endodermal thymic diverticulum from the embryonic pharynx. They have oval, pale-staining nuclei and intercellular junctions with many typical desmosomes having well-marked tonofibrillae. Many of the cells show, in addition to typical lysosomes and vacuoles, other prominent smooth, round or oval, electron-dense granules in their cytoplasm, possibly secretory in nature. The epithelial cells of the cortex are quite uniform in their fine structure, whereas those of the medulla take many varied forms, some having very irregular surfaces and others being quite smooth in outline; the cytoplasm of the medullary cells is likewise pleomorphic, suggesting that these cells may have different functions. Where their surfaces abut on the trabecular, capsular or perivascular reticulin fibres, they are separated from them by a prominent basement membrane. Many investigators believed that the outer layers of the epithelial framework formed a partial *haemothymic barrier* which limited access of certain circulating materials, including antigens, into the tissue spaces of the thymus. Paradoxically, the interruptions in the cell layers are sufficient to allow passage of nutrients, metabolites and a small population of stem cells and lymphocytes to and from the thymus. (However, *see* further more recent discussion below concerning the blood–thymus barrier.) The thymic epithelial reticular cells are not members of the reticuloendothelial system in that they do not phagocytose diffusable dyes or particulate matter used in investigation of this system, but they are widely thought to be the origin of the thymic humoral factors important in lymphopoiesis and in the establishment of immunologic competence (*vide infra*). Macrophages are also present throughout the thymus, although

6.151B A scheme of thymic structure—the various elements are not drawn to scale to enable representation in a single diagram. they are much fewer than in many other lymphoid organs (e.g. the spleen).

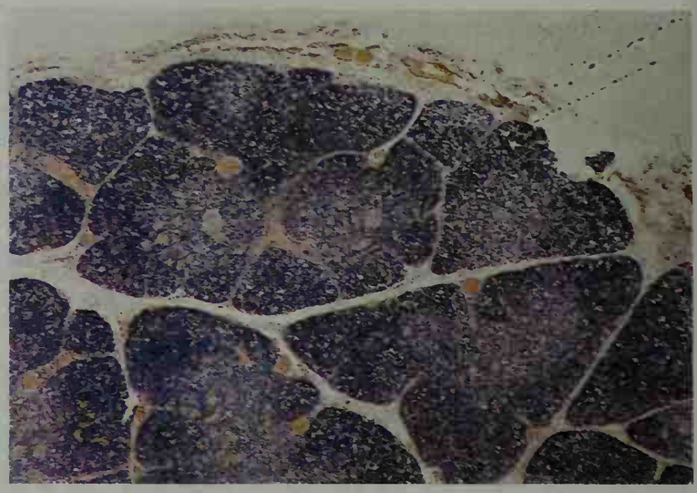
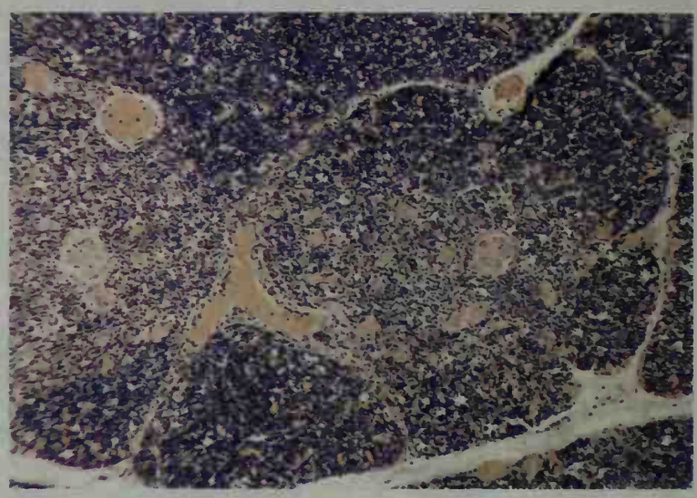
The cortical cells. Densely packed small lymphocytes predominate in the cortex, occupying the interstices of the epithelial reticulum, which they largely obscure, and are so numerous that they form about 90 per cent by weight, of the total organ. Two *cortical zones* are present, an outer region containing numerous large lymphoblasts, some in stages of mitosis, and an inner cortex occupied mainly by small lymphocytes. Macrophages occur in both zones (Hwang *et al.* 1974). Thymic lymphocytes are quite distinct from those of the peripheral lymphoid organs and circulating pool of lymphocytes (*vide infra*). They arise mainly or entirely in the outer cortex by division of stem cells which have originally migrated to the thymus from the bone marrow. The need for a continual supply of stem cells, however, is quite low despite the lymphopoietic level of the thymic cortex which is the highest of any lymphoid tissue. This is because the stem cells divide asymmetrically, one resultant cell retaining the potential for further divisions, the other, being a potential lymphocyte. The majority of the thymic lymphocytes have a short life span (3–5 days) and undergo degeneration still within the thymus, whilst the remainder leave the thymus to form a part of the circulating pool of lymphocytes which are not at first immunologically mature.

However, in the perivascular regions and near the capsule and trabeculae are found a number of true macrophages which are large, vacuolated and largely concerned with phagocytosis of the products of the massive lympholysis occurring in the cortex. The fate of these phagocytes may also be intimately associated with the natural history of further interesting specializations of the thymic medulla, i.e. the concentric corpuscles. In a similar position, plasma cells are also present, although their numbers are never large. These cells are thought to enter the medulla from the bloodstream through the post-capillary venules, rather than differentiating within the thymus itself, and their functional significance is uncertain, although their presence has intriguing possibilities for interactions between B- and T-lymphocytes in the thymus (Hwang *et al.* 1974).



The concentric corpuscles of Hassall are first formed in fetal life and are then continuously formed throughout the life of the thymus. A medullary epithelial cell enlarges, develops an intense eosinophilia and then follows a train of further degenerative changes. Progressive vacuolation of its cytoplasm and fragmentation of its nucleus is followed by engulfment of the nuclear débris by the vacuoles which then become confluent. Further epithelial cells increase in size, approach the degenerating central cell, and become arranged as a series of eosinophilic concentric cellular lamellae around the central hyalinizing mass. As the corpuscle grows, further degenerate epithelial cells are added to the central mass together, it has been claimed, with effete macrophages which carry the products of cortical lympholysis. They pass between the epithelial cell coverings of the corpuscle to

reach its centre, where they undergo hyalinization or are made soluble. The corpuscles vary from 30 to 100 μm in diameter and they increase in size and number during periods of intense lympholysis and during thymic involution.



Thymic involution. From the age of 5–6 years until puberty there is a slow, relative, reduction in the number of cortical lymphocytes even though the organ continues to grow. After puberty there is a more massive, progressive reduction in both cortical lymphocytes and epithelial cells, and these are replaced by fibro-adipose tissue, and at the same time the number of Hassall's corpuscles increases. There is an absolute reduction in size and weight so that in the later years of life the gland is identified only with difficulty, and consists of nests of corpuscles surrounded by a thin coat of fibrous and adipose tissue which entraps a few degenerating lymphocytes.

Vessels and nerves. The *arteries* are derived from the internal thoracic and inferior thyroid arteries, and the branches of these main vessels pass into the depths of the interlobular trabeculae where they give off a series of arterioles which enter the substance of the lobule. Here, they course along the junction of cortex and medulla where they remain at least partly ensheathed by epithelial cells, macrophages, pericytes, and other perivascular elements. From the arterioles a series of radial capillaries pass into the cortex and less regular vessels into the medulla. The returning post-capillary venules of the cortico-medullary junction present a thickened endothelium similar to that of the post-capillary venules of the lymph node (p. 770), across which lymphocyte passage is a frequent event. Some venules retrace their arteriolar path and converge to form principal veins again in the interlobular septa. However, a proportion of venous return occurs via a capsular venous plexus. In the latter case, therefore, the circulation from arteriole to radial capillary continues its *transcortical centrifugal* path as radial venules and small veins, finally draining into the capsular veins (**6**.151B). These contrasting microvascular routes may be important in the cell dynamics of the thymus (Blau 1976). The main *veins* end in the left brachiocephalic, internal thoracic and inferior thyroid veins; frequently one or more veins emerge from the medial side of each lobe and join together to form a common trunk which opens into the left brachiocephalic vein.

The blood–thymus barrier is a concept arising from the observation that materials injected intravascularly do not penetrate to the extravascular spaces of the thymic cortex where the lymphocytes are proliferating, suggesting that the walls of thymic blood vessels may act as efficient barriers to the passage of antigens and other materials into the thymic tissue which would thus be an *immunologically sequestered site*, allowing the untroubled differentiation of lymphocytes (*vide infra*). This subject was investigated by Raviola and Karnovsky (1972) who found that in rodents, electron-opaque tracers passed readily through the intercellular junctions of the medullary vascular endothelia, particularly those of the post-capillary venules, and diffused extensively into the medullary tissue. However, the endothelium of the cortical capillaries forms a much better barrier, and the small amount of tracer which passed through by vesicular transport was immediately phagocytosed by the perivascular macrophages. Presumably macrophage action also prevents diffusion of particulate substances from the medulla into the cortex. The lymph vessels are described on p. 800. The *nerves* are small and are derived from the sympathetic (cervicothoracic ganglion or ansa subclavia) and the vagus; branches from the phrenic and descendens cervicalis are distributed mainly to the capsule of the thymus.

Blau, Guy's Hospital Medical School.)

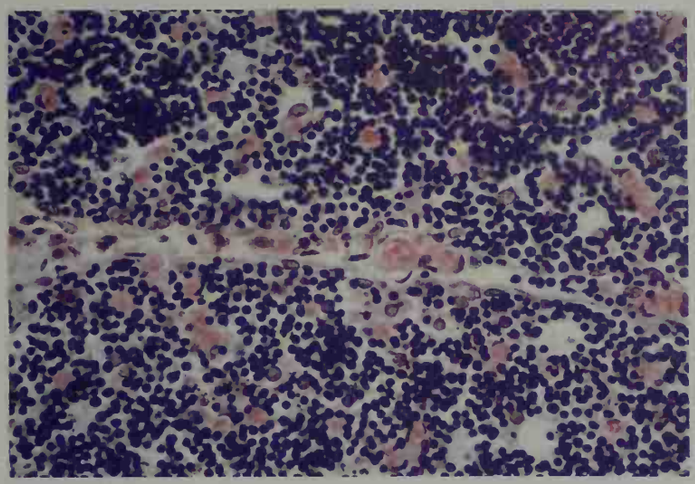
FUNCTIONS OF THE THYMUS

Our understanding of thymic function is by no means complete and still under intensive investigation, but in recent years dramatic advances have occurred. The evidences upon which recent views of thymic function are based stem from a variety of experimental approaches. These include studies of the effects of thymectomy or radiation-induced thymic destruction in neonatal and mature animals, and the study of certain mutant mouse strains, e.g. *nude*, in which the thymus is vestigial or absent in homozygous individuals. Attempts have been made to compensate for the results of thymectomy by administering cell suspensions from a variety of lymphoid tissues or bone marrow; also with normal or irradiated thymic tissue, either as a free graft,

or surrounded by a cell-impermeable barrier; finally, with cell-free thymic extracts.

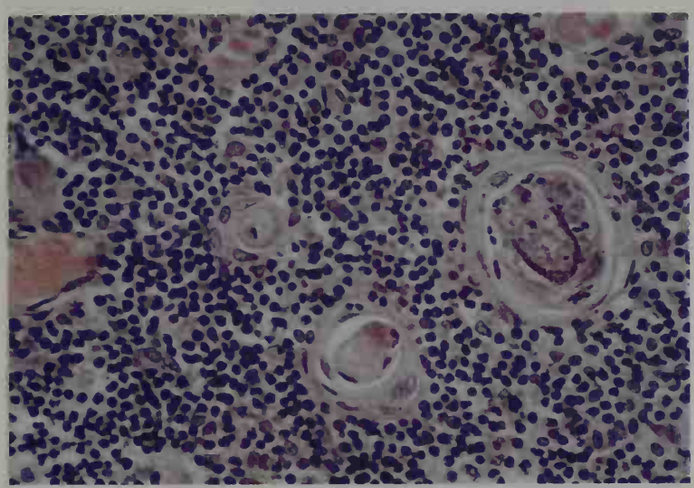
The stem cell sources concerned in the repopulation of cell-depleted lymphoid tissues or thymic grafts, have been followed using chromosome-marker or autoradiographic techniques. Further studies have followed the restoration of immune competence in animals rendered immunologically tolerant to certain antigens, by exposing them to these antigens, in the early neonatal period.

A full review of this complex and highly important field of experimentation lies outside the scope of this volume. What follows is a short summary of some of the principal concepts which are emerging.



The essential functions of the thymus are the differentiation of lymphocytes into immunologically competent T-cells (thymocytes), and the maintenance of an effective pool of these cells in the circulation and peripheral lymphoid organs, able to react to a wide and increasing array of antigenic stimuli, and to modify the activities of B-lymphocytes. Thus, during the neonatal period and in early postnatal life, thymic function is essential for the normal development of the lymphoid tissues. Thymectomy at this time leads to a progressive, eventually fatal disease, with hypoplasia of the peripheral lymphoid organs, wasting, and infective processes which reflect an inability to mount a cellular immune response. By puberty, the main lymphoid tissues are fully developed, and thymectomy in the mature animal is less dramatic, but in time, there follows a reduction in the effectiveness of responses to unfamiliar antigens.

A second major function is the *control of lymphopoiesis* in the *central* and *peripheral lymphoid organs*, including the thymus itself, both with respect to the rate of cell division and the differentiation of lymphocytes into immunologically competent cells. These effects appear to be mediated by humoral factors, e.g. *lymphopoietin* probably secreted by the epithelial cells of the thymus, which stimulates lymphoblast division.



A third possible role is the production of hormones not necessarily directly connected with lymphocyte proliferation (*thymosins*), which have been considered by some authors to be concerned with neuromuscular junction maintenance amongst other activities. However, recent evidence suggests that these hormones may be similar to, or identical with, the factors controlling lymphocyte production, and that neuromuscular disease of the myasthenia gravis type is basically an auto-immune condition (*vide infra*).

Origin and fate of thymic lymphocytes: The cortical lymphocytes of the thymus arise from stem cells of the bone marrow, and in earlier fetal life, the spleen, which migrate in the circulatory system to the thymus, passing into its tissues through the post-capillary venules. Such cells become lymphoblasts in the outer cortex, and proliferate there extensively, but about 90 per cent of the progeny die within the thymus in the course of a few days; the remainder apparently become immunologically competent T-lymphocytes, and can pass back into the circulatory system to join the circulating lymphocyte pool, and populate the thymus-dependent areas of lymph nodes and other peripheral lymphoid organs.

The observed death of lymphocytes in the thymus is an intriguing problem, and its massive scale suggests that it may have considerable biological importance. Some authors have suggested that it may be part of a mechanism enabling lymphocytes to distinguish between *foreign* antigens and chemicals indigenous within the normal body. In this theory (the *clonal hypothesis* of McFarlane Burnett) it has been proposed that within the population of differentiating lymphocytes, individual stem cells develop the ability to detect and respond immunologically to a restricted range of antigens, or even to a single antigen, so that within the body, any antigen being introduced to the tissues, e.g. the cell walls of bacteria or the coats of viruses, will already be matched by a group of lymphocytes (a *clone*) which has descended from an appropriate stem cell, and which is able to inactivate the antigen. On meeting the matching antigen, this clone would itself proliferate and so provide an overwhelming defensive force. In the case of B-lymphocytes this initial differentiation into separate classes of stem cells presumably occurs in the bone marrow, to

6.153 Neonatal thymus. A cortical field showing a delicate interlobular connective tissue septum, densely packed cortical lymphocytes and scattered profiles of larger, pale, eosinophilic, epithelial, reticular cells.

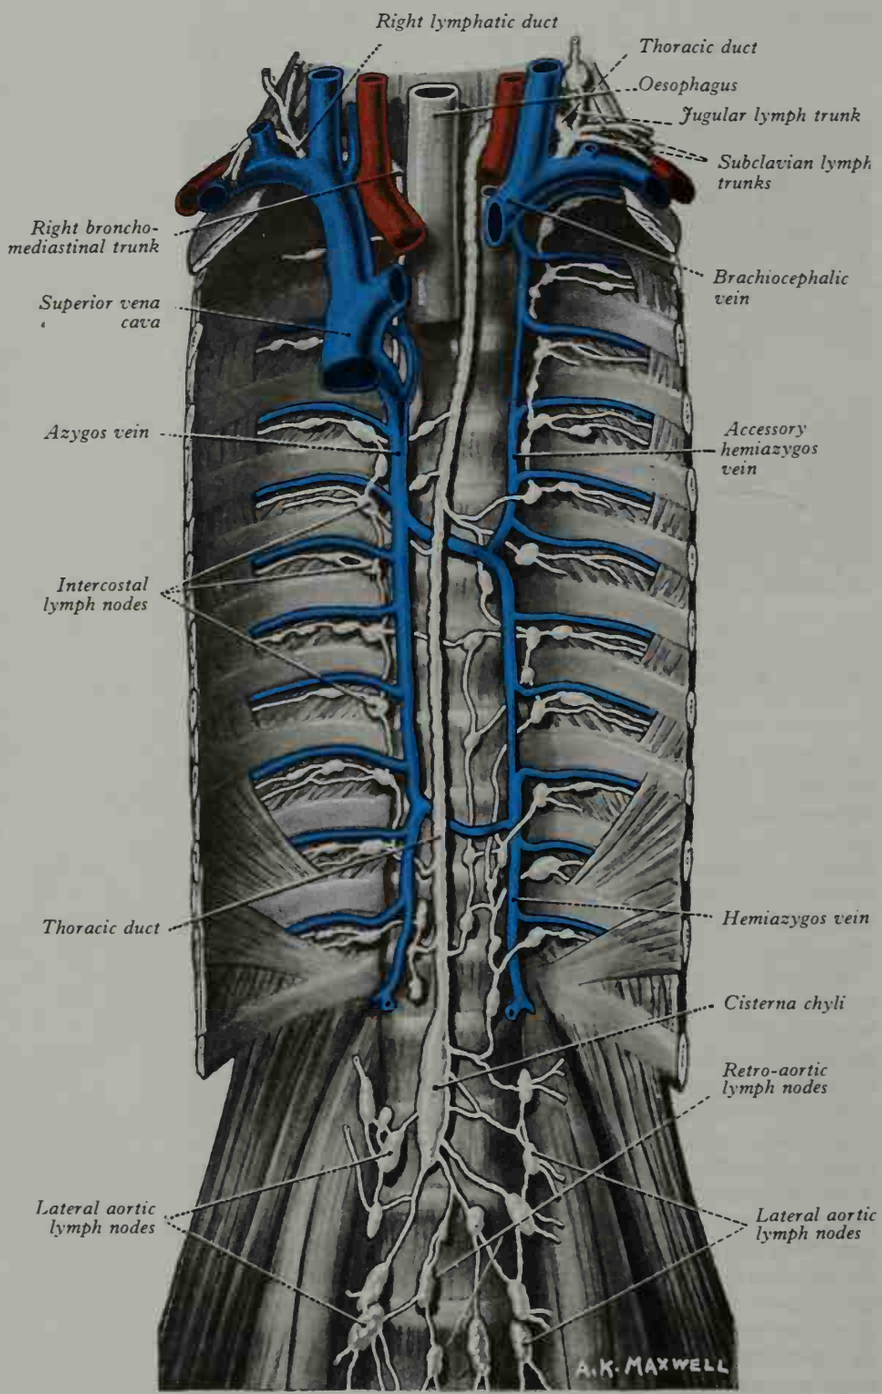
provide an extensive battery of cells capable of producing an enormous range of antibodies. With the T-lymphocytes, differentiation of stem cells committing them to become T-cells takes place in the thymus, and results in cells collectively able to recognize a wide range of antigens, and to respond to them by cytotoxic cell killing, 'arming' of macrophages, triggering of large mononuclear cells ('killer cells'), 'helper' activities with respect to B-lymphocyte reactions, and so forth.



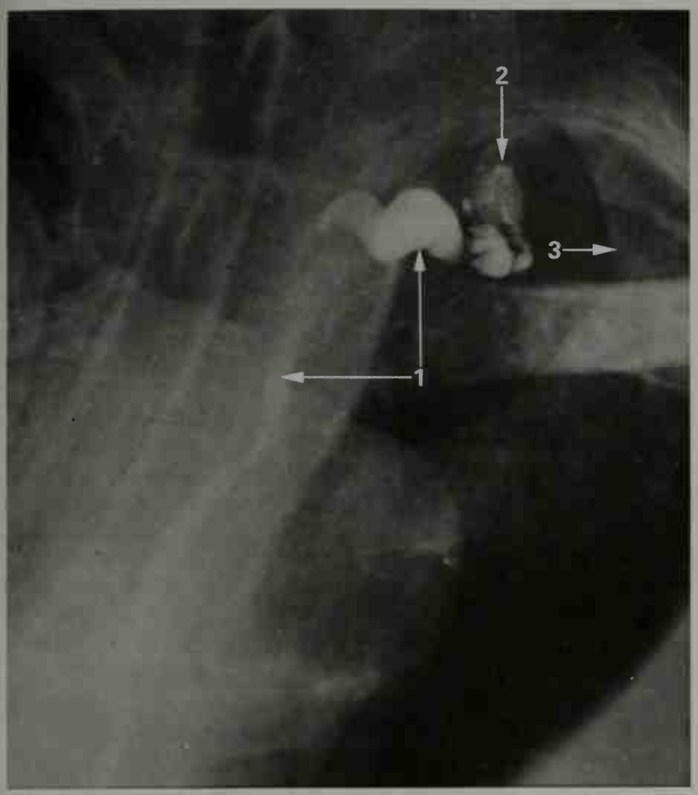
Recently it has been shown that T-lymphocytes require 'priming' by macrophages which have ingested antigenic material, adding significance to the numerous macrophages of the thymus. However, it is also known that T-lymphocytes respond by killing mainly, or perhaps only, the cells of the body bearing normal HLA antigens together with a 'foreign' or altered antigen (e.g. of viral origin), so the process of 'education' in the thymus must presumably include the recognition of 'self' by surviving T-lymphocytes; clearly the picture is more complex than we yet understand. However, this having been said, it is obviously important that lymphocytes can distinguish foreign antigens from the substances natural to the body, and certain disease conditions are known where this distinction breaks down and the lymphocytes attack the normal tissues (*auto-immune diseases*). In the clonal selection theory it is further proposed that the great many types of stem lymphocyte which the body produces include those directed against the body, but that these are eliminated to leave only those directed against external antigens. The massive destruction of lymphocytes observed in the thymus may be part of this 'weeding-out' process. The actual site of destruction is a matter of some debate; certainly the numerous macrophages of

the thymus ingest many dead or dying lymphocytes, and it has been suggested that such macrophages subsequently enter the Hassall's corpuscles and degenerate.

The cortical thymic lymphoid tissue of normal mammals does not form germinal centres, but these are formed in a number of types of auto-immune disease, perhaps reflecting a defect in the normal role of the thymus of recognizing and destroying auto-allergic cells.

Applied Anatomy. Castration or adrenalectomy delays involution of the thymus, whereas hypertrophy of the suprarenal cortex (or injection of cortisone) or the injection of androgenic hormones causes atrophy of the thymus.

In young children, a large thymus may, in rare cases, press on the trachea and cause attacks of respiratory stridor, or noisy and difficult breathing. Tumours of the thymus may press on the trachea, the oesophagus, and the large veins at the root of the neck, causing hoarseness; cough, dysphagia and cyanosis.



6.155 The thoracic and right lymphatic ducts. The accessory hemiazygos vein is crossing the median plane lower and the hemiazygos higher than usual. The reader should also note the comments concerning the more common course of the azygos vein made in the caption to illustration **6**.132 and on p. 755.

Myasthenia gravis is a chronic auto-immune disease in adults (Castleman 1966) characterized by diminution in the power of contraction of certain voluntary muscles after repetitive contractions have been carried out. The muscles most commonly involved are the levator palpebrae superioris (leading to ptosis or drooping of the upper eyelid) and the orbital muscles (leading to diplopia or double vision). Other muscles (facial, masticatory, neck and limb muscles) may be involved, including in severe cases, the respiratory muscles. In many of these cases some abnormality of the thymus has been observed, such as a general enlargement (hyperplasia) or a tumour (thymoma, composed of epithelial cells derived from the reticular cells or possibly from the lymphocytes), and in a number of these cases transient or more lasting improvement may follow removal of the thymus. Although there may be more than one condition bearing somewhat similar symptoms, it is now thought that myasthenia gravis is an auto-immune disease in which the acetylcholine receptor proteins of the neuromuscular junctions are attacked by the body's defensive systems; the coincidence of this disease with thymic disorders may reflect the part which the latter organ plays in modulating the immune responses of the body as a whole.

Topography of the Lymph Nodes and Vessels

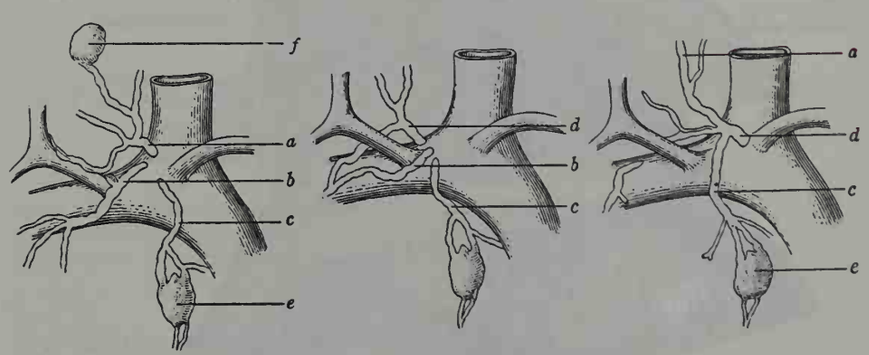
The thoracic duct (**6**.155, 156) conveys the greater part of the lymph back into the circulating blood. It is the common trunk of all the lymph vessels of the body, except those of the right side of the head, neck, and thoracic wall, the right upper limb, right lung, right side of the heart, and part of the convex surface of the liver. In the adult it varies in length from 38 to 45 cm and, including the cisterna chyli, extends from the second lumbar vertebra to the root of the neck. The duct proper begins at the upper end of the cisterna chyli (p. 785) near the lower border of the twelfth thoracic vertebra and enters the thorax through the aortic opening of the diaphragm. It then ascends through the posterior mediastinum with the aorta on its left and the azygos vein on its right. In this part of its course the vertebral column and anterior longitudinal ligament, the right aortic intercostal arteries, and the terminal parts of the hemiazygos and accessory hemiazygos veins are behind it. The diaphragm and the oesophagus are in front of it, but a recess of the right pleural cavity may intervene between the duct and the oesophagus. Opposite the fifth thoracic vertebra the thoracic duct inclines to the left, enters the superior mediastinum, and ascends to the thoracic inlet along the left side of the oesophagus. Crossed anteriorly by the aortic arch, it then lies behind the commencement of the left subclavian artery in close contact with the mediastinal pleura of the left side.

Passing into the neck, it arches laterally at the level of the transverse process of the seventh cervical vertebra, the arch rising about 3 or 4 cm above the clavicle. Here the duct runs anterior to the vertebral artery and vein, the sympathetic trunk and the thyrocervical trunk or its branches. It also passes in front of the phrenic nerve and the medial border of scalenus anterior, but is separated from these by the prevertebral fascia. In this situation it is placed behind the left common carotid artery, vagus nerve, and internal jugular vein. Finally, it descends in front of the first part of the left subclavian artery and ends by opening into the junction of the left subclavian and internal jugular veins (**6**.157). Sometimes the duct joins the adjacent parts of the subclavian or internal jugular veins and sometimes it breaks up into a variable number of smaller vessels before terminating (*see* also below). At its commencement it is about 5 mm in diameter, but it diminishes considerably in calibre in the middle of the thorax, and in about half the cases is again slightly dilated just before its termination. It is slightly sinuous, constricted at intervals and appears varicose. Not infrequently it divides in the middle of its course into two unequal vessels which soon unite, or into several branches which form a plexiform interlacement. It occasionally divides at its upper levels into two branches, right and left, the left ending in the usual manner, while the right opens into the right subclavian vein with the right lymphatic duct. The thoracic duct has several valves, and these correspond to sites of exposure to pressure. At

6.156 Lymphangiogram showing the upper part of the thoracic duct. There has been some filling of a cervical lymph node. 1. Thoracic duct. 2. Lower deep cervical lymph node. 3. First rib. (Kindly supplied by Professor J. B. Kinmonth.)

its entry into the venous system a bicuspid valve faces into the vein to prevent reflux of blood into the duct. After death, however, blood regurgitates into the terminal part of the duct, which therefore looks like a vein. Kinnaert (1973) has collected the recorded accounts of 480 dissections of the cervical termination of the thoracic duct adding 49 further cases. He gives full statistics of all previous studies. In 0 to 4·5 per cent, in different studies, no thoracic duct was found on the left. Multiple terminal openings were noted frequently (in 10 to 40 per cent, according to different observers). In Kinnaert's series the duct was multiple near its termination in 66 per cent of dissections, but in only 21 per cent were actual terminal openings multiple. Patterns of termination varied greatly in different studies, but in the two largest series, those of Jdanov (1959) and Kinnaert (1973), the percentages for sites of termination were respectively 48 and 36 per cent into the internal jugular vein, 9 and 17 per cent into the subclavian, 35 and 34 per cent into the jugulo-subclavian junction. Termination in the left innominate vein occurred in 8 per cent of Jdanov's series, but in none of Kinnaert's.

The cisterna chyli (**6**.155) is commonly described as a saccular dilatation in the lymphatic route from the abdomen and lower limbs, extending for 5 to 7 cm in front of the first and second lumbar vertebral bodies, immediately to the right of the abdominal aorta (but see also below). The upper two right lumbar arteries and the right lumbar azygos vein (p. 754), when it is present, are between the cisterna chyli and the vertebral column. Anteriorly the cisterna is covered by the medial edge of the right crus of the diaphragm. It is joined by right and left lumbar and intestinal lymphatic trunks. The *lumbar trunks* are formed from the efferent vessels of the lumbar (lateral aortic) lymph nodes; they receive the lymph from the lower limbs, the walls and viscera of the pelvis, the kidneys and suprarenal glands, the testes or ovaries, and the deep lymph vessels of the greater part of the abdominal wall. The *intestinal trunks* comprise the large lymph vessels which receive the lymph from the stomach, intestine, pancreas and spleen, and from the lower and anterior part of the liver. They join the cisterna chyli, lumbar lymph trunks or thoracic duct.



Although this description of the cisterna as a single, simple receptaculum is repeated by most textbooks, a large statistical study of the formation of the cisterna and thoracic duct in mankind appears to be lacking. Anson (1963) depicted a number of variations, and in many of these no cisterna was shown; when present it appeared to be often multilocular. No statistics of incidence were given. Kubik (personal communication, 1978) has observed a true cisterna in only 14 of 70 dissections. In 7 of these a single cisterna existed, while there were two cisternae in 5 specimens and three in 3 of them. In the remaining 56 dissections no clearly distinguishable cisterna was observed; in about half of these the collecting channels formed a thoracic duct without cisternal formation; in the other half intercalated lymph nodes (as also depicted by Anson 1963) simulated cisternae by their external appearance. If these findings are confirmed, the customary description of the cisterna chyli, and the concept of it as a usual feature of the human lymphatic system, will require modification.

Tributaries. At its start the thoracic duct receives a *descending trunk* from the intercostal lymph nodes of the lower six or seven intercostal spaces, on each side. In the thorax the thoracic duct is joined by two *ascending trunks* draining the upper lumbar lymph nodes which pierces the crura of the diaphragm. It also receives efferents from the posterior mediastinal lymph nodes and from the intercostal lymph nodes of the upper six spaces of the left side. In the neck it is joined usually by the *left jugular trunk* from the left side of the head and neck, and the *left subclavian trunk* from the left upper limb, but these vessels may open independently into the internal jugular or subclavian vein, respectively; sometimes it is joined by the *left bronchomediastinal trunk*, but this usually opens independently into the junction of left subclavian and internal jugular veins. The tributaries of the thoracic duct are usually described as possessing terminal valves which prevent reflux of lymph. Sapin and Boryiak (1974) studied the behaviour of injected masses in the thoracic ducts of 180 cadavers, and they observed that reflux into several groups of mediastinal and paravertebral lymph nodes was a usual occurrence, a fact of great importance in the spread of metastases.

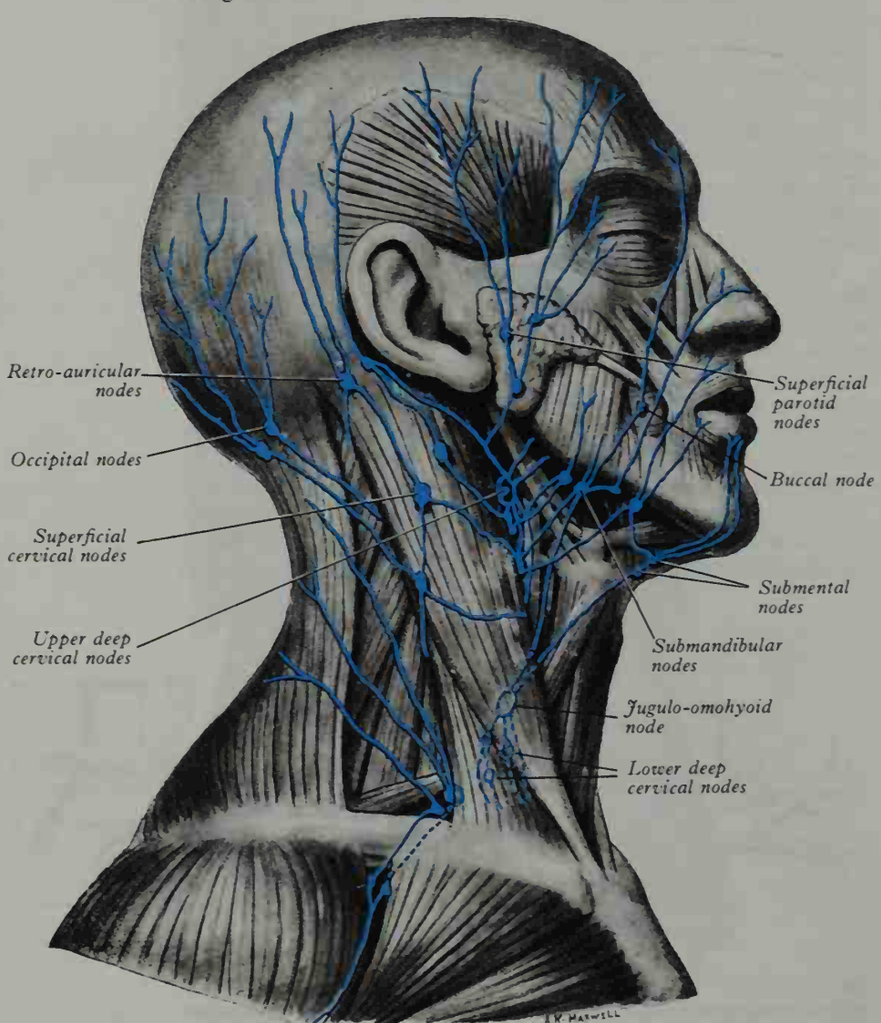
The right lymphatic duct (**6**.155, 157), about 1 cm in length, courses along the medial border of the scalenus anterior at the root of the neck, and ends by opening into the junction of the right subclavian and internal jugular veins. At its orifice two semilunar valves prevent the passage of venous blood into the duct.

Tributaries. The duct receives lymph from the right half of the head and neck collected into the *right jugular trunk*, from the right upper limb through the *right subclavian trunk*; from the right side of the thorax, right lung, right side of the heart, and part of the convex surface of the liver, through the *right bronchomediastinal trunk*. A single right lymph duct occurs in about one-fifth of subjects; more frequently its three tributaries open separately at the union of the two veins (**6**.157).

Applied Anatomy. Blockage of the thoracic duct, usually the result of malignant disease, leads to no signs or symptoms; hence alternative routes for the passage of lymph to the venous circulation must exist. Widespread blockage of multiple pathways

6.157 Variations in the terminal lymph trunks of the right side. (After Poirier and Charpy.) *a*. Jugular trunk. *b*. Subclavian trunk, *c*. Bronchomediastinal trunk. *d*. Right lymphatic duct. *e*. Lymph node of parasternal chain. *f*. Lymph node of deep cervical chain.

may occasionally occur, e.g. in filariasis, and cause effusions into the peritoneal or pleural cavities; nevertheless such effusions are more likely to result from rupture of the duct from trauma, surgical accidents, or a malignant disease.



The Lymphatic Drainage of the Head and Neck

The lymph nodes of the head and neck comprise a terminal group and a number of intermediary, outlying groups. The terminal group is closely associated with the carotid sheath and is named the *deep cervical group*. All the lymph vessels of the head and neck drain into this group, either directly from the tissues themselves, or indirectly after passing through one of the outlying groups. The efferents of the deep cervical lymph nodes form the *jugular trunk*, which, on the right side, may end in the junction of the internal jugular and subclavian veins or may join the right lymphatic duct; on the left side, it usually enters the thoracic duct, although it may join either the internal jugular or the subclavian vein.

The Deep Cervical Lymph Nodes

These nodes lie along the carotid sheath and may be divided into superior and inferior groups.

The superior deep cervical lymph nodes (**6**.158 adjoin the upper part of the internal jugular. Most of them are deep to sternocleidomastoid, but a few extend beyond it. One group, consisting of one large and several small nodes, is in the triangular region bounded by the posterior belly of digastric, the facial vein, and the internal jugular vein, and is termed the *jugulodigastric group*; it is concerned particularly with lymph drainage of the tongue.

6.158 The superficial lymph nodes and lymph vessels of the head and neck.

Efferents from the upper deep cervical lymph nodes pass to the lower deep cervical group and direct to the jugular trunk.

The inferior deep cervical lymph nodes are partly deep to the lower part of sternocleidomastoid, and extend also into the subclavian triangle, and are closely related to the brachial plexus and the subclavian vessels. One node of this group lies on, or just above, the intermediate tendon of the omohyoid; it is called the *jugulo-omohyoid lymph node* and is concerned especially with the drainage of the tongue (p. 788). The efferents from the lower deep cervical lymph nodes join the jugular trunk.

In their lymphatic drainage the tissues of the head and neck, like other regions, can conveniently be considered in two groups: (*a*) the superficial tissues and (*b*) the deeper structures, including the viscera.

Lymphatic Drainage of the Superficial Tissues of the Head and Neck (6.158)

Most of the superficial tissues are drained by vessels which go first to locally sited groups of lymph nodes and the efferents from these drain into the deep cervical lymph nodes. Some, however, may pass directly to the deep cervical nodes.

Regional groups concerned in the drainage of the superficial tissues are:

In the head.	*In the neck.*
Occipital.	Submandibular.
Retro-auricular (mastoid).	Submental.
Parotid.	Anterior cervical.
Buccal (facial).	Superficial cervical.

Lymphatic drainage of the scalp and ear. Lymph vessels from the frontal region just above the root of the nose drain into the submandibular group (**6**.158) and are considered with the face (*vide infra*).

The vessels from the rest of the forehead, the temporal region, and the upper half of the lateral surface of the auricle and the anterior wall of the external acoustic meatus drain into the *superficial parotid lymph nodes*. These are immediately in front of the tragus, on, or deep to, the fascia of the parotid gland. These nodes also drain the lateral lymph vessels from the eyelids and the skin over the zygomatic bone. Their efferent vessels pass to the upper deep cervical lymph nodes.

A strip of scalp above the auricle, the upper half of the cranial surface and margin of the auricle, and the posterior wall of the external acoustic meatus are drained by vessels which pass, some to the upper deep cervical lymph nodes and others to the retro-auricular group.

The *retro-auricular lymph nodes* (**6**.158) are superficial to the mastoid attachment of the sternocleidomastoid, and deep to the auricularis posterior. Their efferents pass to the upper deep cervical lymph nodes.

The lobule of the auricle, the floor of the meatus, and the skin over the angle of the jaw and the lower part of the parotid region are drained by vessels which may pass to the superficial cervical lymph nodes or the upper deep cervical group. The *superficial cervical lymph nodes* extend along the external jugular vein superficial to sternocleidomastoid. Some of the efferents from this group pass round the anterior border of sternocleidomastoid to reach the upper deep cervical lymph nodes; others follow the external jugular vein and join the lower deep cervical lymph nodes in the subclavian triangle.

The occipital region of the scalp is drained partly to the occipital group of lymph nodes, and partly by a trunk along the posterior border of sternocleidomastoid ending in the lower deep cervical lymph nodes. The *occipital lymph nodes* are in the upper angle of the posterior triangle and superficial to the attachment of trapezius.

Lymphatic drainage of the face. The lymph vessels draining the eyelids and conjunctiva commence in a superficial plexus beneath the skin and a deep plexus in front of and behind the tarsi; these communicate with one another, and medial and lateral sets of vessels arise from them. The lateral vessels drain the whole thickness of the upper lid with the exception of the skin over its medial part; they also drain the whole thickness of the lateral half of the lower lid and all the ocular conjunctiva. They

pass laterally from the lateral commissure to end in the superficial parotid lymph nodes and also in the *deep parotid lymph nodes*, which are embedded in the parotid salivary gland. The deep parotid lymph nodes receive vessels also from the middle ear (p. 787). The lymph vessels of the medial set drain the skin over the medial part of the upper eyelid, the whole thickness of the medial half of the lower lid, and the caruncula lacrimalis. Following the course of the facial vein, they terminate in the submandibular group of lymph nodes.

The *submandibular lymph nodes* (**6**.158) are internal to deep cervical fascia in the submandibular triangle. There are usually three, one at the anterior end of the submandibular gland, one in front of and another behind the facial artery where it reaches the mandible. Additional members of this group are often embedded in the gland or on its deep surface. The submandibular nodes receive afferents from a wide area, including vessels from the submental, buccal and lingual groups of lymph nodes; their efferents pass to upper and lower deep cervical lymph nodes.

The external nose, cheeks, upper lip, and lateral parts of the lower lip send their lymph to the submandibular nodes. These vessels may have along their course a few *buccal lymph nodes* lying in relation to the facial vein. The mucous membrane covering the oral surfaces of the lips and cheeks is drained by vessels which also end in the submandibular nodes. Lymph from the lateral part of the cheek drains into the parotid nodes, whilst that from the skin over the root of the nose and the central part of the forehead just above this drains partly into the parotid nodes, and partly, along the facial lymphatics, into the submandibular nodes.

The central part of the lower lip, the floor of the mouth and the tip of the tongue drain to the submental group of nodes. The *submental lymph nodes* are placed on the mylohyoid between the anterior bellies of the two digastrics (**6**.159). They receive afferents from both sides of the median plane, some of the vessels decussating over the symphysis of the mandible; their efferents pass to the submandibular and jugulo-omohyoid nodes.

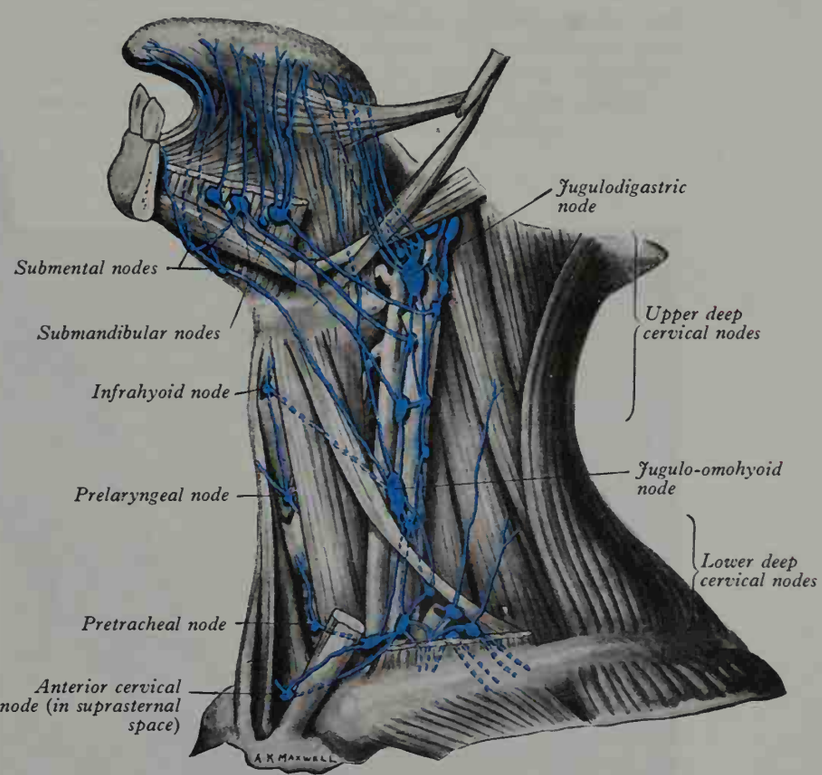
Lymphatic drainage of the neck. Many of the vessels draining the superficial tissues of the neck pass round the borders of sternocleidomastoid to either the upper or the lower deep cervical lymph nodes. Some, however, pass from the region over the upper part of the sternocleidomastoid and the posterior triangle of the neck to the superficial cervical and occipital lymph nodes. The lymph from the upper part of the anterior triangle of the neck is drained into the submandibular and submental nodes; vessels from the skin of the anterior part of the neck below the hyoid bone pass to the *anterior cervical lymph nodes*, which are associated with the anterior jugular veins. The efferents from this group pass to the deep cervical lymph nodes of both sides of the neck: they pass to infrahyoid, prelaryngeal, and pretracheal nodes (*vide infra*). One of the anterior cervical lymph nodes often occupies the suprasternal space (p. 537).

Lymphatic Drainage of the Deeper Tissues of the Head and Neck

The deeper tissues of the head and neck drain to the deep cervical lymph nodes either directly, or indirectly through one of the outlying groups. In addition to the outlying groups which have been considered already, the following also are concerned with drainage of the deeper tissues, viz.: retropharyngeal, paratracheal, lingual, infrahyoid, prelaryngeal and pretracheal.

The *retropharyngeal lymph nodes* comprise a median and two lateral groups, the former near the midline, the latter in front of the lateral mass of the atlas along the lateral border of the longus capitis. They are all between the fascia covering the pharynx and the prevertebral fascia. They receive afferents from the nasopharynx, the auditory tube and the atlanto-occipital and atlanto-axial joints. Their efferents pass to the upper deep cervical lymph nodes.

The *paratracheal lymph nodes* flank the trachea and oesophagus, along the recurrent laryngeal nerves. Efferents from both groups pass to the corresponding deep cervical nodes.



The *infrahyoid, prelaryngeal and pretracheal lymph nodes* are deep to the investing layer of the deep cervical fascia. Some of their afferents are from the anterior cervical nodes and their efferents join the deep cervical groups. The nodes of the infrahyoid group are on the front of the thyrohyoid membrane; those of the prelaryngeal group lie on the conus elasticus and its cricovocal membrane; the pretracheal lymph nodes are in front of the trachea in close relation with the inferior thyroid veins.

The *lingual lymph nodes* are small and inconstant. They are situated on the external surface of hyoglossus and between the genioglossi.

Lymphatic drainage of the nasal cavity, nasopharynx and middle ear. The lymphatics of the nasal cavity can be injected from the subarachnoid space, through communications along the course of the olfactory nerves. The lymph vessels from the anterior part of the nasal cavity pass superficially to join those draining the skin covering the external nose and end in the submandibular nodes. The remainder of the nasal cavity, paranasal sinuses, nasopharynx, and pharyngeal end of the auditory tube drain to the upper deep cervical nodes, either directly or through the retropharyngeal lymph nodes. It is probable that the posterior part of the floor of the nasal cavity is drained by vessels which enter the parotid groups of nodes.

The lymph vessels of the mucous lining of the tympanic cavity and mastoid antrum pass to the parotid or upper deep cervical lymph nodes; those from the tympanic end of the auditory tube probably end in the deep cervical nodes. Lymphatic channels have been identified in the submucosa of the tube by injection and electron microscopy (Pulec *et al.* 1975).

Lymphatic drainage of the larynx, trachea, and thyroid gland. The lymph vessels of the larynx comprise upper and lower groups; on the lateral wall the two systems are distinct, the line of division being the vocal fold; the two systems anastomose on the posterior wall. The vessels of the upper set pierce the thyrohyoid membrane, and accompany the superior laryngeal vessels to end in the upper deep cervical nodes. The vessels of the lower set either pass between the cricoid cartilage and the first tracheal ring

6.159 The lymphatic drainage of the tongue. (After Jamieson and Dobson.) Removal of sternocleidomastoid has exposed the whole chain of deep cervical lymph nodes.

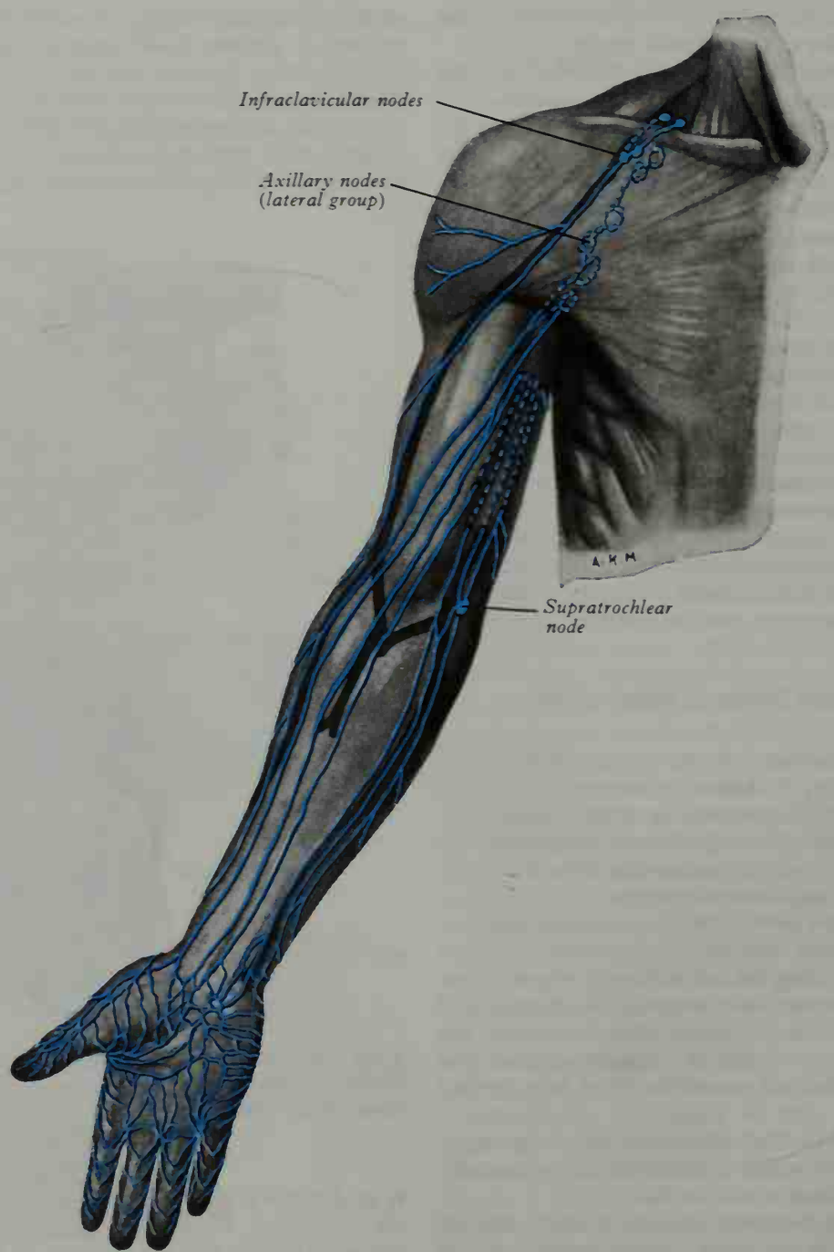
to go directly to the lower deep cervical lymph nodes, or, piercing the cricovocal membrane, pass to the pretracheal and prelaryngeal groups which drain into the deep cervical lymph nodes.

There is a dense network of lymph vessels in the wall of the trachea. The cervical part of the trachea is drained to the

pretracheal and paratracheal nodes, or directly to the nodes of the lower deep cervical group.

The lymph vessels of the thyroid gland communicate freely with the tracheal plexus. They pass to the prelaryngeal nodes just above the isthmus and to the pretracheal and paratracheal nodes; some may drain into the brachiocephalic lymph nodes, which are related to the thymus in the superior mediastinum. Laterally, the gland is drained by vessels which accompany the superior thyroid vein to the deep cervical lymph nodes. Some lymph vessels from the thyroid gland may enter directly into the thoracic duct (p. 784).

Lymphatic drainage of the mouth, teeth, tonsil and tongue. The *mouth*. The vessels of the gums end in the submandibular lymph nodes; those of the hard palate are continuous in front with those of the upper gum, but run backwards to pierce the superior constrictor, and end in the upper deep cervical and retropharyngeal lymph nodes; those of the soft palate pass backwards and laterally and end partly in the retropharyngeal, and partly in the upper deep cervical nodes. The vessels of the anterior part of the floor of the mouth go to the inferior nodes of the upper deep cervical group, either directly or indirectly through the submental lymph nodes; the vessels from the rest of the floor of the mouth pass to the submandibular and upper deep cervical nodes.



The *teeth*. Lymph vessels pass to the submandibular and deep cervical lymph nodes.

The *tonsil*. The vessels from the tonsil pierce the buccopharyngeal fascia and the superior constrictor and pass between the stylohyoid and the internal jugular vein to the upper deep cervical lymph nodes. Most of them end in the jugulodigastric nodes; occasionally one or two additional vessels run to small nodes on the lateral side of the internal jugular vein, deep or medial to the sternocleidomastoid.

The *tongue* (**6**.159). The lymphatic plexus in the mucous membrane of the tongue is continuous with the intramuscular plexus. The part of the tongue in front of the vallate papillae is drained into marginal and central lymph vessels. The part of the tongue behind the vallate papillae drains into a set of dorsal lymph vessels.

(1) *Marginal vessels*. The vessels from the tip of the tongue and the region of the frenulum descend under the mucous membrane and end in widely distributed lymph nodes.

(*a*) Vessels pierce the origin of the mylohyoid in contact with the periosteum of the mandible; one or two of these vessels enter the submental lymph nodes, and one descends over the hyoid bone to the jugulo-omohyoid node. It should be noted that vessels arising in the plexus on one side of the tongue may cross under the frenulum and end in the lymph nodes of the opposite side, and

6.160 The lymphatic drainage of the superficial tissues of the upper limb. Anterior aspect. Semi-diagrammatic.

that the efferent vessels of the submental nodes, which are placed in or near the median plane, pass impartially to either side.

(*b*) Some vessels pierce the origin of the mylohyoid, and enter the anterior or middle submandibular lymph node.

(*c*) Some vessels pass deeply under the sublingual salivary gland and, accompanying the companion vein of the hypoglossal nerve, end in the jugulodigastric nodes. One vessel often descends over or deep to the intermediate tendon of the digastric to reach the jugulo-omohyoid lymph node.

Some of the lymph vessels from the lateral margin of the tongue pass over the sublingual salivary gland, pierce the mylohyoid, and end in the submandibular nodes; others pass under the sublingual salivary gland and end in the jugulodigastric or jugulo-omohyoid nodes.

The vessels from the posterior part of the margin of the tongue make their way through the pharyngeal wall to the jugulodigastric lymph nodes.

(2) *Central vessels.* There is no clear line of demarcation between areas on the surface of the tongue draining into the marginal or central vessels. The central lymph vessels descend in the median plane between the genioglossi. Some turn laterally through the muscles, but the majority appear between their free borders and diverge to the right or left, i.e. the vessels from one side of the tongue may run to the lymph nodes of the opposite side. They follow the lingual blood vessels, and end in the deep cervical lymph nodes, especially in the jugulodigastric and jugulo-omohyoid lymph nodes. Some pierce the mylohyoid and enter the submandibular nodes.

(3) *Dorsal vessels.* The vessels draining the area of the vallate papillae, and the part of the tongue behind these papillae, run downwards and backwards—those near the median plane may divide and run to both sides. They turn laterally to join the marginal vessels, and all pierce the pharyngeal wall, passing in front of or behind the external carotid artery, to reach the jugulodigastric and jugulo-omohyoid lymph nodes, or the nodes between them. One vessel may descend behind the hyoid bone, perforate the thyrohyoid membrane, and end in the jugulo-omohyoid node.

Lymphatic drainage of the pharynx and cervical part of the oesophagus. The collecting vessels from the pharynx and cervical part of the oesophagus pass to the deep cervical nodes either directly, or indirectly through the retropharyngeal or paratracheal nodes. From the region of the epiglottis the lymph vessels run to the infrahyoid nodes.

The Lymphatic Drainage of the Upper Limbs

All the lymph vessels of the upper limb drain into a terminal group of lymph nodes in the axilla, either directly, or after passing through an outlying group of lymph nodes. Vessels internal to the deep fascia follow the principal vascular and neurovascular bundles, while the superficial vessels, except in the hand and on the back of the forearm, converge towards the superficial veins, which they closely accompany.

The axillary lymph nodes (**6**.161, 163), which are the terminal group for the whole of the upper limb, are of large size; they vary from twenty to thirty in number, and may be divided into five groups, which are not, however, sharply demarcated:

(1) A *lateral group* (**6**.160) of from four to six lymph nodes lies medial to, and behind, the axillary vein, the afferents of this group drain the whole limb except for the part whose lymph vessels accompany the cephalic vein. The efferent vesssels pass partly to the central and apical groups of axillary nodes, and partly to the lower deep cervical nodes.

(2) An *anterior* or *pectoral group* of four or five lymph nodes lies along the lower border of the pectoralis minor, in relation to the lateral thoracic vessels. Its afferents drain the skin and muscles of the anterior and lateral walls of the body, above the level of the umbilicus, and the central and lateral parts of the mammary gland (p. 790); its efferents pass partly to the central, and partly to the apical groups of axillary lymph nodes.

(3) A *posterior* or *subscapular group* of six or seven lymph nodes extends along the lower margin of the posterior wall of the axilla in the course of the subscapular vessels. The afferents of this group drain the skin and muscles of the lower part of the back of the neck and of the dorsal aspect of the trunk, as low down as the iliac crest; their efferents pass to the apical and to the central group of axillary lymph nodes.

(4) A *central group* of three of four large lymph nodes is embedded in the fat of the axilla. It has no special area of drainage, but it receives afferents from all the preceding groups of axillary lymph nodes: its efferents pass to the apical group.

(5) An *apical group* of six to twelve lymph nodes is situated partly posterior to the upper portion of the pectoralis minor and partly above its upper border, and extends upwards into the apex of the axilla along the medial side of the axillary vein. The only *direct* territorial afferents of this group are those which accompany the cephalic vein and one or two which drain the upper and peripheral part of the mammary gland, but it receives the efferents of all the other axillary lymph nodes. The efferent vessels of this group unite to form the *subclavian trunk*, which opens either directly into the junction of the internal jugular and subclavian veins or into the jugular lymphatic trunk; on the left side it may end in the thoracic duct. A few efferents from the apical group usually pass to the lower deep cervical lymph nodes.

The outlying lymph nodes in the upper limb are few in number. They comprise (1) the supratrochlear group, (2) the infraclavicular group (both interposed on the path of the superficial vessels), and (3) a few isolated lymph nodes occasionally present along the course of the principal blood vessels of the arm and forearm.

(1) The *supratrochlear lymph nodes*, merely one or two in number, are superficial to the deep fascia above the medial epicondyle of the humerus medial to the basilic vein. Their efferents accompany the basilic vein and join the deep lymph vessels.

(2) The *infraclavicular lymph nodes*, one or two in number, are found beside the cephalic vein, between pectoralis major and deltoid, immediately below the clavicle. Their efferents pass through the clavipectoral fascia to the apical group of axillary nodes, or, more rarely, they may pass anterior to the clavicle to reach the lower deep cervical (supraclavicular) group.

6.161 Normal axillary lymphangiogram, four days after injection of ultrafluid lipiodol into a lymph vessel on the dorsum of the hand. 1. Lateral group of lymph nodes. 2. Pectoral group of lymph nodes. 3. Brachial lymph vessels. (Kindly supplied by Professor J. B. Kinmonth.)

(3) Isolated lymph nodes, small in size, sometimes occur in the forearm along the radial, ulnar and interosseous vessels, in the cubital fossa near the bifurcation of the brachial artery, and in the arm along the medial side of the brachial vessels.

Lymphatic drainage of the superficial tissues of the upper limb. The superficial lymph vessels being in the lymphatic plexuses in the skin.

In the hand, the meshes of the plexus are much finer on the palmar than on the dorsal surface. The digital plexuses are drained by vessels which run along the borders of the digits to the webs, where they join vessels from the distal part of the palm and then pass back to the dorsal aspect of the hand (**6**.160, 162). The rest of the palm is drained by vessels which pass proximally towards the wrist, medially to join vessels along the ulnar border of the hand, and laterally to joint those on the thumb. Several collecting vessels from the central part of the palmar plexus unite to form a trunk which winds round the metacarpal bone of the index finger to join the dorsal vessels from the same finger and from the thumb.

In the forearm and arm, the superficial vessels mostly run with the superficial veins. Collecting vessels from the hand pass into the forearm on all aspects of the wrist.

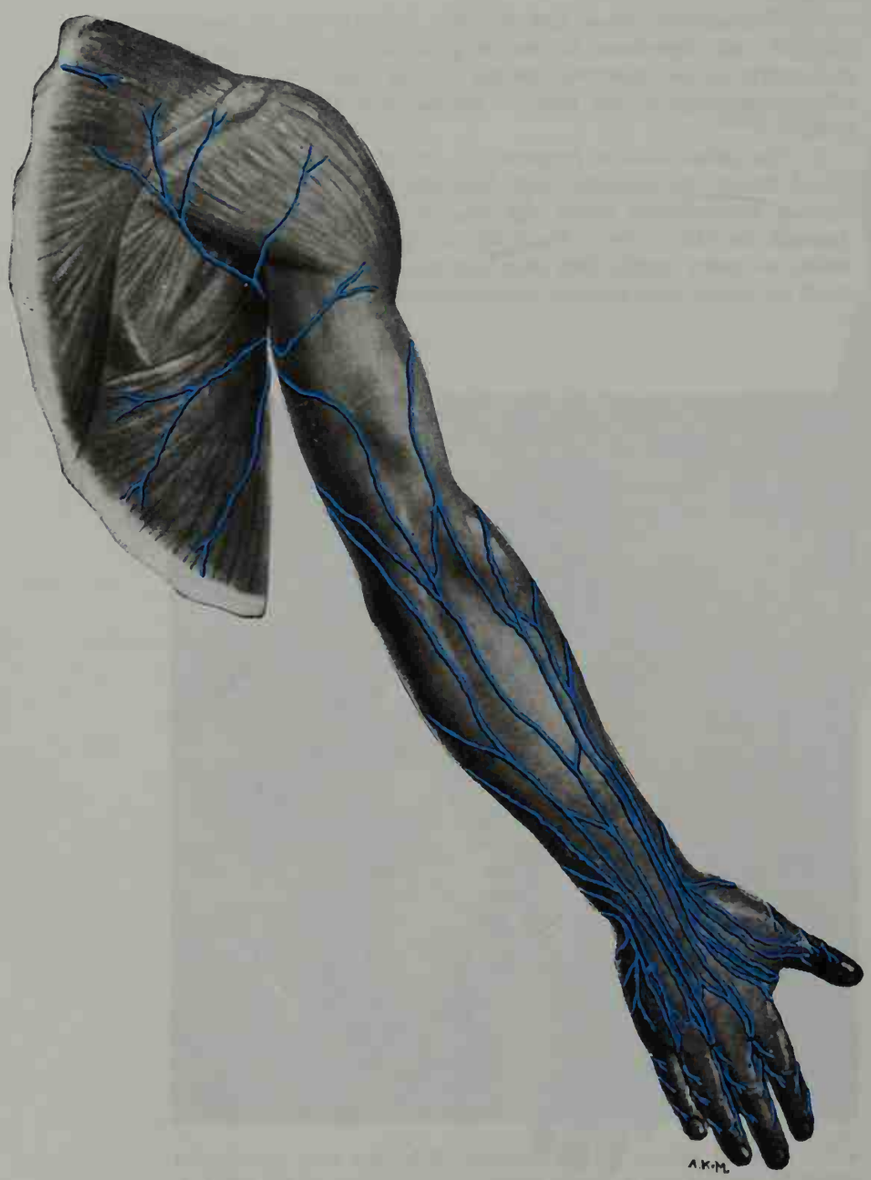
The vessels on the dorsum, after running upwards parallel with one another, finally pass successively round the borders of the limb to join vessels on the front (**6**.162). The vessels on the front of the wrist pass up the forearm parallel with the median vein of the forearm to the cubital region. Beyond this point they follow the medial border of the biceps and pierce the deep fascia at the anterior axillary fold, to end in the lateral group of axillary lymph nodes.

The lateral vessels become associated in the forearm with the cephalic vein. They follow it to the level of the insertion of deltoid, where most incline medially to enter the lateral group of axillary nodes; a few continue with the cephalic vein and end in the infraclavicular nodes. These lateral lymph vessels receive those which wind round the lateral border of the limb from the posterior surface.

The medial vessels follow the basilic vein in the forearm. Just above the elbow some of them end in the supratrochlear lymph nodes. The efferents from these, together with the medial vessels which have bypassed the supratrochlear nodes, pierce the deep fascia with the basilic vein, and end in the lateral group of axillary nodes or the deep lymph vessels. The vessels which wind round the medial border of the limb from the back join those of this medial set.

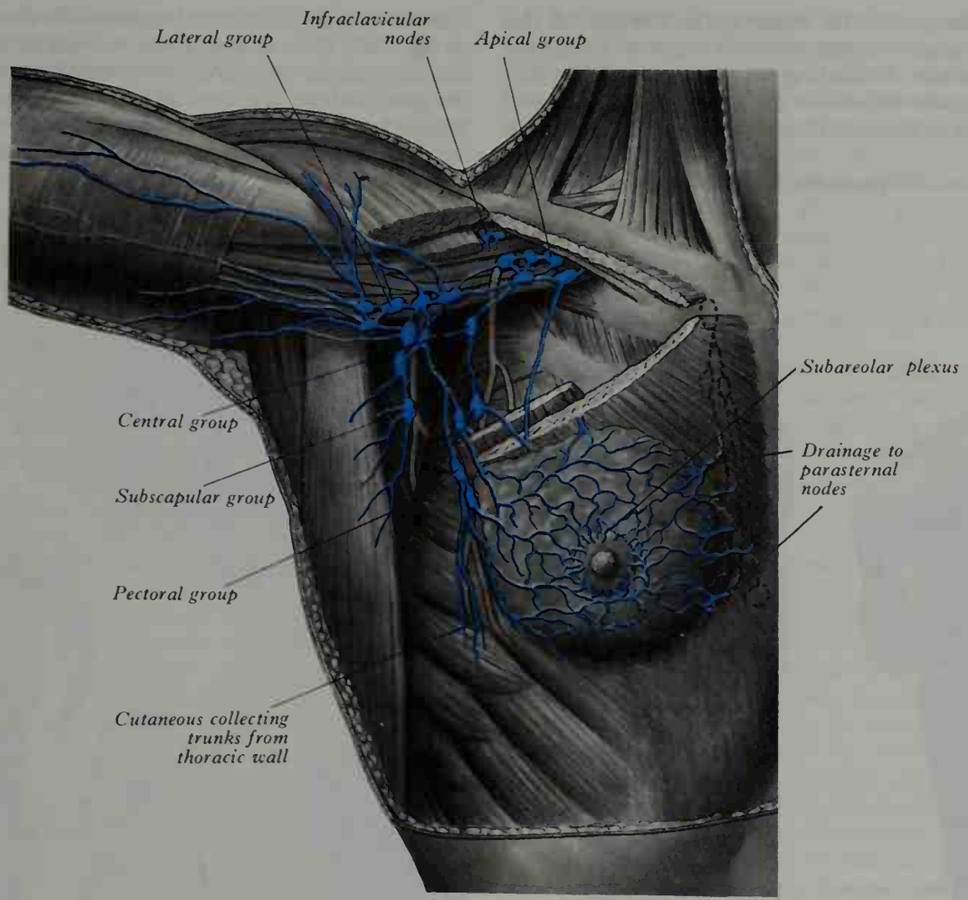
The collecting vessels from the front and back of the deltoid region pass respectively round the anterior and posterior axillary folds to end in the axillary nodes. The skin over the scapular region drains either into the subscapular group of axillary nodes, or following the transverse cervical vessels into the lower deep cervical lymph nodes.

Lymphatic drainage of the deep tissues of the upper limb. The deep lymph vessels follow the main neurovascular bundles (radial, ulnar, interosseous and brachial) and end in the lateral axillary nodes. They are less numerous than the superficial vessels, with which they communicate at intervals. Along their course a few lymph nodes occur.



The muscles of the scapular region are drained by vessels which pass mainly to the subscapular group of axillary lymph nodes. Lymph from the pectoral muscles is drained into the pectoral, central and apical groups.

Lymphatic drainage of the breast (**6**.163). The lymph vessels of the mammary gland originate in a plexus in the interlobular connective tissue and in the walls of the lactiferous ducts. This communicates with the overlying cutaneous lymphatic plexus especially around the nipple in the *subareolar plexus*. It is also claimed to communicate with the plexus of minute vessels on the deep fascia underlying the breast; this anastomosis may play no part in the normal lymphatic pathway from the breast nor in the early spread of cancer from the organ (Turner-Warwick 1959). It offers an alternative route when the usual pathways are obstructed.



Efferent lymph vessels arising directly from the breast pass around the anterior border of the axilla, pierce the axillary fascia and end in the pectoral lymph nodes. Some lymph may pass directly to the subscapular nodes. From the upper part of the breast a few lymph vessels pass to the apical nodes; this pathway may be interrupted in the infraclavicular nodes or in small and inconstant interpectoral nodes. The axillary lymph nodes commonly receive more than 75 per cent of the lymph from the breast. Most of the remainder enters the parasternal nodes which receive lymph vessels from both the medial and lateral halves of the organ; these vessels accompany the perforating branches of the internal thoracic artery. Lymph vessels from the breast occasionally follow the lateral cutaneous branches of the posterior intercostal arteries to the intercostal lymph nodes.

The drainage of the skin over the breast is dealt with on p. 798.

Applied Anatomy. Enlargement of the axillary lymph nodes is frequent in malignant disease and also in infective processes implicating the upper part of the back and shoulder, the front of the chest and mammary gland, the upper part of the front and side of the abdomen, or the upper limb. In operations for carcinoma of the breast the pectoralis major and the deep fascia overlying it and the surrounding muscles are usually removed on account of the wide ramifications of the lymphatics. The axillary lymph nodes, the sternocostal head of pectoralis major and, frequently, the pectoralis minor are also taken away, in an endeavour to ensure, as far as possible, the complete removal of affected lymph vessels and nodes. (Some surgeons, however, now advocate less radical extirpation.) It should be noted that, in disease, the pathological blockage of some of the normal lymph channels can result in a flow of lymph and consequently the spread of disease along other than the usual pathways.

6.162 The lymphatic drainage of the superficial tissues of the upper limb. Posterior aspect. Semi-diagrammatic.

6.163 The lymph vessels of the mammary gland and the axillary lymph nodes.

The Lymphatic Drainage of the Lower Limbs

Most of the lymph from the lower limb traverses a terminal group of lymph nodes in the groin. Before reaching these terminal nodes the lymph may pass through outlying, intermediary nodes, which, however, are less numerous in the lower limb than elsewhere.

The terminal nodes are the inguinal groups, superficial and deep to the deep fascia.

The superficial inguinal lymph nodes (**6**.164, 166, 167) are arranged in upper and lower groups. The *upper group*, usually of five or six nodes, forms a chain immediately below the inguinal ligament. The lateral members of the group receive afferent vessels from the gluteal region and from the adjoining part of the anterior abdominal wall below the umbilicus. The medial members of the group receive the superficial vessels from the external genitalia (including in the female the vagina below the hymen), from the lower part of the anal canal and the perianal region, from the adjoining part of the anterior abdominal wall the umbilicus and uterine lymph vessels which run along the round ligament of the uterus.

The *lower group*, usually four or five in number, is disposed vertically along the terminal part of the great saphenous vein. It receives all the superficial lymph vessels of the lower limb, except those from the back and lateral side of the calf of the leg.

All the superficial inguinal nodes send their efferents to the external iliac lymph nodes, some traversing the femoral canal, others passing in front of, or lateral to the femoral vessels. In addition numerous vessels interconnect the individual nodes.

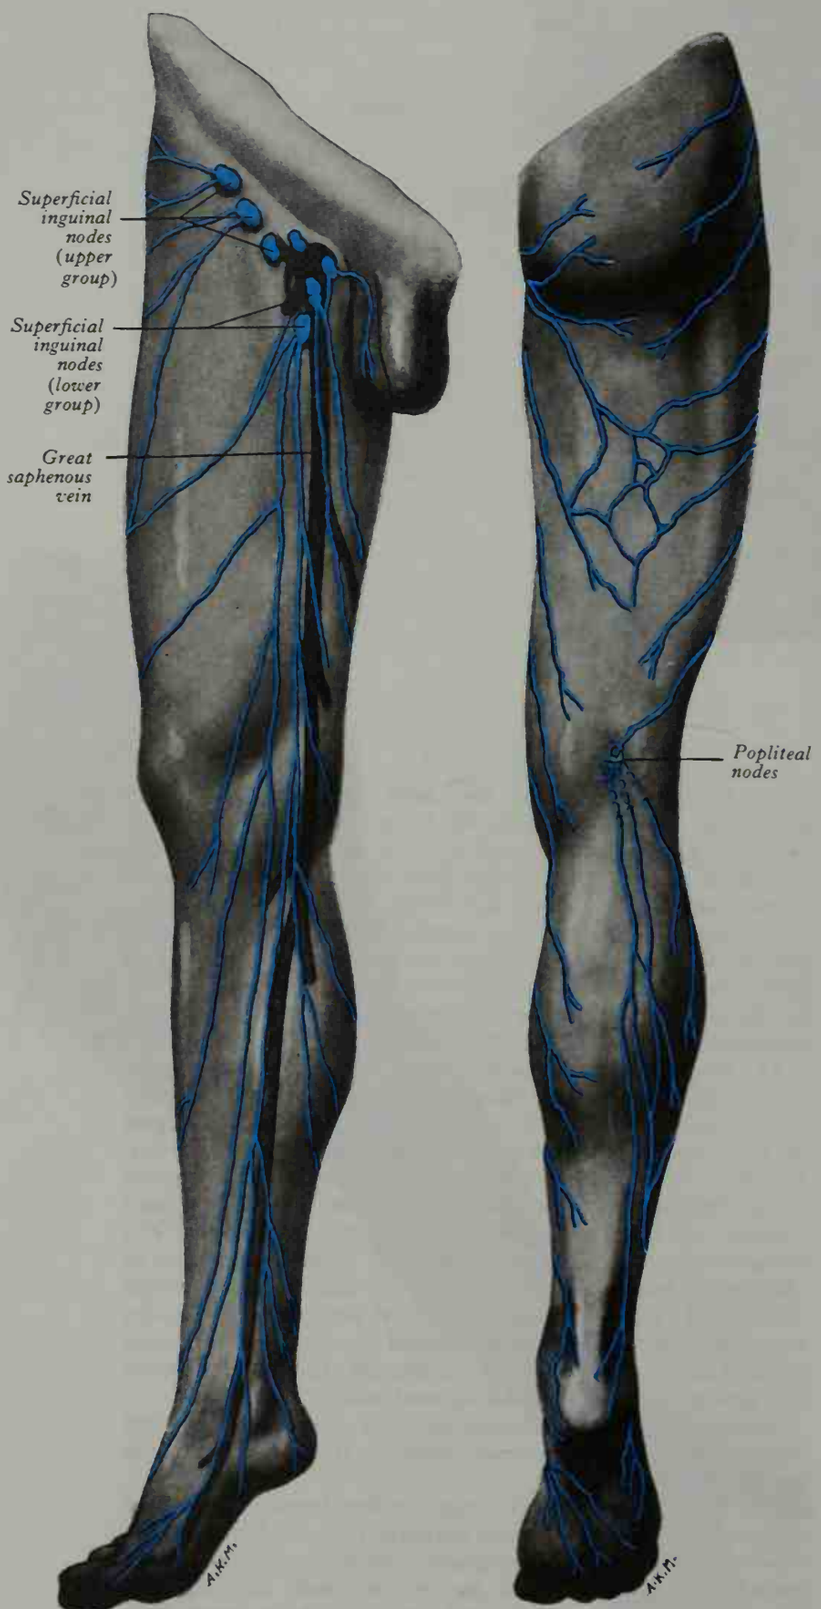
The deep inguinal lymph nodes vary from one to three, and are on the medial side of the femoral vein. When three are present, the lowest is situated just below the junction of the great saphenous and femoral veins, the middle in the femoral canal, and the highest in the lateral part of the femoral ring. The middle one is the most inconstant, but the highest is also frequently absent. They receive as afferents the deep lymph vessels which accompany the femoral vessels, the lymph vessels from the glans penis (or glans clitoridis), and a few of the efferents from the superficial inguinal lymph nodes; their efferents pass through the femoral canal to the external iliac lymph nodes.

The outlying, intermediary lymph nodes are few in number and are all deeply placed. Except for a single node, sometimes present on the upper part of the interosseous membrane of the leg in relation with the anterior tibial vessels, they are restricted to a single group found in the popliteal fossa.

The popliteal lymph nodes (**6**.165), small in size and six or seven in number, are embedded in fat in the popliteal fossa. One lies near the termination of the small saphenous vein, and drains the superficial region from which this vein derives its tributaries. Another is between the popliteal artery and the posterior surface of the knee joint; it receives the lymph vessels from the knee joint together with those which accompany the genicular arteries. The remainder lie at the sides of the popliteal vessels, and receive as afferents the trunks which accompany the anterior and posterior tibial blood vessels. The efferents of the popliteal lymph nodes ascend in close relation with the femoral blood vessels to the deep inguinal nodes, but a few may accompany the great saphenous vein and end in the superficial inguinal nodes.

Applied Anatomy. Inflammation and suppuration of the popliteal lymph nodes are most commonly due to a lesion on the lateral side of the heel.

The superficial inguinal lymph nodes frequently become enlarged in diseases implicating the parts from which their lymph vessels originate. Thus in malignant or syphilitic affections of the prepuce and penis, or labia majora, in scrotal carcinoma, in abscess in the perineum, anus and lower part of the vagina, or in similar diseases affecting the skin and superficial structures in those parts, or the infra-umbilical part of the abdominal wall, or the gluteal region, the upper group of lymph nodes is almost invariably enlarged, the lower group being implicated in diseases affecting the lower limb.



Lymphatic drainage of the superficial tissues of the lower limb. The superficial lymph vessels begin in lymphatic plexuses beneath the skin. Collecting vessels leave the foot in a medial set, whose vessels follow the general course of the great saphenous vein, and a lateral set, associated with the small saphenous vein.

The vessels of the *medial group* are larger and more numerous than those of the lateral, and begin on the tibial side of the dorsum of the foot. They ascend, some in front of the medial malleolus and others behind it, and accompany the great saphenous vein to the groin, where they end in the lower group of the superficial inguinal nodes. The vessels of the *lateral group* begin on the fibular side of the dorsum of the foot. Some of them cross the front of the leg to join the vessels of the medial group and so reach the lower group of the superficial inguinal lymph nodes; others accompany the small saphenous vein and end in the popliteal nodes.

The superficial lymph vessels of the buttock pass round to the front of the limb and terminate in the upper group of the superficial inguinal lymph nodes.

Lymphatic drainage of the deeper tissues of the lower limb. The deep lymph vessels accompany the main blood vessels of the limb and so comprise anterior tibial, posterior tibial, peroneal, popliteal and femoral sets. The deep vessels of the foot and leg are interrupted by the popliteal nodes, but those from the thigh pass direct to the deep inguinal nodes.

The deep lymph vessels of the gluteal and ischial regions follow

6.164 The lymphatic drainage of the superficial tissues of the lower limb. Anteromedial aspect. Semi-diagrammatic.

6.165 The lymphatic drainage of the superficial tissues of the lower limb. Posterior aspect. Semi-diagrammatic.

6.166 Lymphangiogram showing the inguinal lymph vessels and nodes taken immediately following injection of ultrafluid lipiodol into a lymph vessel on the dorsum of the foot. 1. Inguinal lymph nodes. 2. External iliac lymph node. (Kindly supplied by Professor J. B. Kinmonth.)

the course of the corresponding blood vessels. Those accompanying the superior gluteal vessels end in a lymph node which lies on the intrapelvic portion of the superior gluteal artery, near the upper border of the greater sciatic foramen. Those following the inferior gluteal vessels traverse one or two small nodes which lie below the piriformis, and end in the internal iliac lymph nodes.

The Lymphatic Drainage of the Abdomen and Pelvis

The lymph from most of the abdominal wall and from all the abdominal viscera (except a small part of the liver) is returned to the bloodstream via the thoracic duct. The lymph vessels run with the corresponding arteries. The lymph nodes comprise a large number of outlying, intermediary groups which are placed along the arteries concerned, and a smaller number of terminal groups which are all in close relation with the abdominal aorta.

The lumbar lymph nodes (**6**.167) include three principal groups of terminal nodes and one subsidiary group, each of which, though not sharply separated from the others topographically, nevertheless has its own particular area of drainage. These four groups are *pre-aortic*, *lateral aortic* (right and left), and *retro-aortic*. The pre-aortic group drains the viscera supplied by the *ventral branches* of the aorta, i.e. the abdominal part of the alimentary canal and its derivatives. The lateral aortic groups drain the viscera and other structures supplied by the *lateral* and *dorsal branches* of the aorta and receive the efferents from the large, outlying groups associated with the iliac arteries. They therefore constitute the terminal groups for the suprarenal glands, kidneys, ureters, testes, ovaries, pelvic viscera (apart from the gut) and the posterior abdominal wall. The retro-aortic group has no particular area of drainage; although it may have been primarily associated with the drainage of the posterior abdominal wall, it may be regarded as being formed by peripheral members of both lateral aortic groups.

The Pre-aortic Lymph Nodes and their Region of Drainage

The pre-aortic lymph nodes are directly anterior to the abdominal aorta. They receive lymph from the regional, intermediary nodes associated with the subdiaphragmatic part of the alimentary canal, the pancreas, liver and spleen. Their efferents form the *intestinal trunks* which enter the cisterna chyli (p. 785). They are divisible into coeliac, superior mesenteric and inferior mesenteric groups, intimately related to the origins of these arteries.

In the alimentary canal the lymph vessels begin as minute subepithelial radicles, blind at one end but opening at the other into a fine *periglandular plexus*. In the small intestine each villus contains a central lymphatic vessel, known as a *lacteal* from the milky nature of its contents. From the periglandular plexus vessels pierce the muscularis mucosae and join the *submucous plexus*, efferents from which pass through the muscular coat, where they anastomose with or sometimes by-pass vessels draining the muscular coat. The submucous plexus is also joined by vessels from the lymph spaces at the bases of the solitary lymphatic follicles. The lymphatics of the intestinal muscle drain into a plexus of vessels found mainly between the longitudinal and circular coats. The collecting vessels from both sets leave the gut by piercing the muscle and entering larger vessels which follow the arteries in the mesentery.

The collecting vessels from the alimentary canal pass through local groups of lymph nodes before reaching the pre-aortic group.

The coeliac lymph nodes and their areas of drainage. The coeliac lymph nodes lie on the front of the abdominal aorta close to the origin of the coeliac artery. They are the terminal group for the stomach, duodenum, liver, gall bladder, pancreas and spleen, and their afferents are derived from the regional nodes along the branches of the coeliac artery. Of these there are, therefore, three main sets, gastric, hepatic and pancreatico-splenic.

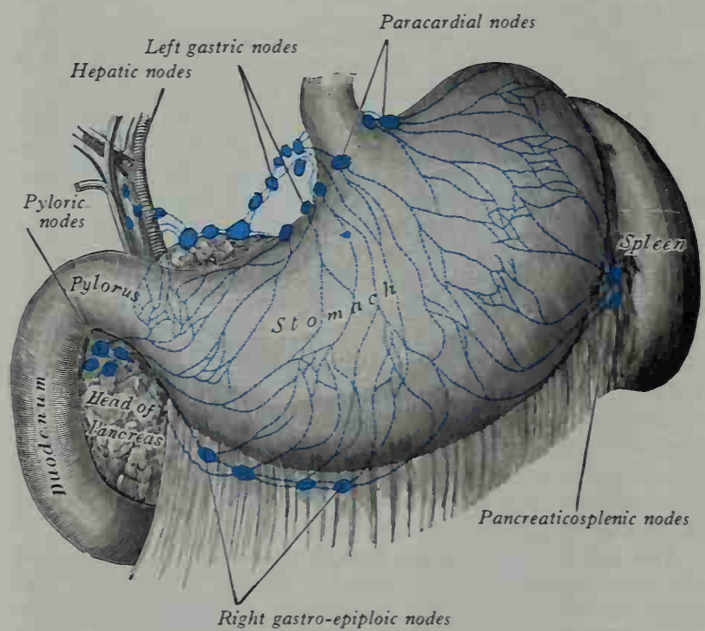
The gastric lymph nodes (**6**.168, 169) consist of left gastric, right gastro-epiploic and pyloric groups.

The *left gastric lymph nodes* lie along the left gastric artery and are themselves divisible into groups, *upper*, on the stem of the artery, *lower*, associated with the descending branches of the artery along the cardiac half of the lesser curvature of the stomach, in the lesser omentum, and *paracardial*, a chain around the cardiac orifice of the stomach. They receive their afferents from the stomach and the abdominal part of the oesophagus; their efferents pass to the coeliac group of pre-aortic nodes.

The *right gastro-epiploic lymph nodes*, four to seven in number, are in the greater omentum along the pyloric half of the greater curvature in relation with the vessels of the same name. They receive afferents from the stomach; their efferents mostly pass to the pyloric lymph nodes.

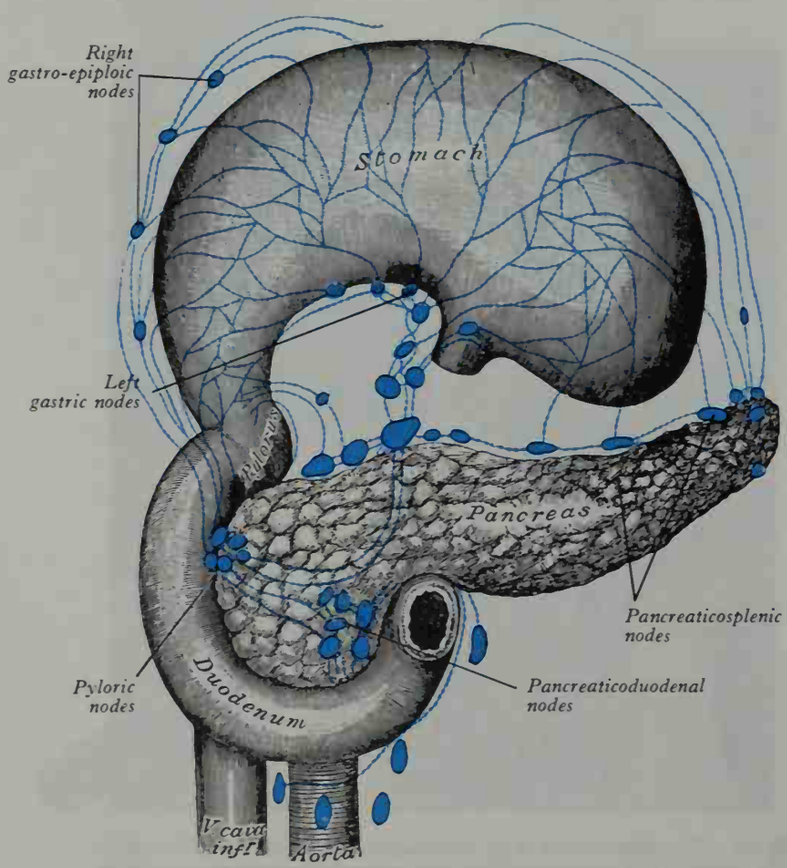
Four or five *pyloric lymph nodes* lie close to the bifurcation of the gastroduodenal artery, in the angle between the superior and descending parts of the duodenum; an outlying member of this group is sometimes found above the duodenum on the right gastric artery. They receive afferents from the pyloric part of the stomach, the first part of the duodenum, and the right gastro-epiploic nodes; their efferents end in the coeliac group.

The hepatic lymph nodes (**6**.168) extend in the lesser omentum along the common hepatic artery and the hepatic artery proper, together with its right and left branches, as well as the bile duct. They vary in number and position, but two are fairly constant: one at the junction of the cystic and common hepatic ducts, known as the *cystic node* (or node of the neck of the gall bladder), the other alongside the upper part of the bile duct is sometimes called the *node of the anterior border of the epiploic foramen*. The hepatic nodes receive afferents from the stomach, duodenum, liver, gall bladder, bile ducts and the pancreas; their efferents pass through the coeliac nodes. Pathologically enlarged hepatic nodes may press on and obstruct the portal vein.



The pancreaticosplenic lymph nodes (**6**.169) accompany the splenic artery, and are related to the posterior surface and upper border of the pancreas; one or two of this group are in the gastrosplenic ligament. Their afferents are derived from the stomach, spleen, and pancreas; their efferents join the coeliac group.

Lymphatic drainage of the stomach and duodenum. The



6.167 The lymph nodes in the inguinal region and abdomen seen after the injection of a contrast medium into a lymph vessel on the dorsum of the foot. 1. Inguinal lymph nodes. 2. External iliac lymph nodes. 3. Common iliac lymph nodes. 4. Lateral aortic lymph nodes. (Kindly supplied by Dr. S. J. R. Reynolds.)

lymph vessels of the stomach (**6**.168, 169) are continuous at the cardiac orifice with those of the oesophagus, and at the pylorus with those of the duodenum. They follow the blood vessels for the most part, and may be described in four sets. Vessels of the first set accompany the branches of the left gastric artery, receive tributaries from a large area on both surfaces of the stomach, and terminate in the left gastric lymph nodes. Those of the second set drain the fundus and body of the stomach to the left of a vertical line from the oesophagus; they accompany the short gastric and left gastro-epiploic vessels and end in the pancreaticosplenic nodes. Vessels of the third set drain the right part of the greater curvature as far as the pylorus, and end in the right gastro-epiploic lymph nodes, the efferents of which pass to the pyloric group. Those of the fourth set drain the pyloric part of the stomach and pass to the hepatic, pyloric, and left gastric nodes. Although the vessels of these regions communicate, their valves are arranged to direct lymph from the right part of the stomach towards the lesser curvature and from the left towards the greater curvature.

6.168 The lymphatic drainage of the stomach and duodenum. (After Jamieson and Dobson.)

6.169 The lymph vessels and nodes of the stomach, duodenum and pancreas. The stomach has been turned upwards. (After Jamieson and Dobson.)

The *lymph vessels of the duodenum* run anteriorly and posteriorly into a series of small *pyloric lymph nodes*, on the anterior and posterior parts of the groove between the head of the pancreas and duodenum. Their efferents run upwards to the hepatic nodes, and downwards to the pre-aortic nodes, around the origin of the superior mesenteric artery.

Lymphatic drainage of the liver. The collecting vessels from the liver are divisible into superficial and deep systems.

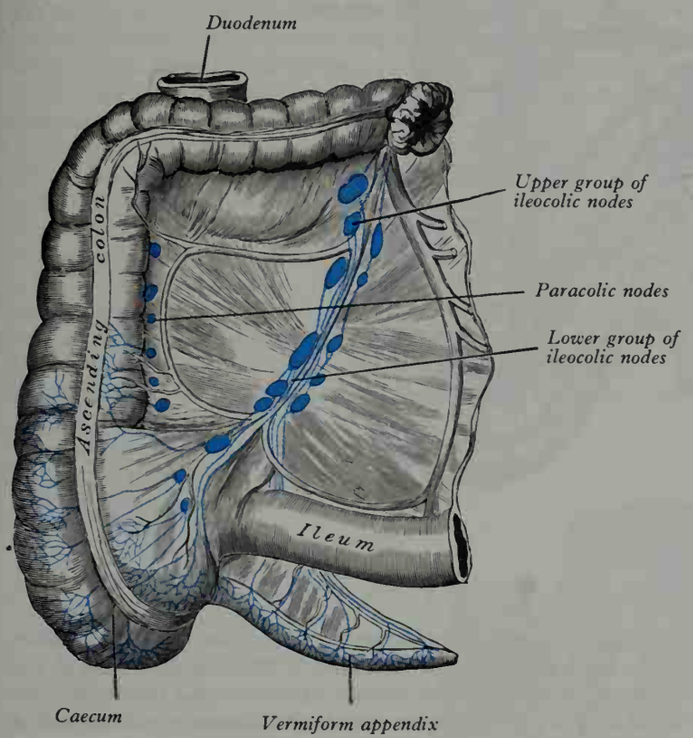
The *superficial lymph vessels of the liver* run in the subserous areolar tissue over the whole surface of the organ. They drain in four directions: (1) From the middle part of the posterior surface, from the caudate lobe, from the posterior part of the convex surfaces of both lobes near the attachment of the falciform ligament, and from the posterior part of the inferior surface of the right lobe the vessels accompany the inferior vena cava to nodes round its terminal part. The lymph vessels in the coronary and right triangular ligaments may enter the thoracic duct. (2) The vessels from the remainder of the inferior surface, and from the anterior part of the convex surface of both lobes near the attachment of the falciform ligament, converge on the porta hepatis and end in the hepatic group of lymph nodes. (3) From the posterior part of the left lobe a few vessels pass towards the oesophageal opening in the diaphragm and end in the paracardial lymph nodes. (4) From the rest of the convex surface of the right lobe one or two trunks accompany the inferior phrenic artery across the right crus of the diaphragm to the coeliac nodes.

The *deep lymph vessels* of the liver join to form ascending and descending trunks. The ascending trunks accompany the hepatic veins and pass through the vena caval opening in the diaphragm to end in the nodes round the end of the inferior vena cava. The descending trunks emerge from the porta hepatis and end in the hepatic lymph nodes. (See also p. 1379.)

Lymphatic drainage of the gall bladder and bile ducts. Numerous lymph vessels run from the submucous and subserous plexuses on all surfaces of the gall bladder and cystic duct, those on the upper surface communicating sparsely with vessels in the liver. They pass to the hepatic nodes, especially the cystic node and the node of the anterior border of the epiploic foramen (p. 793). These nodes also collect the lymph vessels of the hepatic ducts and the upper part of the bile duct, while those of the lower part of the bile duct drain into the lower hepatic nodes and the upper pancreaticosplenic nodes.

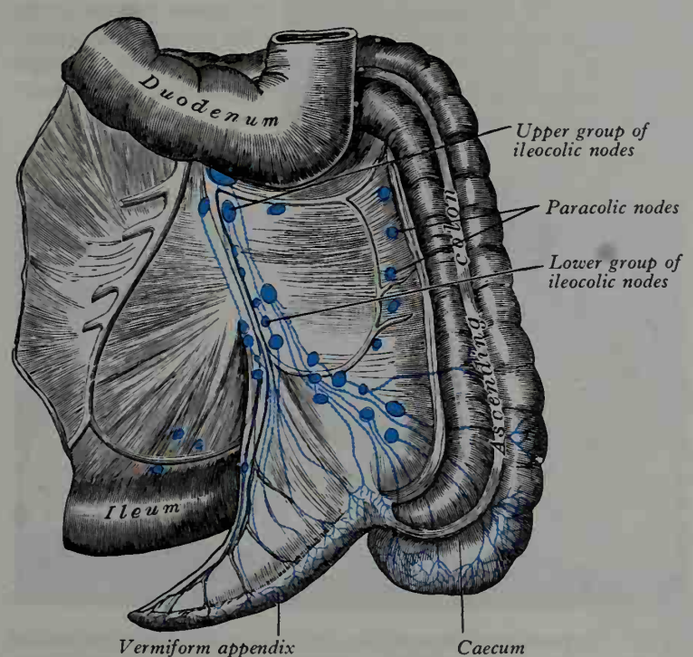
Lymphatic drainage of the pancreas. The lymph capillaries commence around the acini and the lymph vessels follow the course of the blood vessels; there are no lymph vessels in the interalveolar cell islets. Most of the vessels end in the pancreaticosplenic nodes, but some end in lymph nodes along the pancreaticoduodenal vessels and others in the superior mesenteric group of pre-aortic nodes.

Lymphatic drainage of the spleen. The collecting vessels from the capsule of the spleen end in the pancreaticosplenic lymph nodes.



The superior and inferior mesenteric lymph nodes and their area of drainage. The superior and inferior mesenteric lymph nodes lie on the front of the abdominal aorta close to the points of origin of the arteries so named. They are the terminal groups for the alimentary canal, from the duodenojejunal flexure to the upper part of the anal canal, and collect from the outlying groups, which include the lymph nodes of the mesentery, the ileocolic nodes, nodes of the colon and the pararectal nodes.

The lymph nodes of the mesentery number about one hundred to one hundred and fifty and comprise three series, viz.: one close to the wall of the intestine amongst the terminal twigs of the jejunal and ileal arteries; a second, among the loops and primary branches of the vessels; and a third, along the upper part



of the trunk of the superior mesenteric artery. Lymph vessels from the terminal few inches of the ileum follow the ileal branch of the ileocolic artery to the ileocolic nodes.

Applied Anatomy. Enlargement of mesenteric lymph nodes occurs in many diseases of the intestine, and is well marked in typhoid fever, tuberculous ulceration and malignant tumours of the region. The enlarged nodes can often be palpated through the wall of the abdomen.

The ileocolic lymph nodes (**6**.160, 171) form a *chain* of ten to twenty around the ileocolic artery, but show a tendency to subdivision into two groups, one near the duodenum and another along the lower part of the artery. Where the vessel divides into its terminal branches, the chain is broken up into several groups, (*a*) *ileal*, in relation to the ileal branch; (*b*) *anterior ileocolic*, usually three in number, in the ileocaecal fold, near the wall of the caecum; (*c*) *posterior ileocolic*, mostly in the angle between the ileum and the colon, but partly behind the caecum at its junction with the ascending colon; (*d*) appendicular, a single lymph node in the meso-appendix.

6.170 The lymph vessels and nodes of the caecum and vermiform appendix. Anterior aspect. (After Jamieson and Dobson.)

6.171 The lymph vessels and nodes of the caecum and vermiform appendix. Posterior aspect. (After Jamieson and Dobson.)

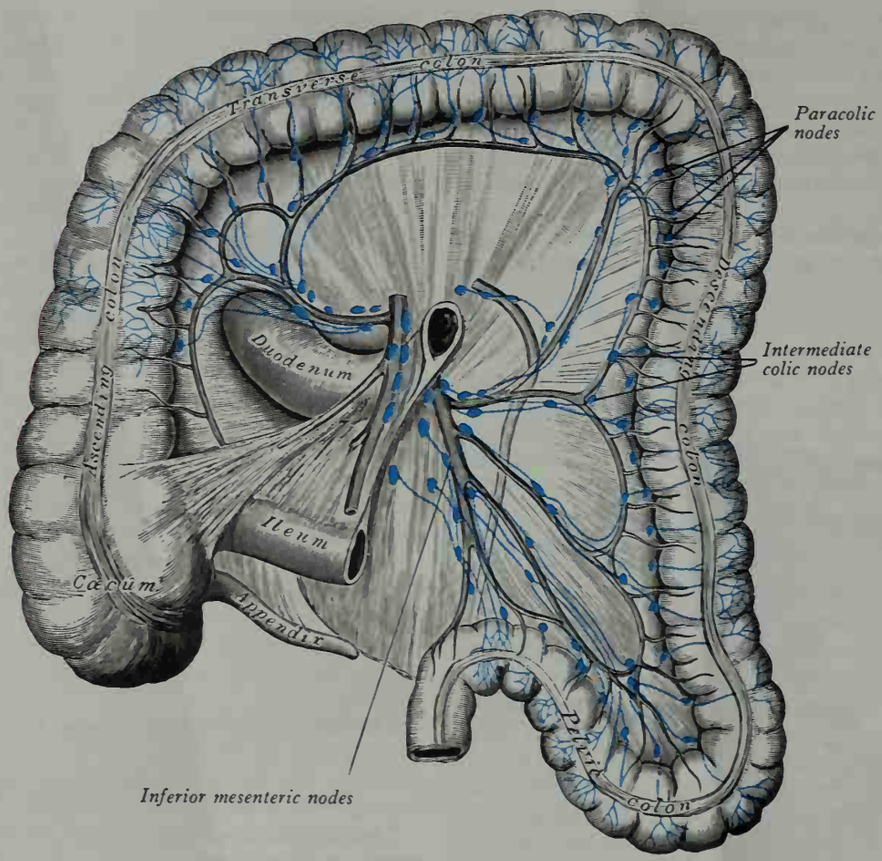
The lymph nodes of the colon are in four groups: (*a*) epicolic, (*b*) paracolic, (*c*) intermediate colic and (*d*) terminal colic.

The *epicolic nodes* are merely minute nodules situated on the wall of the gut, sometimes in the appendices epiploicae. The *paracolic nodes* lie along the medial borders of the ascending and descending colon, and along the mesenteric border of the transverse and sigmoid colon. The *intermediate colic nodes* lie along the right, middle and left colic arteries. The *terminal colic nodes* are near the main trunks of the superior and inferior mesenteric arteries, and are continuous with the corresponding pre-aortic nodes.

The pararectal lymph nodes lie in contact with the muscular coat of the rectum. Their efferents pass to an intermediate group around the superior rectal artery and thence to the nodes at the origin of the inferior mesenteric artery. Others pass to the lymph nodes at the bifurcation of the common iliac artery.

Lymphatic drainage of the jejunum and ileum. The lacteals pass between the layers of the mesentery but, before reaching the superior mesenteric nodes, the lymph passes through the nodes in the mesentery.

Lymphatic drainage of the vermiform appendix and caecum (**6**.170, 171). The lymph vessels are numerous, since there is a large amount of lymphoid tissue in the walls of these parts of the digestive tube. From the body and tip of the vermiform appendix eight to fifteen vessels ascend in the meso-appendix, one or two being interrupted by nodes which lie in this peritoneal fold. They unite to form three or four vessels, which end in the lower and upper lymph nodes of the ileocolic chain. The vessels from the root of the vermiform appendix and from the caecum comprise anterior and posterior groups. The anterior vessels pass in front of the caecum, to the anterior ileocolic nodes and the upper and lower nodes of the ileocolic chain; the posterior vessels ascend over the back of the caecum to the posterior ileocolic nodes and the lower nodes of the ileocolic chain.



Lymphatic drainage of the colon (**6**.172). The lymph vessels of the ascending and transverse parts of the colon end in the superior mesenteric lymph nodes, after traversing the groups of nodes along the right and middle colic arteries and their branches. Those of the descending and sigmoid parts of the colon are interrupted by the small nodes on the branches of the left colic arteries, and ultimately end in the pre-aortic lymph nodes around the origin of the inferior mesenteric artery.

Lymphatic drainage of the rectum and anal canal. From the upper half, or more, of the rectum the lymph vessels emerge from its wall and ascend along the superior rectal vessels, through the pararectal lymph nodes to reach the nodes in the lower part of the sigmoid mesocolon and those associated with the inferior mesenteric artery. From the lower half, and from the anal canal *above the mucocutaneous junction* the lymph vessels pass upwards through the wall of the gut and accompany the middle rectal vessels to the internal iliac nodes. Some of these are said to pierce the insertion of levator ani and to gain the ischiorectal fossa where they accompany the inferior rectal and internal pudendal vessels to reach the internal iliac nodes.

The lymph vessels of the anal canal *below the mucocutaneous junction* descend to the anal margin and then pass laterally to reach the most medial of the superficial inguinal lymph nodes.

The Lateral Aortic Lymph Nodes and their Area of Drainage (**6**.167, 173)

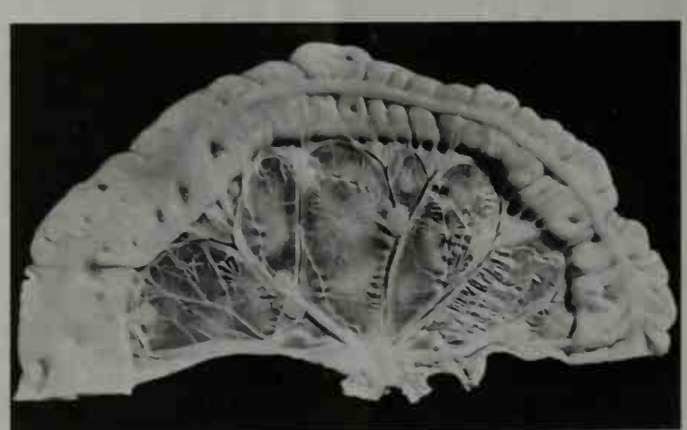
The lateral aortic lymph nodes lie on each side of the abdominal aorta in front of the medial margin of the psoas major, the crus of the diaphragm and the sympathetic trunk. On the right side some

6.172A The lymph vessels and nodes of the colon. (After Jamieson and Dobson.)

of the group lie lateral to the inferior vena cava and in front of the vessel near the termination of the right renal vein. Afferents reach these nodes from the structures supplied by the lateral and dorsal branches of the aorta and from outlying nodes associated with the iliac arteries and their branches. Efferents from the lateral aortic lymph nodes form a *lumbar trunk* on each side, and both terminate in the cisterna chyli. A few efferents may pass to the pre-aortic and retro-aortic groups. Efferents from the right lumbar lymph trunk and its nodes usually cross over the midline to their left counterparts.

The lymph vessels from the kidney, adrenal gland, abdominal part of the ureter, posterior abdominal wall, testis and ovary, uterine tube and upper part of the uterus, all pass directly to the lateral aortic lymph nodes. Lymph vessels from the pelvis, most of the pelvic viscera, and from the lateral and anterior parts of the abdominal wall, pass first through outlying groups of lymph nodes associated largely with the internal iliac arteries and their numerous branches.

They include the following groups:



Common iliac.	Inferior epigastric.
External iliac.	Circumflex iliac.
Internal iliac.	Sacral.

The common iliac lymph nodes (four to six), are grouped around the common iliac artery, one or two below the bifurcation of the aorta in front of the fifth lumbar vertebra or the sacral promontory. They receive efferents from the external and internal iliac nodes, and send their efferents to the lateral aortic group. They are usually arranged in medial, lateral and intermediate (anterior) chains, the lateral being the main drainage route.

The external iliac lymph nodes (**6**.167) (eight to ten), lie along the external iliac vessels. They are usually in three groups, one lateral, another medial, and a third anterior to the vessels, but the anterior group is inconstant. The medial chain or group is considered to be the main channel of drainage. They collect from the inguinal lymph nodes (p. 791), from the deeper layers of the infra-umbilical part of the abdominal wall, from the adductor region of the thigh, from the glans penis or clitoridis, the membranous urethra, prostate, fundus of the urinary bladder, cervix uteri and part of the vagina. Their efferents pass to the common iliac nodes. The *inferior epigastric* and *circumflex iliac nodes*, associated with these vessels and draining corresponding areas, are outlying members of the external iliac group, inconstant in number.

The internal iliac lymph nodes surround the internal iliac vessels. They receive afferents from all the pelvic viscera, from the deeper parts of the perineum, and from the muscles of the buttock and back of the thigh. Their efferents pass to the common iliac nodes. The *sacral lymph nodes*, along the median and lateral sacral vessels, and the *obturator lymph node*, sometimes present in the obturator canal, are outlying members of the internal iliac group.

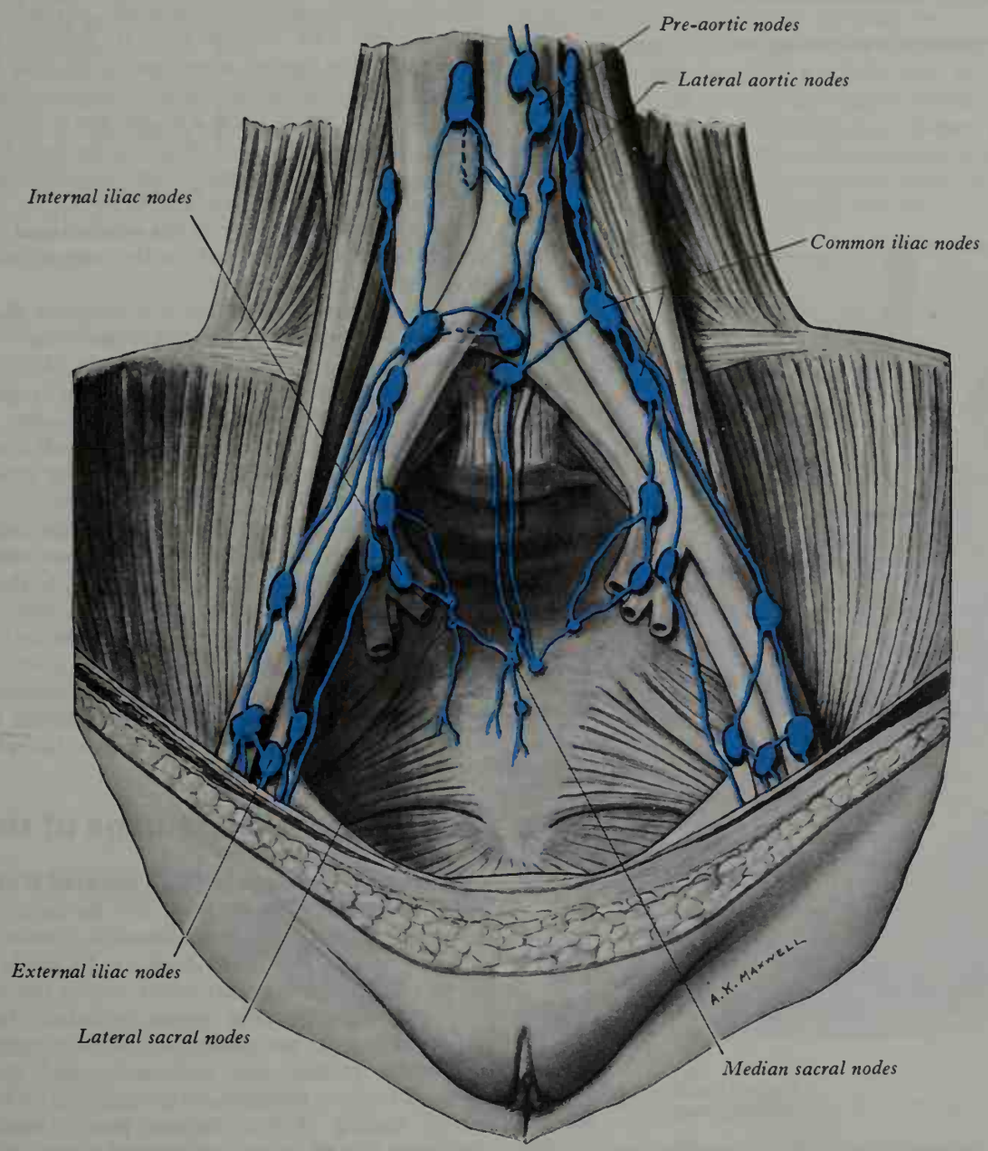
There is considerable by-passing in the iliac groups of lymph nodes. Lymphangiographic studies have also demonstrated interconnexions between the right and left groups.

6.172B Preparation of human colon and mesocolon displaying arterial arcades, neurovascular bundles, lymphatics and paracolic and intermediate lymph nodes. (Kindly provided by Prof. S. Kubic, University of Zürich.)

Lymphatic drainage of the urinary tract. (*a*) The *kidney*. The lymph vessels of the kidney begin in three plexuses: one between and around the renal tubules, a second beneath the fibrous capsule, and a third in the perirenal fat which communicates freely with the sub-capular plexus. The collecting vessels from the intrarenal plexus form four or five trunks which follow the renal vein and end in the lateral aortic nodes; as they issue from the hilum they are joined by the collecting vessels from the sub-capsular plexus. The plexus in the renal fat drains directly into the same nodes.

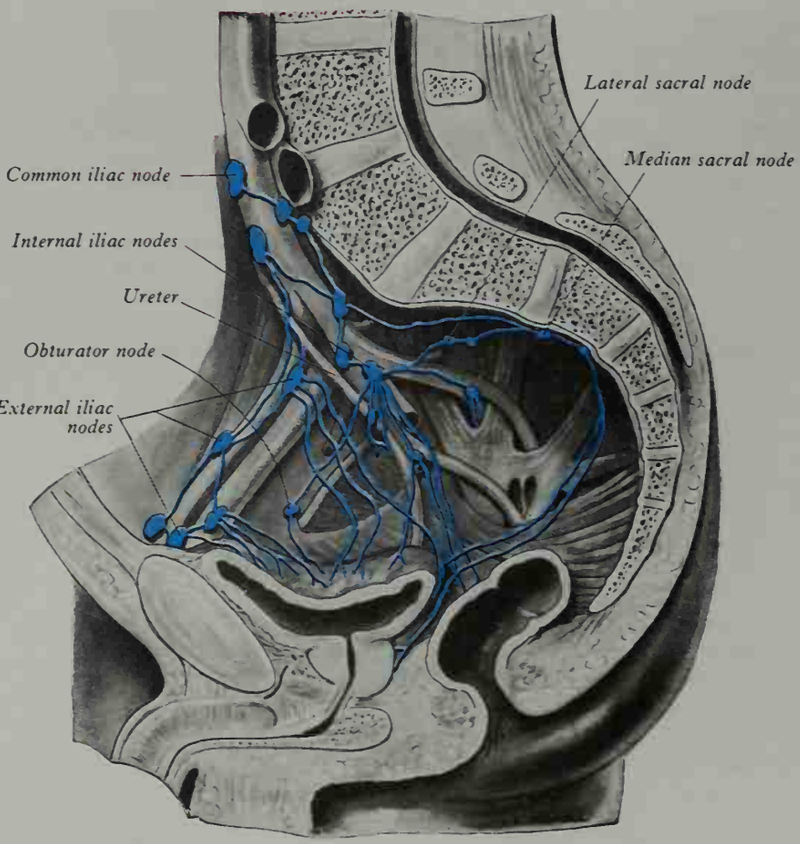
(*b*) The *ureter*. The lymph vessels begin in submucous, intramuscular and adventitial plexuses which communicate with each other. The collecting vessels from the upper part of the ureter may join the renal collecting vessels or may pass directly to the lateral aortic nodes near the origin of the testicular or ovarian artery; those from the succeeding part pass to the common iliac nodes; and those from the pelvic part may end in the common, the external or the internal iliac lymph nodes.

(*c*) The *bladder*. The vesical lymph vessels (**6**.174) take origin in three plexuses—mucous, intramuscular and extramuscular. The collecting vessels, nearly all of which end in the external iliac nodes, are arranged in three sets: the vessels from the region of the trigone emerge on the base of the bladder and run upwards and laterally; those from the superior surface converge on the posterolateral angle and then pass upwards and laterally across the lateral umbilical ligament to reach the external iliac lymph nodes (one of these vessels may go to the internal or common iliac group); those from the inferolateral surface pass upwards to run with those from the superior surface. Minute nodules of lymphoid tissue may be found along the course of the lymph vessels of the bladder.



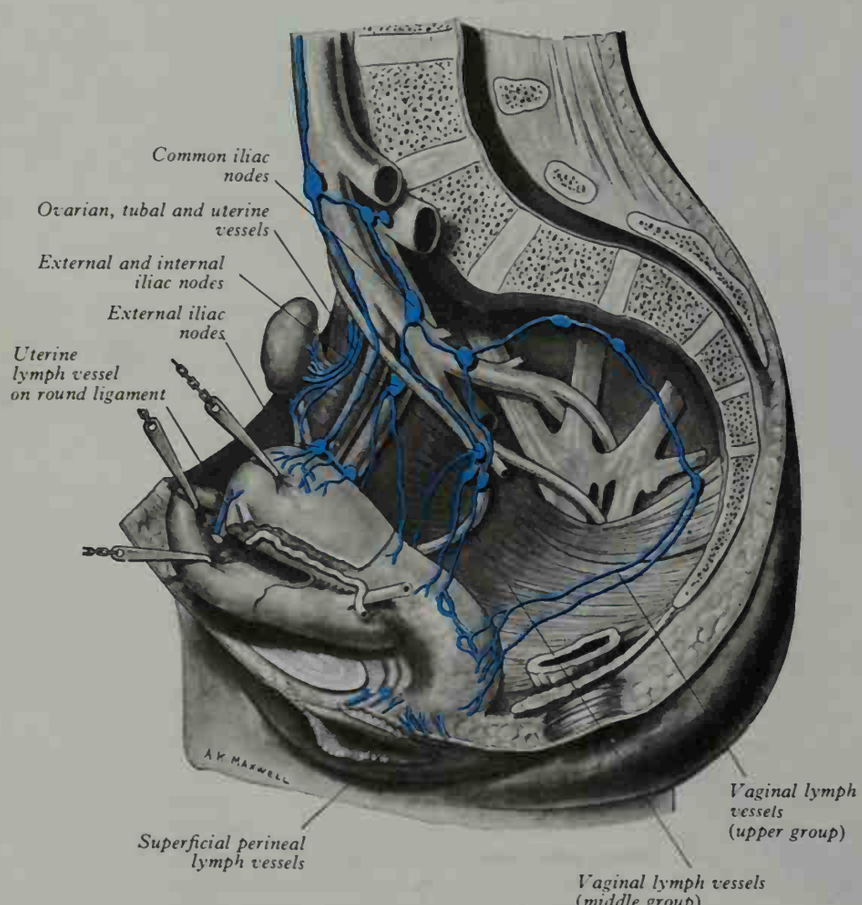
(*d*) The *urethra*. (i) The vessels derived from the prostatic and membranous parts in the male, and from the whole urethra in the female, pass mainly to the internal iliac nodes; a few may end in the external iliac lymph nodes. The vessels from the membranous part accompany the internal pudendal artery.

(ii) The vessels of the male spongiose urethra accompany those of the glans penis and end in the deep inguinal nodes. Some may terminate in the superficial nodes, and others may pass along the inguinal canal to reach the external iliac group.



Lymphatic drainage of the male reproductive organs. (*a*) The *testis*. The lymph vessels of the testis commence in two plexuses—superficial, under the tunica vaginalis, and deep, in the substance of the testis and in the epididymis. Four to eight collecting trunks ascend in the spermatic cord and accompany the testicular vessels as they lie on the psoas major; they end in the lateral aortic and pre-aortic lymph nodes.

(*b*) The *ductus deferens, seminal vesicle and prostate gland*. The collecting vessels from the ductus end in the external iliac nodes, those from the seminal vesicle go to both the internal and external iliac groups.



The prostatic vessels terminate chiefly in the internal iliac and sacral nodes; a trunk from the posterior surface passes with the lymph vessels of the bladder to the external iliac nodes, and another from the anterior surface gains the internal iliac group by joining the vessels of the membranous urethra.

6.173 The lymph vessels and nodes of the pelvis.

6.174 The lymphatic drainage of the urinary bladder. Semi-diagrammatic.

6.175 The lymphatic drainage of the female reproductive organs. Semi-diagrammatic. (After Cunéo and Marcille.)

(*c*) The *scrotum and penis*. The skin covering these parts is drained by vessels which, together with those of the whole of the perineal skin, pass along the course of the external pudendal blood vessels to the superficial inguinal nodes. The lymph vessels of the glans penis pass to the deep inguinal and external iliac groups. The lymph drainage of the erectile tissue and the penile urethra is into the internal iliac lymph nodes.

Lymphatic drainage of the female reproductive organs (**6.175**). (*a*) The *ovary*. The vessels, like those of the testis, ascend along the ovarian artery to the lateral aortic and pre-aortic lymph nodes.

(*b*) The *uterus and uterine tube*. The lymph vessels of the uterus comprise two sets: superficial, beneath the peritoneum, and deep, in the substance of the uterine wall. Collecting vessels from the cervix pass in three directions: laterally in the parametrium to the external iliac nodes; posterolaterally to the internal iliac nodes; and backwards in the sacrogenital fold to the rectal and sacral nodes. Some cervical efferents may also reach the obturator or gluteal nodes. The vessels from the lower part of the body pass mostly to the external iliac lymph nodes, accompanying those from the cervix. From the upper part of the body, the fundus and the uterine tube the vessels accompany those of the ovary to the lateral aortic and pre-aortic nodes; a few, however, pass to external iliac nodes. The region near the point of entry of the uterine tube is drained by vessels which accompany the round ligament and so reach the superficial inguinal nodes. The lymph vessels of the uterus enlarge greatly during pregnancy.

(*c*) The *vagina*. The lymph vessels link up with those of the cervix uteri, the rectum and the vulva. They are in three groups, but the areas drained are not sharply demarcated. The upper vessels accompany the uterine artery to the internal and external iliac nodes. The middle part is drained by vessels which accompany the vaginal artery to the internal iliac lymph nodes. The vessels of the vagina below the hymen, those of the vulva and the skin of the perineum as a whole pass to the superficial inguinal nodes, but the clitoris and labia minora drain to the deep inguinal nodes, and direct efferents from the clitoris may pass to the internal iliac lymph nodes (Kubik 1967).

Lymphatic drainage of the abdominal wall. These vessels are in two sets: superficial, in the superficial fascia, and deep, draining with muscles, etc.

The *superficial lymph vessels* accompany the superficial blood vessels. The lumbar and gluteal vessels, run with the superficial circumflex iliac vessels, those from the skin of the anterior wall below the umbilicus with the superficial epigastric vessels. Both sets drain into the superficial inguinal nodes. The region above the umbilicus is drained by vessels which chiefly run obliquely upwards to the pectoral and subscapular groups of the axillary nodes; a few end in the parasternal nodes.

The *deep lymph vessels* accompany the deep arteries. Those from the posterior abdominal wall pass without interruption along the course of the lumbar arteries, to the lateral aortic and retro-aortic lymph nodes; those from the upper part of the anterior abdominal wall run with the superior epigastric vessels to the parasternal nodes, those of the lower part end in the circumflex iliac, inferior epigastric, and external iliac nodes. The vessels of the pelvic wall follow the internal iliac artery and its parietal branches and end in the iliac or lateral aortic nodes.

The Lymphatic Drainage of the Thorax

Lymphatic Drainage of the Thoracic Walls

Superficial lymph vessels of the thoracic wall ramify subcutaneously and converge on the axillary nodes. Those superficial to trapezius and latissimus dorsi run forwards and unite to form about ten or twelve trunks which end in the subscapular group. Those over the pectoral region, including the vessels from the skin covering the peripheral part of the mammary gland and the subareolar plexus, run backwards, and those superficial to serratus anterior upwards, to the pectoral nodes. Others near the lateral margin of the sternum pass inwards between costal cartilages to end in the parasternal nodes, while the vessels of both sides anastomose across the front of the sternum. A few

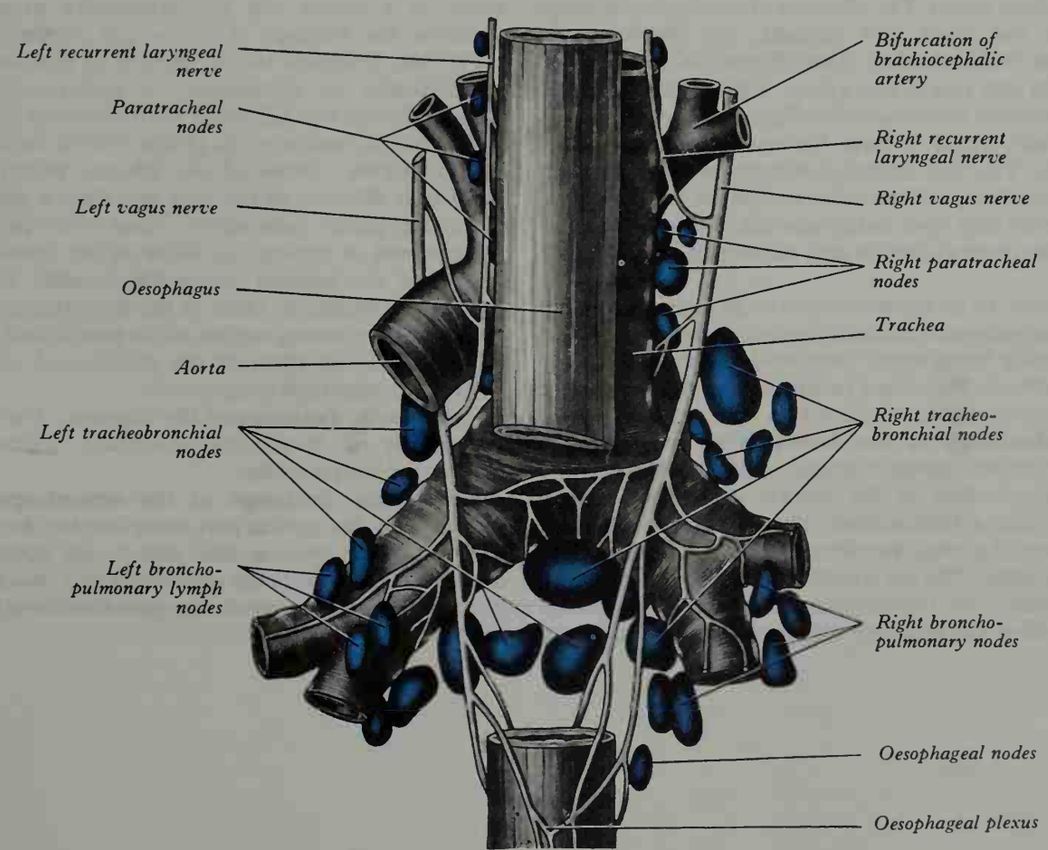
vessels from the upper part of the pectoral region ascend over the clavicle to the inferior deep cervical lymph nodes.

Lymph vessels from the *deeper* tissues of the thoracic walls drain mainly into three sets of nodes—parasternal, intercostal, and diaphragmatic.

(*a*) **The parasternal (internal thoracic) lymph nodes**, four or five on each side, are at the anterior ends of the intercostal spaces, alongside the internal thoracic artery. They derive afferents from the mammary gland, the deeper structures of the anterior abdominal wall above the umbilicus, the upper surface of the liver through a small group of lymph nodes which lies behind the xiphoid process, and from the deeper parts of the anterior region of the thoracic wall. Their efferents usually unite with those of the tracheobronchial and brachiocephalic nodes to form a single trunk, the *bronchomediastinal trunk*; this may open directly into the junction of the internal jugular and subclavian veins, but on the right side it may join the right subclavian trunk, and on the left, the thoracic duct.

(*b*) **The intercostal lymph nodes** are in the posterior parts of the intercostal spaces in relation to the heads and necks of the ribs. They receive the deep lymph vessels from the posterolateral aspect of the chest and from the mammary gland; some of these vessels are interrupted by small lateral intercostal lymph nodes. The efferents of the nodes in the lower four or five spaces unite to form a trunk which *descends* and opens either into the cisterna chyli or into the commencement of the thoracic duct (p. 784). The efferents of the lymph nodes in the upper spaces of the left side end in the thoracic duct, those of the corresponding right spaces in the right lymphatic duct.

(*c*) **The diaphragmatic lymph nodes** are on the thoracic surface of the diaphragm, and consist of anterior, right and left lateral, and posterior groups.



The *anterior* group consists of two or three small nodes behind the base of the xiphoid process, which receive afferents from the convex surface of the liver, and one or two nodes on each side near the junction of the seventh rib with its cartilage, which receive lymph vessels from the front of the diaphragm. The efferent vessels of the anterior set pass to the parasternal nodes.

The *lateral* groups consist of two or three nodes on each side close to where the phrenic nerves enter the diaphragm. On the right side some of the nodes of this group lie within the fibrous wall of the pericardium on the front of the termination of the inferior vena cava. Their afferents are from the middle part of the diaphragm, those on the right side also receiving afferents from the convex surface of the liver. Their efferents pass to the posterior mediastinal, parasternal and brachiocephalic nodes.

The *posterior* group consists of a few nodes on the back of the crura of the diaphragm, connected on the one hand with the lateral aortic nodes, and on the other with the posterior mediastinal nodes.

Lymphatic drainage of the deeper tissues. The collecting lymph vessels from the deeper tissues include the following:

(*a*) Lymph vessels of the muscles attached to the ribs: most of these end in the axillary lymph nodes, but some from pectoralis major pass to the parasternal nodes. (*b*) Intercostal vessels which drain the intercostal muscles and parietal pleura; those from the anterior half of the thoracic wall and pleura end in the parasternal nodes; those from the posterior half, in the intercostal nodes. (*c*) Vessels of the diaphragm, which form two plexuses, one on its thoracic and another on its abdominal surface; these anastomose freely with each other, and are best marked in areas covered respectively by the pleurae and peritoneum. The *plexus on the thoracic surface* unites with the lymph vessels of the costal and mediastinal parts of the pleura, and its efferents are: *anterior*, passing to the anterior diaphragmatic nodes, which lie near the junction of the seventh rib with its cartilage, *middle*, to the nodes on the oesophagus and around the termination of the inferior vena cava, and *posterior*, to the nodes which surround the aorta at the point where it leaves the thoracic cavity. The *plexus on the abdominal surface* is composed of fine vessels, and anastomoses with the lymph vessels of the liver and, at the periphery of the diaphragm, with those of the subperitoneal tissue. The efferents from the right half of this plexus terminate partly in a group of nodes on the trunk of the corresponding inferior phrenic artery, while others end in the right lateral aortic nodes. Those from the left half of the plexus pass to the pre-aortic and lateral aortic

6.176 The lymph nodes of the trachea, bronchi and lungs. Note the large 'carinate' node lodged between the bifurcation of the principal bronchi.

lymph nodes and to the nodes on the terminal portion of the oesophagus.

Lymphatic Drainage of the Thoracic Contents

Lymph from the thoracic viscera traverses one or other of three sets of lymph nodes—brachiocephalic, posterior mediastinal or tracheobronchial—before entering the thoracic duct, the right lymphatic duct or some other vessel which itself enters one of the great veins at the root of the neck.

The brachiocephalic lymph nodes are placed in the anterior part of the superior mediastinum, in front of the brachiocephalic veins and the large arterial trunks which arise from the aortic arch. They receive afferents from the thymus, thyroid, pericardium, and from the lateral diaphragmatic lymph nodes; their efferents unite with those of the tracheobronchial lymph nodes, to form the right and left bronchomediastinal trunks.

The posterior mediastinal lymph nodes are behind the pericardium, close to the oesophagus and descending thoracic aorta. Their afferents are derived from the oesophagus, the posterior part of the pericardium, diaphragm, lateral and posterior diaphragmatic nodes, and, occasionally, the left lobe of the liver. Their efferents mostly end in the thoracic duct, but some join the tracheobronchial nodes.

The tracheobronchial lymph nodes (**6**.176) are arranged in five main groups, and include some of the largest nodes in the body: (*a*) *paratracheal*, at the sides of the thoracic part of the trachea; (*b*) *superior tracheobronchial*, in the angles between the lower part of the trachea and bronchi; (*c*) *inferior tracheobronchial* in the angle between the two bronchi (in clinical and pathological practice these are commonly termed *carinate nodes* because of their close relationship to the *carina* or 'keel-shaped' cartilage sited between the two principal bronchi); (*d*) *bronchopulmonary*, in the hilum of each lung (in clinical practice often simply called *hilar lymph nodes*); (*e*) *pulmonary*, in the lung substance, on the larger branches of the principal bronchi. These groups are not sharply demarcated. The pulmonary lymph nodes become continuous at the hilum of the lung with the bronchopulmonary nodes, and they in turn are continuous with the inferior and superior tracheobronchial nodes, while the latter are continuous with the paratracheal group. The afferents of the tracheobronchial nodes drain the lungs and bronchi, the thoracic part of the trachea, and the heart; some of the efferents of the posterior mediastinal nodes also end in this group. Their efferent vessels ascend upon the trachea and unite with efferents of the parasternal and brachiocephalic nodes to form the *right* and *left bronchomediastinal trunks*. The right bronchomediastinal trunk may join the right lymphatic duct, and the left may join the thoracic duct, but more frequently they open independently of these ducts into the junction of the internal jugular and subclavian veins of their own side.

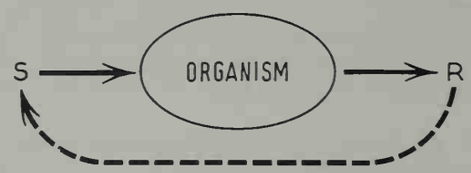
Applied Anatomy. In all town dwellers large quantities of the dust and black carbonaceous pigment that are so freely inhaled in cities are continually being swept into these lymph nodes, from the bronchi and alveoli. In primary tuberculosis of the lungs these lymph nodes are almost always infected.

Lymphatic drainage of the heart. The lymph vessels consist of three plexuses, subendocardial, immediately under the endocardium, myocardial, in the muscle and subepicardial, subjacent to the visceral pericardium. The deeper plexuses open into the subepicardial plexus, the efferents of which form left and right collecting trunks. The *left* trunks, two or three in number, ascend in the anterior interventricular groove, receiving vessels from both ventricles. On reaching the coronary sulcus they are joined by a large trunk from the diaphragmatic surface of the left ventricle which first ascends in the posterior interventricular groove and then turns to the left along the coronary sulcus. The single vessel formed by the union of these trunks ascends between the pulmonary trunk and the left atrium, and ends, usually, in one of the inferior tracheobronchial nodes. The *right* trunk receives its afferents from the right atrium and from the right border and diaphragmatic surface of the right ventricle. It runs upwards in the coronary sulcus, close to the right coronary artery, and then ascends in front of the ascending aorta to terminate in one of the brachiocephalic nodes, usually to the left of the median plane.

Lymphatic drainage of the lungs and pleurae. The lymph vessels of the lungs originate in superficial and deep plexuses. The superficial is beneath the pulmonary pleura, the deep accompanies branches of the pulmonary vessels and the ramifications of the bronchi. In the case of the larger bronchi the deep plexus consists of two networks—submucous, and peribronchial, outside the walls of the bronchi. In the smaller bronchi there is but a single plexus, which extends as far as the bronchioles, but fails to reach the alveoli, in the walls of which there are no traces of lymph vessels. The superficial efferents turn round the borders of the lungs and the margins of their fissures, and converge to end in the bronchopulmonary lymph nodes; the deep efferents are conducted to the hilum along the pulmonary vessels and bronchi, and end, for the most part, in the same nodes. No free anastomosis occurs between the superficial and deep lymph vessels of the lungs, except in the hilar region. In the peripheral parts of the lung small connecting channels exist between the superficial and the deep lymph vessels, capable of becoming dilated so as to direct lymph from the deep to the superficial vessels when the outflow from the deep vessels is obstructed by disease of the lung or pulmonary lymph nodes. At the bottom of the fissures the lymph vessels of the adjoining lobes communicate with one another, so that, although there is a general tendency for the lymph vessels from the upper lobes of the lungs to pass to the superior tracheobronchial nodes and for those from the lower lobes to join the inferior tracheobronchial group, these connexions are not exclusive. At the level of pulmonary lobulation the arrangement of lymphatic vessels is said (Kubik 1970) to follow both the central artery of a lobule and its peripherally situated veins. This confirms the findings of Celtis and Porter (1952). Policard (1950) has described the occurrence of lymphoid aggregations, non-follicular in appearance, in peribronchial sites and in '*placoid*' formations adjoining the pulmonary pleura.

The lymph vessels of the pleura exist in both the visceral and parietal layers. Those of the visceral pleura drain into the superficial efferents of the lung and form a plexus beneath the pulmonary pleura (*vide supra*). Those of the parietal pleura have three modes of ending: (*a*) those of the costal region join the vessels of the internal intercostal muscles and so reach the parasternal nodes; (*b*) those of the diaphragmatic pleura form a plexus on the thoracic surface of the muscle and are dealt with on p. 799, while (*c*) those of the mediastinal pleura end in the posterior mediastinal lymph nodes.

Lymphatic drainage of the thymus. The lymph vessels of the thymus end in the brachiocephalic, tracheobronchial, and parasternal lymph nodes.

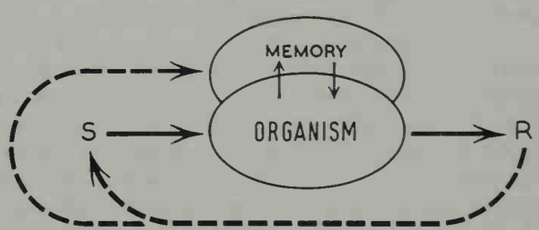


Lymphatic drainage of the oesophagus. The efferent vessels from the cervical part drain into the deep cervical nodes, those from the thoracic part pass to the posterior mediastinal nodes, and those from the abdominal part pass to the left gastric lymph nodes. Some vessels may pass directly to the thoracic duct (p. 784).

7

NEUROLOGY

Introduction



The dependence of living organisms upon environmental energy sources and the essentially dynamic nature of their life processes have been emphasized elsewhere in this volume (pp. 2–4). Many aspects of this dynamic state stem from the ability of organisms continually to interact with a fluctuating external environment whilst preserving their own structural integrity. Such effective adaptations to a varying environment can, as we have seen, be considered in relation to either long or brief time scales (p. 72). Thus, over many generations, the forces of natural selection

7.1 A diagram of the relationship between a stimulus (S) and a response (R) emphasizing its closed-loop nature.

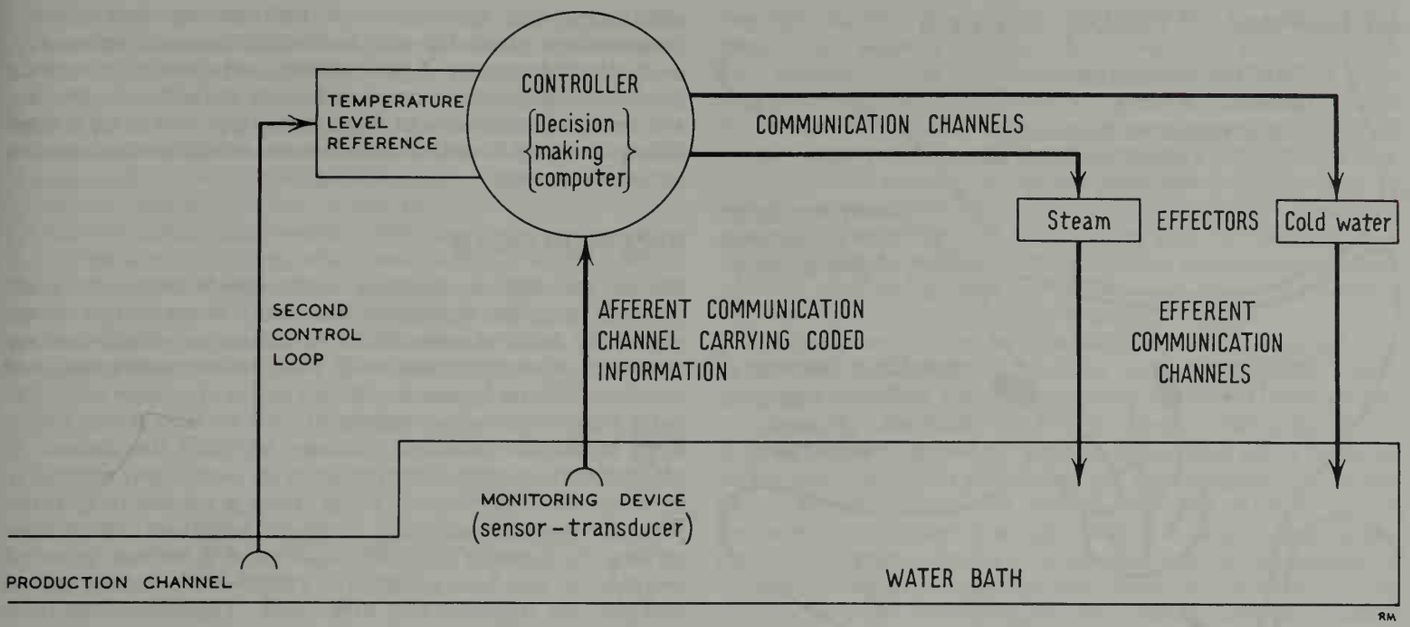
operate upon the genetic variants introduced by sexual reproduction and occasional mutation, resulting in species with an enhanced ability to adapt to changing or different environments. Alternatively, within the lifetime of a complex organism, such adaptive responses range from complicated behaviour patterns, associated with mating, rearing of young, capturing of prey, avoidance or combat with predators, etc. to the innumerable transient readjustments, e.g. of posture, or the reaction and composition of the body fluids which constantly occur. The foregoing are examples of *homeostatic responses* which are a central feature of the behaviour of living organisms and which may be simply summarized as in illustration 7.1.

When an environmental change (S or *stimulus*), to which the

7.2 The stimulus-response loop with the added flexibility of a memory store.

organism is capable of reacting, occurs in its vicinity, an appropriate response (R) follows. In general, the nature of the response is such that it tends to preserve the internal constancy of the organism within the fairly narrow limits necessary for the continued life of its cells and hence ultimately to preserve the whole organism and the species. It should be noted that because of the response, the relationship of the organism to the stimulus is altered (the broken arrow in the diagram), and that in this sense, the whole sequence of events is a *loop*, and not an *arc* with open ends. Further, in the simple case illustrated, the structural organization of the organism (the result of its phylogenetic history) limits the array of stimuli to which it can react, and also restricts the repertoire of its responses, which may be mechanical, chemical, photic or electrical. Accordingly, there are many environmental disturbances to which it is *unable* to respond, or the disturbances may be of such an intensity that any responses are inadequate; the organism 'dies' and gradually undergoes dissolution (i.e. it merges with its environment). In the example quoted the *genetic memory* of the organism, which emerged by natural selection over countless generations, has determined its receptivity of stimuli and its range of responses, and hence its degree of fitness for survival within some particular environment. However, such mechanisms lead to rather stereotyped sets of responses, and in more complex organisms, selective processes have led to the addition of more flexible *memory stores* which operate throughout the life of the individual (7.2). In the latter the general sequence of the stimulus–response loop is similar to the previous example, but in this case the information derived from a particular stimulus pattern is transferred to a memory store, where it is compared with a record of previous experiences. As a result of this comparison, a choice of a particular response is made (out of the many alternatives available), as the one with the highest probability of effectiveness under the circumstances prevailing. It is considered that once having occurred, the effectiveness of the response is somehow assessed, and the results of this assessment are transferred to the memory store, which is modified accordingly; the probability of the same response being chosen under similar conditions in the future being either raised or lowered. In this manner the memory store (or hierarchy of memory stores) is continually modified, readjusted and refined as, with time, further experiences occur, i.e. the organism *learns*.

As implied above, homeostatic responses are a characteristic attribute of *all* living organisms, from unicellular to compound multicellular forms. However, with increasing size and complexity of structure there is a corresponding increase in the range and flexibility of the responses, and this has paralleled the emergence of a *nervous system*—the concern of the present section of this volume.



The human nervous system is, without question, the most complex, widely investigated, and least well understood system known to mankind. Its structure and activities are inseparably interwoven with every aspect of our lives, physical, cultural and intellectual. Accordingly, investigators of many different disciplines, methodologies, motivations and persuasions converge in its study. Similarly, depending upon the context, there are many more or less appropriate ways of embarking upon a study of nervous systems; for example the approach may be developmental, phylogenetic, physicochemical, energetic, structural—gross or cellular, cybernetic, behavioural or ethological.

For our present purposes, the detailed neuroanatomy of the various arbitrary but convenient divisions of the human nervous system is preceded by an account of some relevant experimental methods, the biology of its components in cellular terms, a brief review of some simple nervous systems, and introduced by comparing nervous systems with the information-processing, communication, and control systems of homeostatic machines. (For an extended discussion of the latter approach, the interested reader should consult Young 1964; 1978.)

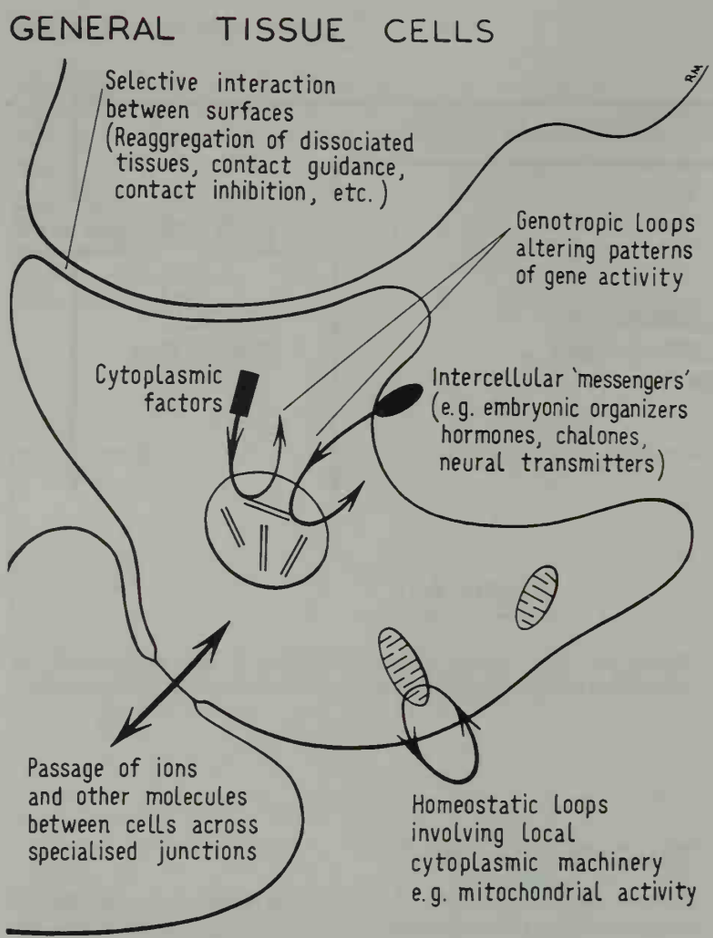
A SIMPLE HOMEOSTAT

It will, perhaps, prove helpful at this point to draw certain analogies with the main features of a simple man-made homeostatic device such as a thermostat (7.3).

In the thermostatic system illustrated, the *energy level* (temperature) of the water bath is continuously *monitored* by an appropriate *sensor* or *receptor* (in this case a thermocouple), and variations in this level are converted into variations in the flow of a *pattern of signals* or *coded information* (in this case current flow) along an *afferent communication channel* to a *controller*. The physical design of the latter is such that it combines or *integrates* the information flow along its afferent channel with that provided by the temperature reference level, and makes a *decision* between alternative patterns of activity (*responses*) of the *effectors* (steam or cold water). If, for example, there is a fall of temperature in the bath (of sufficient magnitude to be detected by the sensor), this change is transformed into signals in the afferent channel which, after comparison and computation in the controlling centre results in an increased flow of steam. It may be noted that it is inherent in the design of such a *control loop system* that there will not be a simple, smooth, immediate return to the reference level of temperature; some overshoot occurs and, with time, there follows a series of oscillations of decreasing amplitude, which gradually converge on the reference level. All the features described in this man-made homeostat have their counterparts in primitive nervous systems. These include the possession of a variety of sensors each capable of monitoring the rate and magnitude of some particular type of environmental change, communication

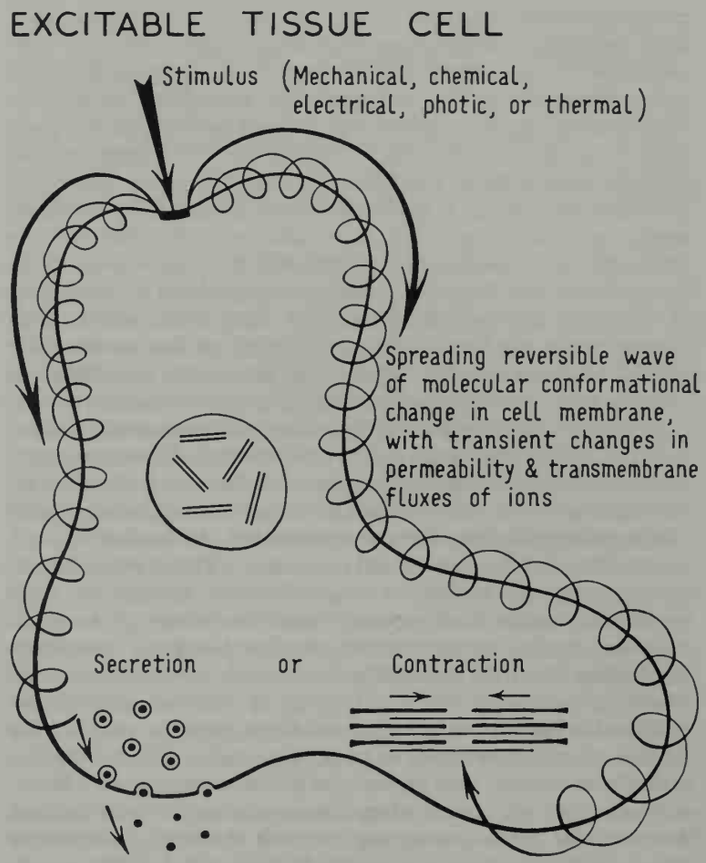
7.3 A diagram of the essential features of a thermostat coupled to an industrial production line. This is an example of a man-made homeostatic device; *see* text for further details and discussion. Modified from an illustration in: *A Model of the Brain*, by J. Z. Young, published by the Clarendon Press, with the permission of the author and the publishers.

channels carrying coded information (nerve fibres bearing temporo-spatial patterns of nerve impulses), integrative computing and decision-making centres (geometric patterns of contact between nerve cells), further communication channels (nerve fibres) and finally effectors (gland or muscle cells) which may be thrown into appropriate patterned responses. All these features will be considered in greater detail in subsequent sections.



As also indicated in illustration 7.3, simple control loops of the type described, which are a characteristic feature of all organisms (and widely used in engineering design), are frequently *coupled* with *further loops*, thus giving more complex responses. For example, the reference level of such a factor as the bath temperature may be continually readjusted to maximize the output of an industrial production line. As we shall see, many features of more complex nervous systems are conveniently considered in terms of an *integrated hierarchical system of control loops*.

Cell Communication



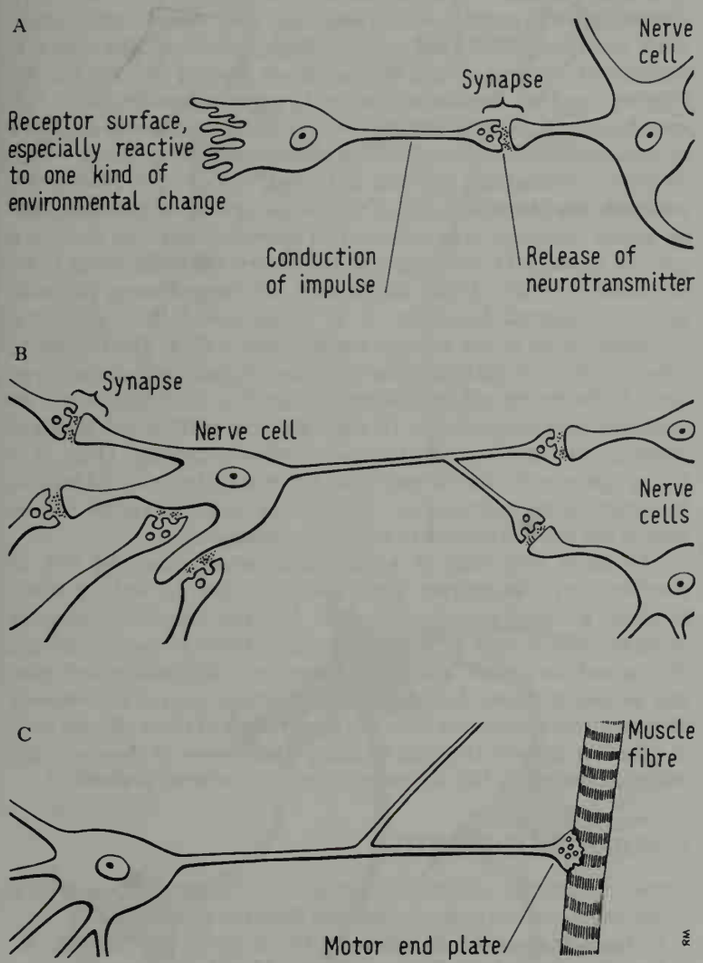
Many aspects of intracellular and intercellular communication (7.4A, B) have been mentioned elsewhere in this volume. Thus, consideration has been given to the selective interaction between cell surfaces, when in close apposition, and the phenomena of contact guidance and contact inhibition (p. 91). The structure and informational role of nucleic acids in cells has been discussed in some detail (p. 21), and brief reviews of current theories concerning how local cytoplasmic factors, or intercellular chemical messengers (embryonic induction factors, hormones, etc.) may effect changes in genotropic control loops, and result in the enhancement or repression of different patterns of gene activity (pp. 24, 25). Where cells are in particularly close apposition (e.g. at maculae communicantes or 'gap junctions') a variety of ions and molecules are able to pass selectively between the cytoplasms of the adjacent cells at such sites (p. 7). (However, much work remains to be carried out concerning the precise nature and variety, mechanisms of transfer, and informational role of the substances involved at these sites, *see* p. 87.) Alternatively, chemical messengers, such as the secretory products of endocrine glandular cells, pass into the blood circulation and then diffuse through the tissue fluid to reach groups of cells which may be quite remote from their site of production. Necessarily, such mechanisms operate upon relatively slow time scales.

EXCITABLE TISSUES

More rapid mechanisms of both intracellular and intercellular communication have evolved in certain specialized *excitable tissues* (including receptor, neural, muscular and certain glandular cells). Some general features of an excitable cell are illustrated in 7.4B. All cells possess a plasma membrane which separates the surrounding tissue fluid from the various intracellular compartments (p. 5, 1.1). By virtue of the permeability characteristics of this membrane, and its associated energy-dependent ionic pumping mechanisms, the ionic composition of the intracellular fluid contrasts sharply with that outside the cell, and consequently a large recordable difference in electrical potential exists between the two compartments across the membrane. Upon the receipt of an appropriate form of *stimulus* at some point upon its surface, a transient, reversible wave of change spreads over the surface of the excitable cell from this point. Whilst the details of the change in molecular terms (presumably involving conformational alterations in the membrane substructure) are not yet understood, changes in the permeability (conductance) of the membrane result. Accordingly there is a rapid local redistribution of ions across the membrane, as they flow down their concentration gradients; this soon ceases as the permeability returns to its resting state. These ionic fluxes may be recorded as variations in electrical potential using suitable equipment, and they are also accompanied by characteristic energetic (thermal) exchanges between the cell and its environment. These properties of excitable cells are discussed in greater detail elsewhere, as are the features which lead to *trains* or *volleys* of such *impulses* upon prolonged stimulation, and the relationship of stimulus strength to impulse pattern (number and frequency). The impulse, having spread over the surface of the cell, then causes, by some imperfectly understood process, either the release of a specific secretory product or the contraction of actin-myosin complexes, depending upon the type of cell involved. The different cells which cooperate in the functioning of nervous systems are modified in various ways, and exhibit these properties of excitable tissues to greater or lesser degrees (7.5A, B, C). Thus, whilst in unicellular forms, and some primitive multicellular forms, *individual cells* are capable of reacting to stimuli, in the majority of multicellular forms possessing nervous systems, a *division of labour* occurs between the excitable cells which make up the system. Thus, we see the emergence of *receptor* cells specialized particularly for the reception of stimuli, *neurons* for the

7.4A A diagram illustrating various forms of cellular and intercellular communication systems.

7.4B A summary of the main events which may follow the application of an effective stimulus to the surface of an excitable tissue cell.



integration and conduction of information, and *effectors* (contractile or glandular cells) for the operation of responses. A more detailed account of the cytology, and theories concerning the functioning and evolutionary history of these cell varieties, will be found elsewhere in this volume (pp. 820 *et seq.*); what follows is a brief introduction to features common to many types of nervous system.

RECEPTOR CELLS

Within the various epithelial layers which clothe the body surfaces, and their associated sub-epithelial connective tissue, within the walls of some blood vessels, incorporated into the structure of many of the solid and hollow viscera and into muscles, tendons, ligaments, etc. are arrays of *receptor cells*. The latter possess specialized regions of their surfaces which enable them to monitor selectively changes in either the internal or external environment. Some receptors are particularly responsive to mechanical deformation whilst others are sensitive to either thermal, chemical, electrical or photic variations. Views concerning the *degree of specificity* of action of individual 'types' of receptor cell have been modified on a number of occasions during the last one hundred and fifty years. Thus, since the first enunciation of a law of *specific nerve energies* by Johannes Müller in 1840, many investigators have held that any particular receptor reacted preferentially to only one type of energetic change, and this constituted its usual physiological role. A receptor was considered to exhibit a *low threshold* with respect to this form of stimulation, i.e. it reacted to small variations in energy level, whereas to all other types of change it exhibited a *high threshold*, only reacting if the stimulus strength was of relatively great, perhaps abnormal, intensity. Following experiments on cutaneous innervation in mammals, however, other investigators reached the opposite conclusion—that the cutaneous receptors were *non-specific* and that sensory perception depended entirely upon the *spatio-temporal patterns* of nerve impulses in a *common set* of neural pathways (Weddell 1941). With more refined methods of recording from individual nerve fibres and nerve cell bodies, however, there has been a partial return to the specificity theory, but with many complexities, subtleties and grades of interaction, not envisaged in the earlier theories (Mountcastle and Powell 1959; Sinclair 1967; Wall 1967). Thus, some nerve fibres have been identified which stem from receptors reacting to more than one class of environmental change (*polymodal receptors*). Further, receptors may be *fast* or *slowly adapting*: the former respond to a brief stimulus with a sharp volley of nerve impulses which ends as the stimulus ceases, but if the stimulus is maintained the frequency of nerve impulse firing rapidly drops to the resting level. Slowly adapting receptors may continue to generate a volley of impulses for prolonged periods if the stimulus strength persists. Yet other varieties of receptor show a resting level of impulse discharge which may be either raised or lowered with different changes in the environment. These variants will be further considered with the anatomy of the individual receptor cells (p. 849).

The intimate molecular mechanisms whereby an environmental change, whether mechanical, chemical or thermal, causes an alteration in the receptor cell are imperfectly understood (although more is known concerning the activation of photosensitive pigments in retinal receptors—p. 1166). Nevertheless, electrophysiological recording from some varieties of receptor cell has demonstrated that, when the cell is exposed to a stimulus of adequate strength, there follows a change of permeability to ions in its specialized receptor surface. Consequently, some of the ions which are differentially concentrated in the intra- and extracellular compartments flow down their concentration gradients across the specialized receptor surface; a microelectrode inserted into the cell records these ionic fluxes as variations in electrical potential—the so-called *receptor potential*. The circuit for this flow of ionic current is completed by a flow of ions in the opposite direction across the neighbouring non-specialized (but excitable) regions of the receptor cell membrane, where the resulting *graded variations* in potential are termed the *generator potential*. The detailed consequences of fluctuations in the level of the generator

potential have only been analysed in a few sites, but vary with the type and geometry of different receptors. In some situations, for example, the gustatory cells of the tongue, the generator potential may *directly* affect the level of activity of the points of synaptic contact between the receptor cell and the peripheral process of a neuron (*vide infra*). In other situations (the Pacinian corpuscle is a particularly well investigated example, p. 855), where the specialized receptor surface is the peripheral part of a long cytoplasmic conducting process (nerve fibre) which proceeds to the central nervous system, other events occur. If the variation in the generator potential reaches a critical *threshold* level, it causes a dramatic but rapidly reversible series of changes of ionic permeability in the regions of cell membrane which border the specialized receptor surface. The consequent ionic fluxes are

7.5A–C The three main avenues of differentiation which may be followed by a primitive nerve cell: A a receptor neuron; B an interneuron; and C an effector neuron. See text for further discussion.

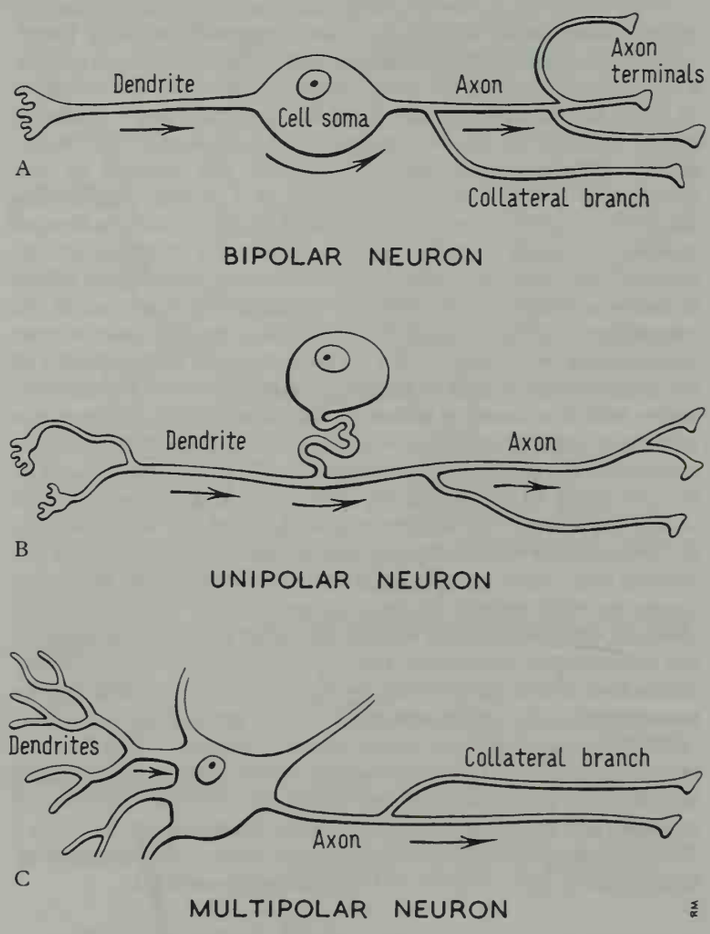
recordable as an *action potential*, and they set in train a self-generating wave of similar changes which spreads along the conducting process as a *nervous impulse*. Maintenance of the generator potential at an adequate level above threshold results in a *volley of impulses* which passes centrally along the fibre. The *frequency* of the impulses constituting the volley is related (logarithmically) to the energy level, or *intensity* of the stimulus. In this manner, receptors act as *transducers*, whereby fluctuations in various environmental energy levels are transformed into coded volleys of nerve impulses. Much work is currently in progress attempting to analyse the detailed mechanisms and quantitative aspects of their responses.

SYNAPTIC CONTACTS

Excitable cells (receptors, neurons, and effectors) can communicate at specialized points of intercellular contact termed *synapses* and these are of two principal kinds; by far the most common are *chemical synapses* where chemicals (neurotransmitters) released by one cell stimulate the plasma membrane of an adjacent cell so that its permeability to certain ions, and hence its electrical state is altered. Such junctions are found throughout the animal kingdom wherever a nervous system exists. A second type is the *electrical synapse*, similar to the *communicating junctions* or *nexuses* between many classes of cell including cardiac myocytes, non-striated myocytes, etc. (*see* pp. 515, 518). At such junctions the adjacent cells establish channels of direct ionic communication between their cytoplasms so that one cell can excite another without the intermediary step of transmitter release.

As noted above at most mammalian synapses (as in the majority of sub-mammalian and invertebrate synapses) chemical transmission occurs. The cell membranes are, in this case, separated by a *synaptic cleft*, and in the simplest synapses transmission occurs in one direction only, i.e. the synapse is *polarized* and is bounded by the membranes of a *presynaptic* and a *postsynaptic* cell. As the nerve impulse which has spread over the surface of the presynaptic cell (either a receptor cell, or a neuron) approaches the presynaptic membrane, it causes the release of a *neurochemical transmitter* which rapidly diffuses across the confines of the synaptic cleft and approaches the postsynaptic membrane, where it causes a change in its ionic permeability. The action of the transmitter is short-lived, as it is removed or broken down almost immediately by the action of a specific enzyme. The character of the permeability change in the postsynaptic membrane, however, varies with the chemical nature of the transmitter substance at a particular synapse, and also with the nature of the membrane. In some cases the permeability change is such that the resulting flow of ions tends to *depolarize* the postsynaptic membrane, i.e. to *reduce* the level of the electric potential difference which reflects the asymmetric distribution of ions across the membrane of the 'resting cell'. Such synapses and their transmitters are said to be *excitatory* with respect to the postsynaptic cell (*vide infra*). In contrast, other varieties of neurotransmitter tend to *hyperpolarize* the postsynaptic membrane and are said to be *inhibitory*. These distinctive effects, as recorded by a microelectrode impaling the postsynaptic cell, are known as *excitatory postsynaptic potentials* (EPSP's) and *inhibitory postsynaptic potentials* (IPSP's) respectively. (Further information concerning the detailed architecture and modes of operation of different varieties of synapse, and groups of synapses, will be found on pp. 826–834.) To understand some features of their interaction, the morphology of a common type of nerve cell must now be outlined.

NEURONS



Neurons or *nerve cells* are essentially excitable cells which are specialized for the *reception*, *integration*, *transformation* and *onward transmission* of coded information.

Vertebrate neurons consist of a *cell body* or *soma*—a localized mass of specialized cytoplasm which carries a diploid nucleus and is bounded by an excitable membrane, from the surface of which project one or more *neurites*. The latter are delicate, branching, cytoplasmic processes, each enclosed by an excitable plasma membrane, which extend varying distances from the cell body. Accordingly, neurons may be classified as either *unipolar*, *bipolar* or *multipolar* (7.6A–C). The neurites in each case may be divided into those which conduct towards or directly influence the cell body, namely one or more *dendrites*, and another one (which may branch more or less profusely), and conducts away from the cell body, the *axon*.

Neurons present a great range of shapes, sizes and interrelationships with other cells, both in different species and in different regions of the nervous system. Many of these variations will be treated in greater detail in subsequent parts of the present section. For our present introductory purposes it should be noted that the dendrites of a bipolar or unipolar neuron are either in synaptic contact with specialized receptor cells in the tissues of the body, or, by their dendritic terminals, themselves function as specialized peripheral receptor surfaces. In contrast, virtually all the nerve cells of the vertebrate *central* nervous system (brain and spinal cord) are some form of the multipolar variety (7.7).

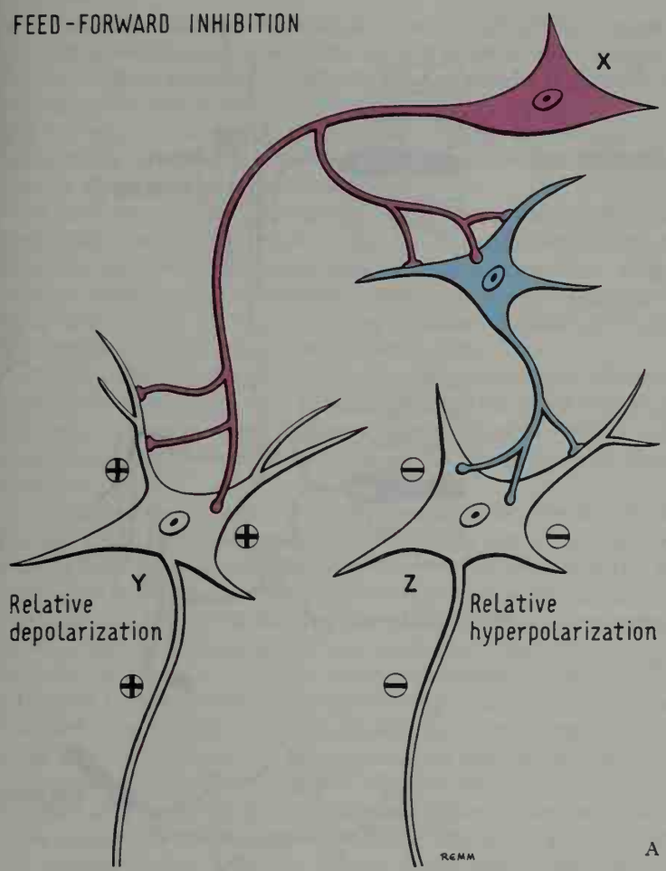
It is clear that the surfaces of the dendritic tree and of the cell body provide a large area, which receives the synaptic terminals of other neurons. Such terminals may be relatively few in number, but usually they number many thousands, being derived from the axonal branches of some hundreds of neurons which are presynaptic relative to the one on to which they converge. Such presynaptic cells may be widely scattered in different regions of the nervous system; evidently there is a great *convergence* of information paths in such a case.

The synaptic contacts illustrated may thus be classified as *axodendritic*, or *axosomatic*, according to their site on the postsynaptic membrane; other less common varieties include *axoaxonic* synapses involving either the initial segment of the axon or the presynaptic terminals of the cell concerned, *dendrodendritic* synapses, *reciprocal* and *serial* synapses, and finally synaptic *cartridges* and *glomeruli*, in which a number of neurites are interrelated in complex geometrical patterns. The latter provide the *higher integrative units* or *microcircuits* of the functioning nervous system. The cytological details and possible modes of operation of these and other varieties will be described in later pages (pp. 827, 829).

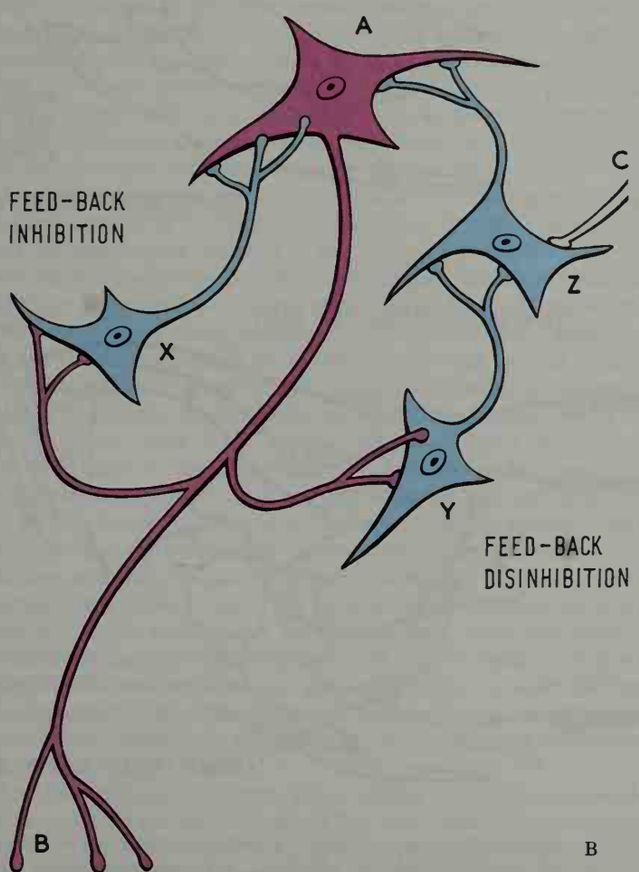
7.6A–C Three general morphological groups of neurons classified according to the number of neurites which arise from the surface of the cell soma: A bipolar neuron; B unipolar neuron; and C multipolar neuron. For a more detailed analysis of the branching patterns of neurites, see 7.15.

Of the numerous synaptic terminals clustered over the dendrites and cell soma of a multipolar neuron, those from certain sources are *excitatory* whilst the remainder, from other sources, are *inhibitory*. Depending upon the states of relative activity or quiescence of these different sources, the proportion of excitatory and inhibitory synapses which are active also varies continuously with the passage of time. Accordingly, their overall effect is summated (*integrated*) and the *excitatory state* of the cell, i.e. the relative level of depolarization or hyperpolarization of its cell membrane also fluctuates. Only when the depolarization reaches a critical *threshold level* are the local electronic current flows, which encircle the dendritic tree and cell soma, sufficient so to alter the permeability characteristics of the *initial segment* of the axon, that an action potential is generated and spreads down the axon as a *nervous impulse*. If the threshold excitatory state continues to be exceeded, a volley of such impulses is discharged along the axon and its collateral branches. It is to be noted that, since the excitatory level of the neuron *continuously* reflects the innumerable variations in pattern of the information paths which converge upon it, the nerve cell bears some similarity to the operation of an *analogue computing device*. In contrast, the outflow information channel, the axon, exhibits an *all or none* response. Thus, it is either quiescent, or carries one or more discrete, identical, intermittent nerve impulses—only their frequency varies. In this regard the axon is more like a *digital computer*.

The axon terminals of a particular neuron may be few in number and concentrate their effect on one or only a small localized group of postsynaptic cells. In other situations *collateral branches*, which may be numerous, arise from an axon at points throughout its course, and each of these may themselves arborize and *diverge* to many destinations. The 'many to one' *convergence* of information channels with the integration of their effects, and, in other situations, the 'one to many' *divergence* of channels, are essential features of all advanced forms of nervous system.

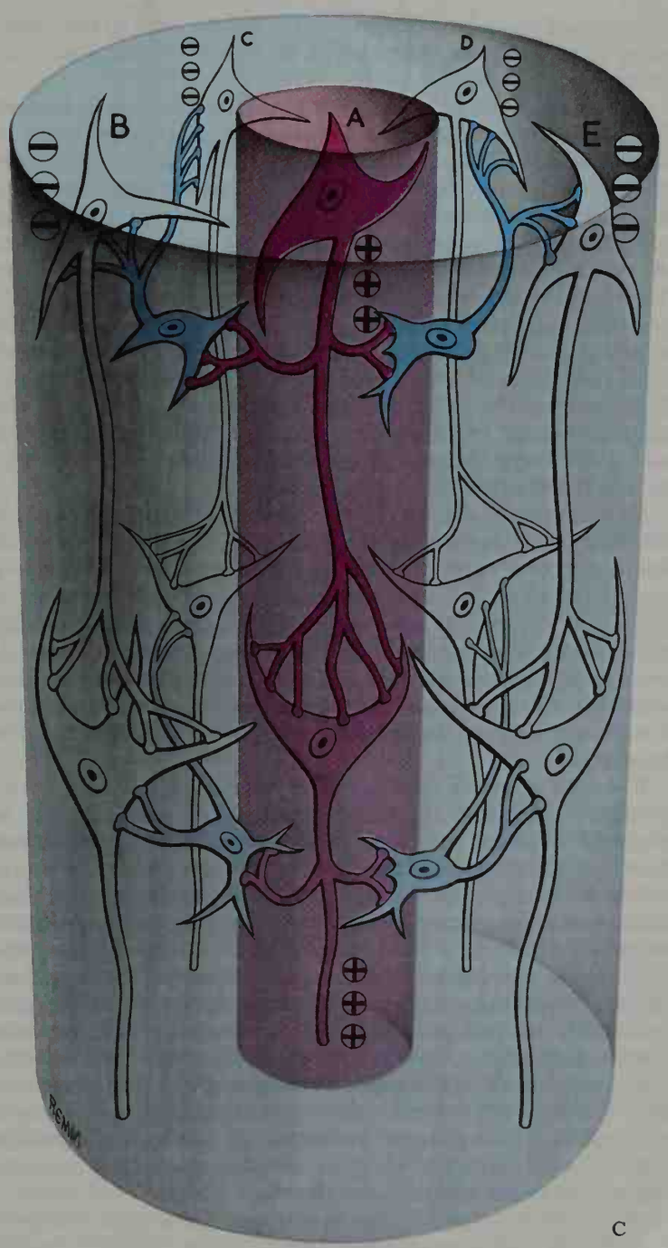


INHIBITORY CIRCUITS

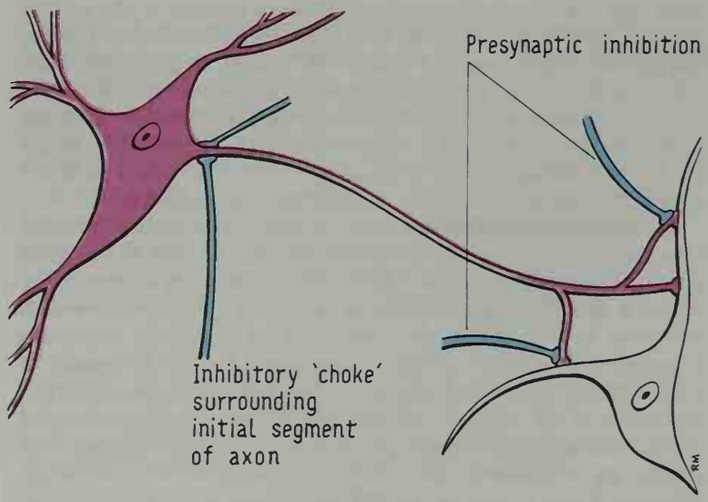


Some elementary inhibitory circuits, currently proposed as a result of microelectrode studies, are illustrated in 7.8A–C.

In **feed-forward inhibition** (7.8A) an excitatory neuron (X) is functionally linked with two others (Y and Z). However, it is



7.7 A diagram to illustrate a generalized multipolar neuron and the parts of its surface upon which synaptic terminals from other neurons may converge. These include the surfaces of the dendrites, the cell soma, the initial segment of the axon, and the proximal surface of its own axonal synaptic terminals. For a more detailed representation of the cytology and surface contacts of a multipolar neuron see 7.17.



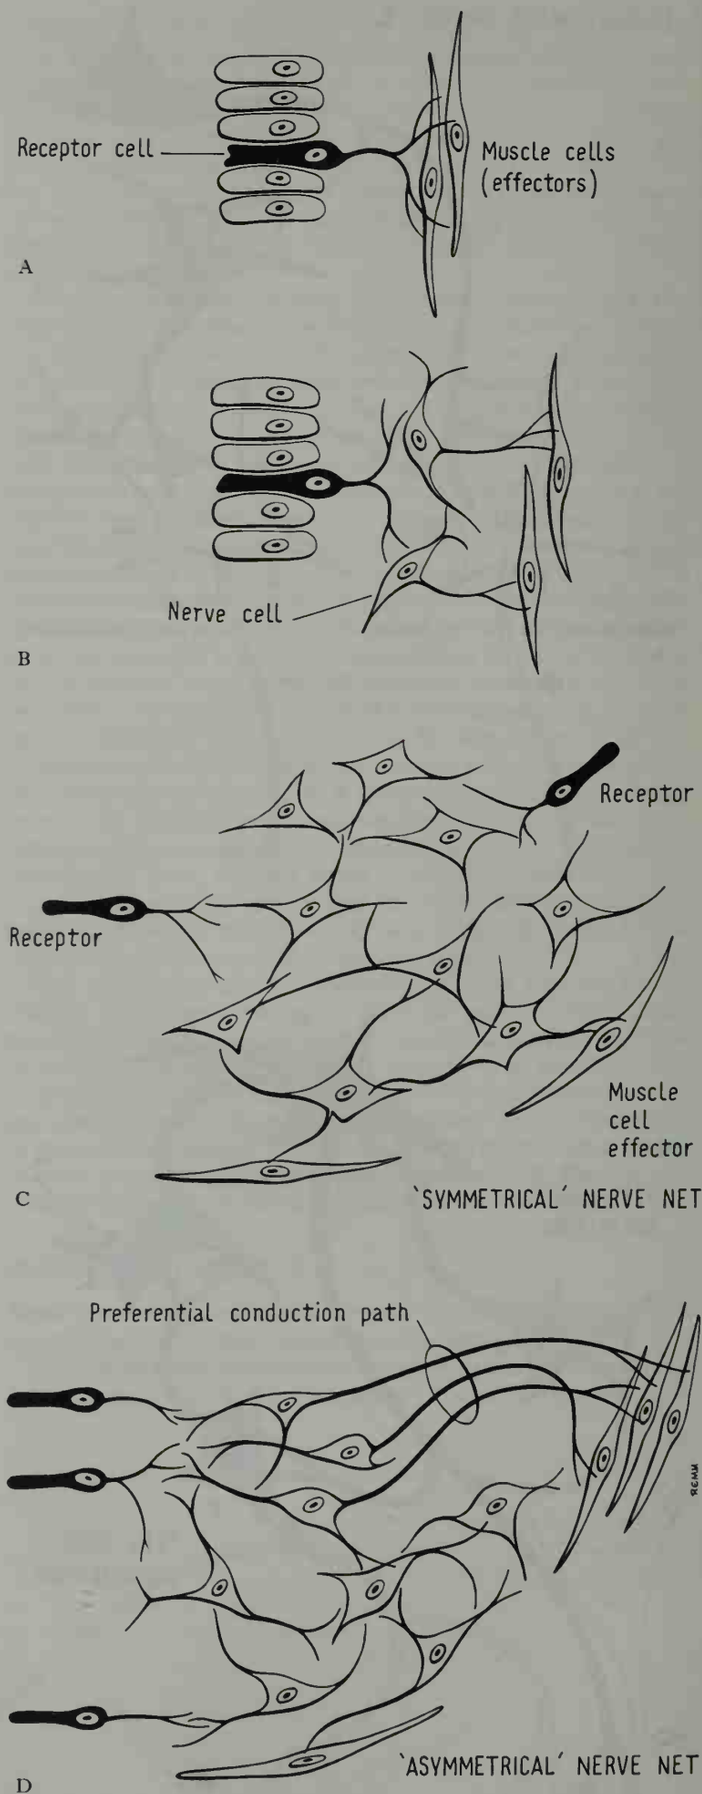
clear that the interposition of an inhibitory neuron on the second path causes the excitatory level of Z to fall whilst that of Y rises, during the period that X is active. Of course, in practice, many other local circuits are simultaneously active; nevertheless, the principle illustrated probably accounts in part for such examples as the increase in force of contraction of a muscle group during a particular activity, whilst, concurrently, the contraction level of a cooperative group of muscles is progressively reduced.

In **feed-back inhibition** (7.8B) a volley of impulses initiated by a multipolar neuron (A) proceeds down its axon to its principal group of synaptic terminals (B). However, the persistence of the volley is limited in time by the operation of a feed-back loop. A collateral branch leaves the axon and its excitatory terminals synapse with a single inhibitory neuron (X), the terminals of which pursue a recurrent course and synapse with the dendrites and soma of the original cell (A), where their hyperpolarizating effect terminates the volley. Such feed-back circuits may vary greatly in complexity, and in some situations two inhibitory neurons (Y and Z) may be interposed at some point in a recurrent loop. Evidently, some inhibitory effect on A by neuron Z, perhaps initiated by an alternative source (C), is diminished by the

7.8A–C Examples of elementary inhibitory circuits; excitatory neurons shown in red, inhibitory neurons in blue: A a direct excitatory circuit (on the left) is compared with a simple feed-forward inhibitory circuit (on the right); B feed-back circuits of two orders of complexity with one (on the left) and two (on the right) inhibitory interneurons interposed on the recurrent pathway; C lateral inhibition. A central excitatory train of neurons is surrounded by a hollow cylindrical zone of inhibition, mediated by shells of inhibitory interneurons which are activated by the central column. See text for further discussion.

7.9 The multipolar neuron, shown in red, has inhibitory synaptic terminals (blue) applied to the initial segment of its axon, and others to the surfaces of its own axonal synaptic terminals.

operation of inhibitory neuron Y. This release from an inhibitory effect by a second one, in series with the first, is termed, somewhat inelegantly, *disinhibition*.



In 7.8C one form of feed-forward inhibition known as **lateral inhibition** or **inhibitory surround**, of great importance in many neural pathways, is illustrated. A series of parallel pathways A–E which carry functionally similar types of information is shown. It may be imagined that all these channels are transmitting sporadically with a rather low information content. If, however, the excitatory state of one (e.g. channel A) rises significantly above the others, by the operation of neighbouring shells of inhibitory neurons, the activity in B–E is reduced. Consequently, the centrally activated channel becomes surrounded by a quiescent zone; there is less chance of confusion by random activity in the neighbouring channels, and the discriminative value of the central channel is greatly increased—a phenomenon termed *neural sharpening*. Many examples of this important process will be referred to in the subsequent sections.

Mention should also be made at this point of two further sites of inhibitory interaction between neurons (7.9). These forms are of less common occurrence, but they evidently have completely contrasting roles. An inhibitory terminal surrounding the initial segment of the axon is advantageously placed to *prevent* rapidly and completely an outflow from the neuron. On the other hand, *presynaptic inhibitory terminals* may *selectively diminish* the activity or effectiveness of some terminals whilst others continue to act unimpeded—a number of examples will be encountered in later sections.

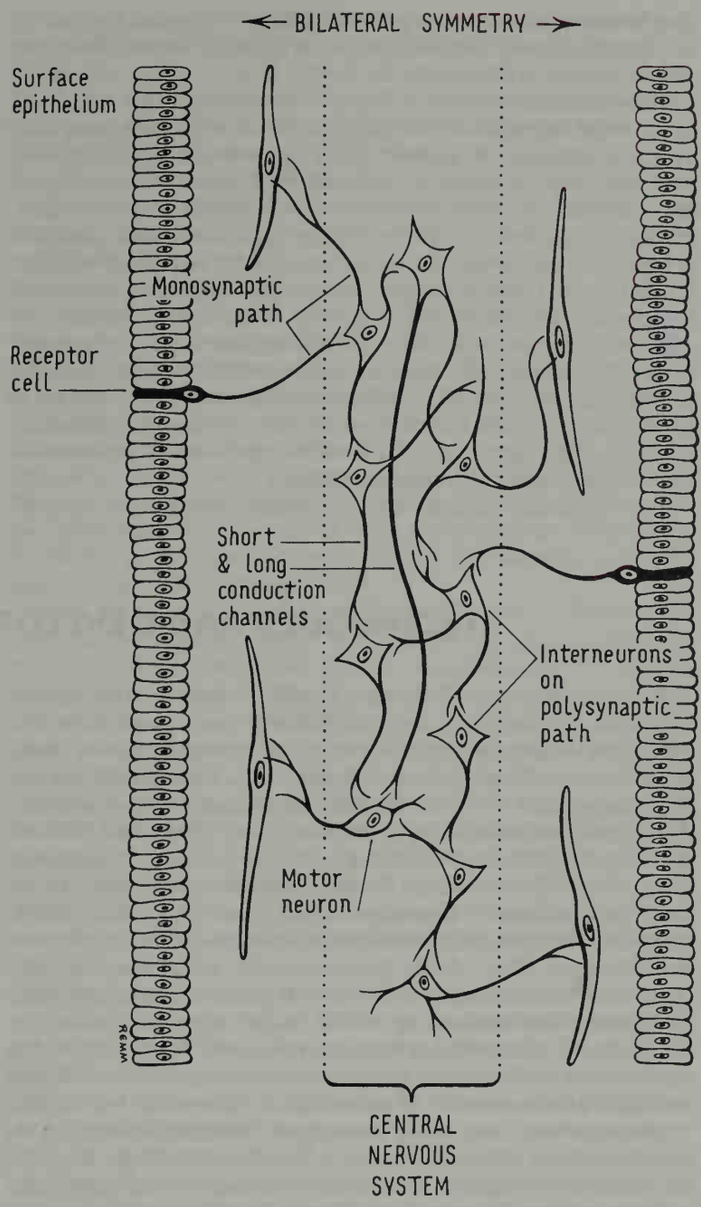
It should be stated here, however, that our knowledge of the geometry of dendritic trees, cell somata and axonal branching, in quantitative terms, of the three-dimensional interconnexions between neurons, and the spatial distribution of synaptic types, is still in its infancy. So, too, is our knowledge of how individual neurons and cooperative groups of neurons transform patterns of information flow, and how these relate to the operation of the whole nervous system and the overall economy of the organism. For the same reason, much research is currently concentrated upon investigations into the causal mechanisms which operate during neurogenesis, to determine which features of neurons, and neuron assemblies, are specified by the genome, and on what is the nature of the modifications which occur during the establishment of acquired memory traces during the lifetime of the organism. Some specific examples, where illuminating research is proceeding, will be mentioned in the appropriate sections.

Some General Features of Neural Organization

What follows is an attempt to present some aspects of the organization of nervous systems, of varying intricacy, which may

7.10A–D Simple nervous systems: A direct interaction between a receptor cell and the muscle cell effectors. B interneurons which make functional contacts with each other are interposed between the receptor cell terminals and the muscle cell effectors. C receptor cell terminals feed into a fairly symmetrical network of interneurons which in turn makes contact with the effectors. D the interneurons between the receptors and effectors are organized where 'diffuse' multisynaptic conduction pathways predominate, and others where more direct routes are present.

be of assistance before embarking upon a study of the complex nervous arrangements of vertebrates, and in particular mankind. It is in no sense intended to reflect a phylogenetic history, and no consideration will be given here to the distribution of inhibitory and excitatory neurons, to synaptic morphology, or chemical or behavioural studies; comments are limited to the elemental aspects of the arrangement of neurons.



In the unicellular protozoans, of course, the single cell constitutes the whole organism, and its various parts can act as primitive receptor, conductor and effector mechanisms. Some ciliated protozoans, for example, show coordinated beating of their cilia, so that the organism may advance towards or retreat from particular sources of stimulation (p. 18).

Simple multicellular forms possess many *independent effectors*, such as the contractile cells which surround the pore-system of sponges, or the stinging organs of coelenterates, which can respond to direct mechanical or chemical stimulation of their surfaces.

Coelenterates are the simplest multicellular forms which possess a true nervous system: and in various species and bodily regions different orders of complexity can be recognized (7.10). In some sites specialized receptor cells situated between the general epithelial cells of the surfaces of the organism send a conducting process from their bases which is in direct functional contact with underlying effectors (muscle cells). Elsewhere, however, the processes from the receptor cells discharge into a sub-epithelial '*network*' of nerve cells which are functionally interconnected in a tangential plane. From the latter, processes pass to the effectors. The interconnexions or 'synapses' between the cells forming the network are, however, not functionally polarized as they are in more complex systems; a strong stimulus applied to any point on the surface of the organism causes motor effects that spread widely. A superficial examination might indicate that the network of neurons is random (7.10c), but closer study shows that some regions have a greater density of receptor cell inputs, others have closer meshes in the network, and in yet others the conducting fibres are longer and have a distinct orientation. These features presumably subserve the more complex behavioural patterns associated with the capturing of prey, avoidance reactions, and other locomotor activities of these simple organisms. It should also be noted that these structural characteristics foreshadow similar fundamental arrangements which persist in more complex nervous systems, including those of Mammalia.

In simple forms which exhibit *bilateral symmetry* we see the first appearance of a *central nervous system* (7.11). The receptor cells are still largely situated in the surface epithelial layers, but their basal conducting processes are longer, since they traverse the tissue layers to approach the region on each side of the plane of symmetry. Here, many neuronal somata and their associated neurites are concentrated as the central nervous system, and the synaptic terminals of the receptor cells end in relation to some of them. The somata of motor (effector) neurons are sited within this concentration, and their axonal processes leave the central nervous system to reach the effectors. The remaining nerve cells are interposed between some of the receptor cell terminals and the motor neurons. They may possess short or longer axonal processes and are termed *interneurons* (*intercalated* or *internuncial* neurons are less frequently used synonyms). Thus, paths of varying complexity connect the receptor cell input and the motor neuron output; some paths are *polysynaptic*, with a number of neurons successively interposed, whilst in others a direct receptor-effector *monosynaptic* path exists. It is in such diversity of *connectivity*, that the variations in speed and complexity of behavioural responses to different environmental conditions reside.

In the higher invertebrates, which exhibit *metametric segmentation* of the body, many of the same considerations apply. The receptor cells are still largely intra-epithelial in position and their centrally directed nerve fibres collect into bundles, or *sensory nerves*, within each segment, as they approach the central nervous system. The latter consists of masses of interneurons and motor neurons—usually a ventrally situated pair of masses (or 'ganglia') in each segment. Each pair is interconnected by axonal processes which *cross the midline*, and the masses are also interconnected

7.11 Some features of the nervous system in a primitive organism with bilateral symmetry. Note the intraepithelial positions of the receptor cells, and the aggregation of interneurons and motor neurons near the plane of symmetry as a central nervous system. Note also the different orders of complexity of the conduction pathways, and the possibility of cooperative actions involving both sides of the body.

longitudinally on both sides of the midline, so that a structure often likened to a rope-ladder is formed. The axons of the motor neurons emerge from the central nervous system as a series of bundles, *motor nerves*, within each body segment. The transverse communications also carry axonal processes of interneurons and are responsible for cooperative responses involving both sides of the body. Similarly, short-axoned neurons interconnect adjacent body segments longitudinally in both directions. Others possessing longer axons interconnect more distant segments, including the increasingly important 'head' end, whose specialized receptors often adopt a dominant role in behaviour.

As we have seen elsewhere (p. 112), during embryogenesis in *Chordata*, including *Mammalia* and mankind, the central nervous system develops in the dorsal midline, as a hollow tube-like structure which contains a *central canal*, and expands cranially to form a *brain* containing extensions of the central canal termed *ventricles*. Throughout the vertebrates, the walls of the brain and spinal cord again consist of interneurons and, less numerous, motor neurons, together with associated non-nervous glial cells

and blood vessels; but two quite distinctive tissue varieties can be recognized, namely *grey matter* and *white matter*, when freshly cut nervous tissue is examined.

Grey matter consists of the cell somata, dendritic trees and initial axon segments of the neurons, the terminal segments and synaptic endings of axons which are associated with them, together with varieties of glial cell and blood vessels. Some interneurons have short axons that remain wholly within the grey matter. Many, however, possess longer axons and these leave the grey matter, where they course in functionally associated bundles termed *tracts*. Outside the grey matter each acquires a laminated lipo-protein sheath of *myelin* derived from certain varieties of neighbouring glial cells. The sheaths are essentially concerned with the functional efficiency of the nerve fibres during impulse conduction, in terms of an enhanced conduction velocity for a given diameter, and a reduction in their energy requirements (p. 843). They impart a pinkish-white opalescence to the fresh tissue—hence the term **white matter**.

The vertebrate central canal is largely lined by a ciliated columnar epithelium termed *ependyma*, and during early embryogenesis the grey matter develops in a zone immediately surrounding the ependymal lining, whilst the white matter forms external to this. At first these relationships are present throughout the length of the neural tube, and, in the spinal cord, they persist to maturity. With the development and elaboration of hindbrain, midbrain and forebrain vesicles, however, whilst some masses of grey matter are retained in the primitive para-ependymal position, others migrate outwards to insinuate themselves between the developing tracts of white matter on the ventrolateral aspects of the tube. Most importantly, profuse secondary migrations of developing grey matter occur in the roof of each of the three vesicles, where they become arranged as a subsurface series of fibrocellular laminae, which are of the greatest significance in the functioning of the system.

Before embarking upon a detailed account of human neuroanatomy, methods which have been employed in neuroanatomical research and the cytology of nervous tissue will be reviewed.

TECHNIQUES AND DEVELOPMENT OF NEUROANATOMY

The previous section has been largely a consideration of the analytical philosophy of nervous systems—only possible on the results of a long historical process of accumulation of data, hypotheses, and explanations. These results, due to the efforts of a large succession of observers and experimenters (*see*—Anglo-American Symposium 1958; Brazier 1959; Singer and Underwood 1962; Clarke and O'Malley 1968; Meyer 1971; Bellairs and Gray 1974; Neurosciences Study Programs 1967, 1970, 1974) have been primarily dependent upon perceiving relationships between observed phenomena, especially in the most effective contributions. Even these, however, were conditioned by the technical means available at the time. It hence seems appropriate to examine the *methods* by which major advances leading to current levels of knowledge have been achieved. Inevitably such a survey must be brief, and while historical in approach, it is not intended as an account of neurological discovery, but of the neuroanatomical and other techniques involved. Hence, it is impossible here to cite more than a few examples of the fruits of the various techniques and methods included, nor can treatment of these subjects be exhaustive. In any case, other references to technique, and to the advances made by them, will appear in the general description of the nervous system which follows. Ideally, the names of innovators should be kept before us by habitual citation, but this is scarcely practicable in the textbooks of today. Perhaps the ensuing pages will help to correct this deficiency, though necessarily in a limited and irregular manner.

The development of neuroanatomy, as with any other corpus of knowledge, has been linked at every stage to contemporary means of observation and experiment. Hence, it was initially slow: a period of about two millennia separated the earliest recorded observations from the introduction of even simple magnifying lenses. The great accessions to knowledge during the nineteenth and twentieth centuries have coincided with the acceleration of technical innovation and improvement during this period. Until recent times physiology lagged centuries behind anatomy, a frustration to all who find function the chief interest in structure; but in the same explosion of technical progress functional studies have overtaken the purely structural in many fields, and have indeed carried concepts of function beyond structural observation in some. In neurology this has provided a much needed intellectual stimulus to morphologists.

From the Greeks to the Renaissance

Granted the importance of technique, and hence the extremely simple means available, the paucity of neurological observation, or even speculation, recorded by earlier civilizations, prior to classical Greek times, is surprising. Opportunities presented by injury, sacrifice and mummification are obvious; yet the earliest records are limited to a description of the optic nerves by Alcmaeon (*c.* 500 B.C.) and a few statements in the Hippocratic Collection (*c.* 400 B.C.), amounting to little more than recognition of the cleft between the cerebral hemispheres and a belief that the brain is associated with intelligence. Even Aristotle (384–322 B.C.) confused peripheral nerves with tendons (with lasting effects visible in the term 'aponeurosis'); and he unaccountably set intelligence in the heart, unlike Plato (429–347 B.C.), who sited sensation and thought in the brain. Of course, biological thought was already permeated by the Four Elements of Empedocles (*c.* 493–433 B.C.) and the Four Humours of Polybus (*c.* 390 B.C.). The humoral concept in particular was to dominate and, indeed, obstruct biological thought for almost two thousand years, however improbable it now seems or how extraordinary that simple contradictory observations were ignored.

Human dissection began (as far as records support) with the rise of the Alexandrian School, whose leaders in biology, Herophilus and Erasistratus (*c.* 300–250 B.C.), are often regarded as the 'father figures' of anatomy and physiology. (The possible debt of such dissectors to the embalmers of Egypt should not be overlooked, though how far this age-old source of practical knowledge influenced deliberate dissection cannot be assessed; *see* Cave 1958.) Herophilus distinguished cerebrum and cerebellum, describing the fourth ventricle and even its calamus scriptorius; he also differentiated motor and sensory nerves. Erasistratus detailed the ventricles further, ascribing them functions entangled in humoral concepts, as was his entire physiological teaching, complicated further by the *pneuma*, or vital spirit, an intellectual impediment lingering long after the Renaissance. However, he also equated the more elaborate gyral pattern of the human brain with mankind's pre-eminent intelligence, a remarkably prophetic speculation.

With the Roman annexation of Egypt (50 B.C.) the Alexandrian School decayed; but Galen (A.D. 129–199) left his native Pergamon to study there, his most productive years being spent in Rome. His significance in medicine and biology, as a dissector and experimentalist, calls for no reiteration (Sarton 1954; Singer 1956). He classified the cranial nerves, omitting the olfactory and trochlear and confusing others, though his description was not improved until some 1,500 years later. Much of Galen's voluminous and dogmatic writings was theoretical, but his work on spinal cord function was directly based on experiment, and was not extended until Bell and Magendie added their observations early in the nineteenth century. Section between the first two vertebrae, he concluded, led to immediate death, between the third and fourth to respiratory arrest, and at lower levels to paralysis of bladder, intestines and legs. In contrast, most of Galen's prolific output was couched in humoral and vitalistic

ideas which—in view of the veneration with which his teaching was held for many centuries—were a serious brake on progress.

After Galen, biological and medical thinking entered a long suspense. The classical legacy was all but extinguished in Europe during the ensuing 'Dark Ages'. Greek texts survived chiefly in Arabic translations, with little improvement in knowledge; in accord with the general intellectual lethargy, neuroanatomy marked time for a thousand years; indeed, anatomical accuracy degenerated. The rising popularity of astrology and the insistence of early Christian authority upon the unimportance and even degradation of man's physical estate, displaced interest from his own true fabric.

From the eleventh century Greek medical manuscripts were being translated into Latin, at first from Arabic versions. Though this was the start of the rewakening of European science, progress was very slow, the ensuing centuries remaining barren of fresh anatomical or physiological advance. The opinions of Hippocrates, Aristotle, and especially Galen were the approved sources of anatomical knowledge in medieval times, with almost unchallenged authority. Even in the rising universities of the twelfth and thirteenth centuries, observation of natural phenomena was neglected; achievements were literary. Dissection reappeared, but at first as an exercise to confirm established dogma. Even Mondino of Bologna, whose *Anathomia* of 1316 is regarded as the first text in the modern period, ascribed the functions of antique teaching to the brain ventricles, and in sum he added nothing of significance to neuroanatomy. Though dissection continued in Bologna, spreading to other Italian centres and to Montpellier, the fourteenth and fifteenth centuries brought little more than translations from Greek, rather than Arabic texts. The anatomical Humanists of the sixteenth century were preoccupied with the replacement of Arabic anatomical terms by Greek and Latin, but great exceptions from such drab polemics were at work, as we shall now see.

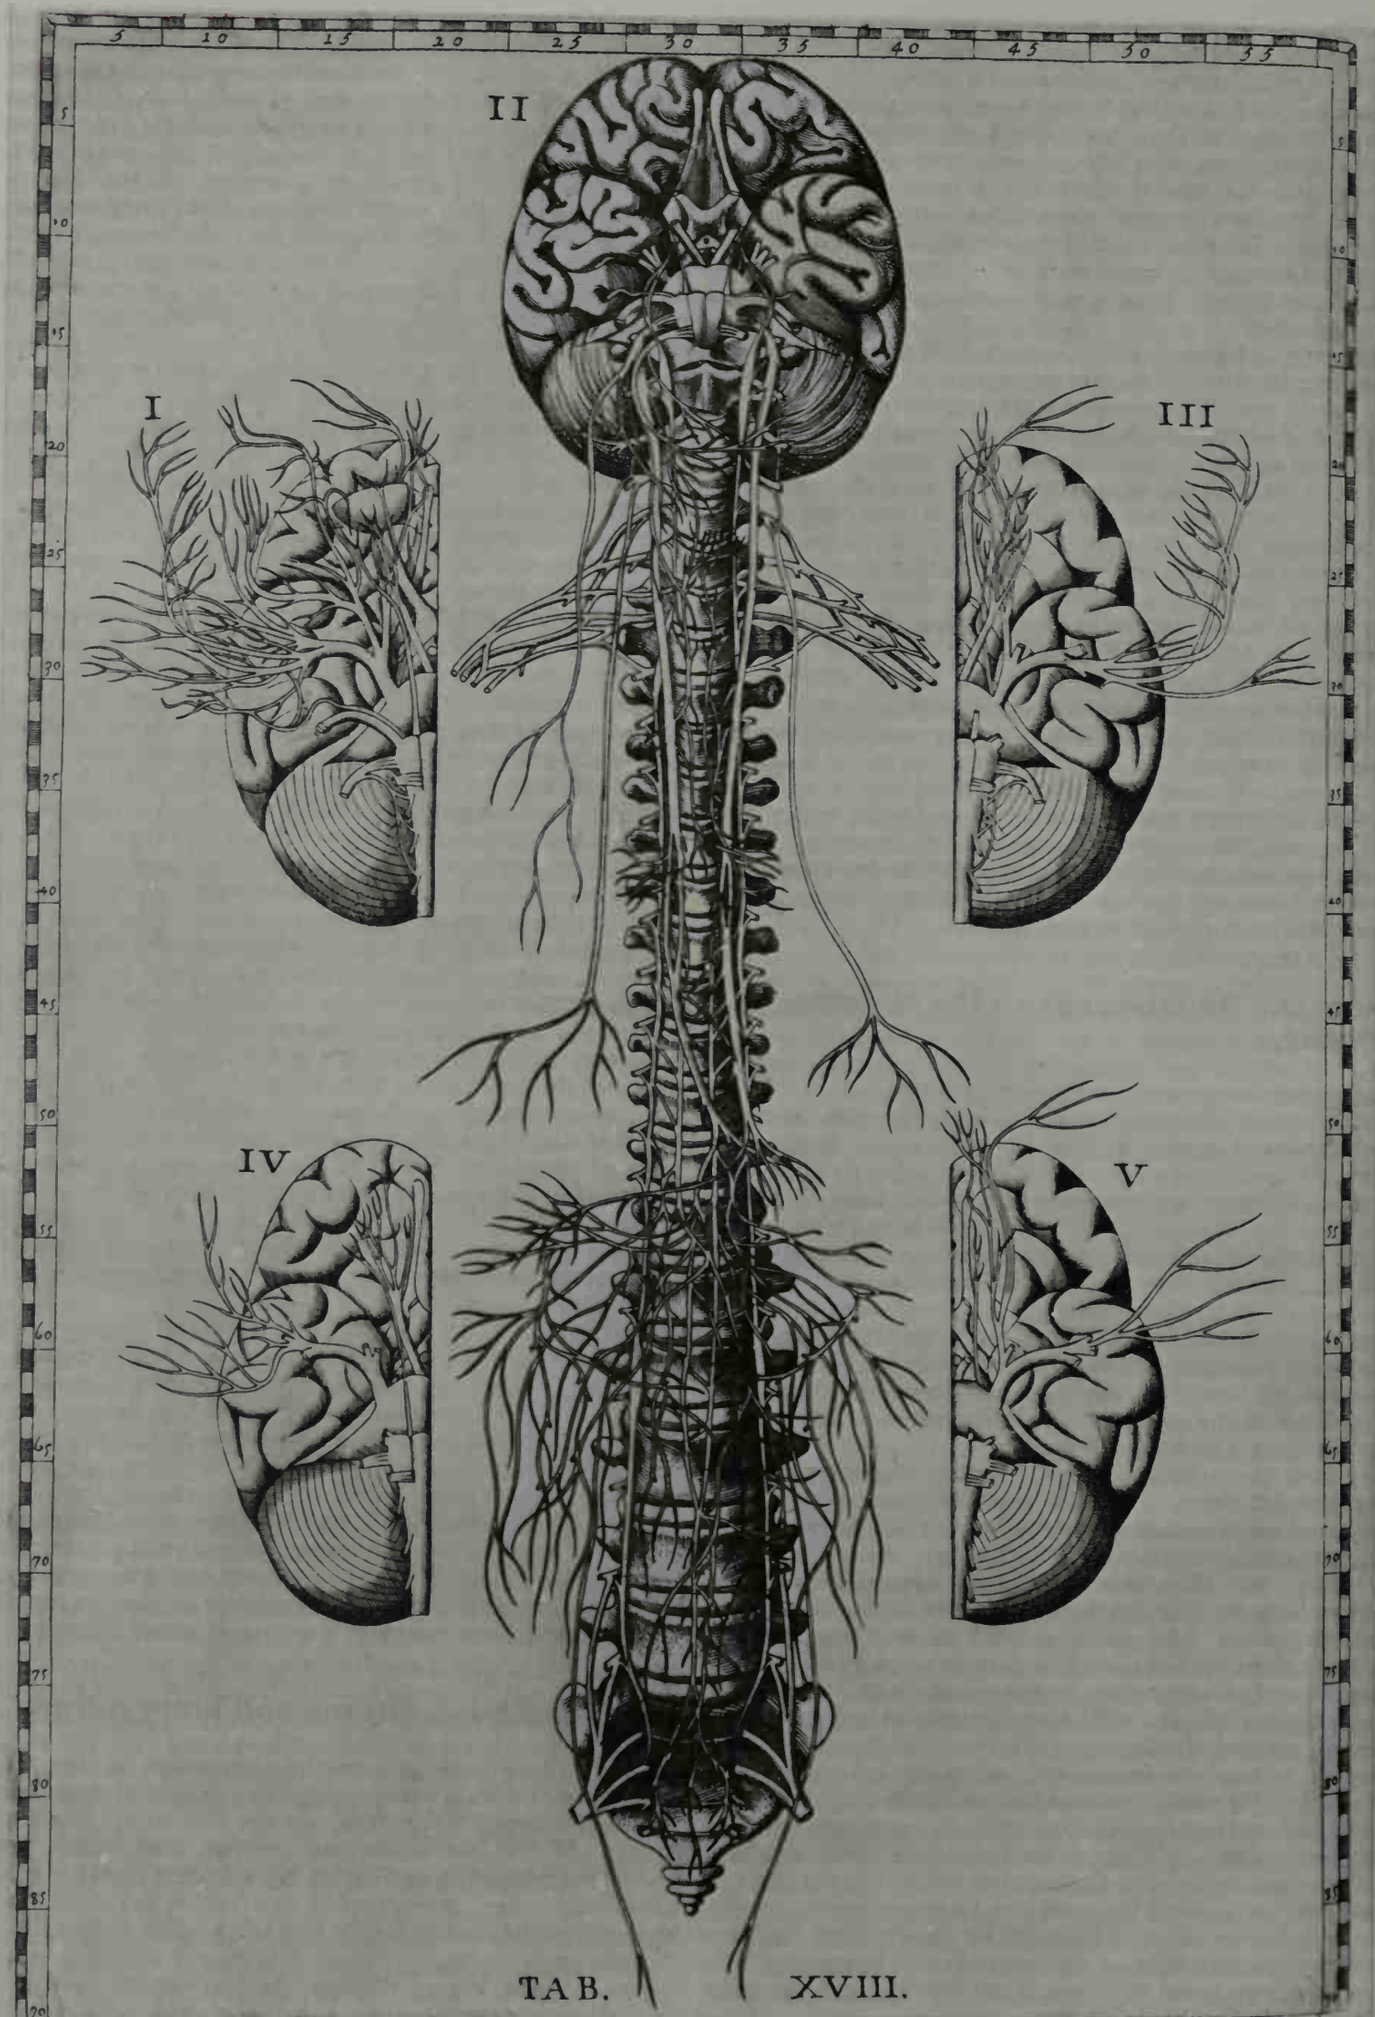
From the Renaissance to the Nineteenth Century

The movement towards naturalism amongst artists of the Renaissance in the late fifteenth and early sixteenth centuries culminated in Leonardo da Vinci (1452–1519)—*see* Belt (1956). Like his great contemporaries, Dürer, Michelangelo and Raphael, he turned to dissection for direct information on human structure. The extent of his contemporary influence is uncertain, but he brilliantly epitomizes the revival of an inquiring spirit in Europe, reacting powerfully against traditionalism and the excesses of scholastic orthodoxy. His contribution to neuroanatomy was limited but impressive—some remarkable figures of the brain, depicting wax casts of the ventricles, a technique invented by him. The movement represented by Leonardo, together with the introduction of improved techniques of engraving, paved the way for Vesalius.

Vesalius (1514–64) has received perhaps excessive medical adulation; his plates, starkly structural when compared with the functional inspiration of Leonardo's, nevertheless introduced an accuracy unrivalled in his time, marking a new era in medicine (*see* O'Malley 1964). Dissatisfied with Galenic inaccuracies, and with the near sanctity accorded them despite the ascertainable facts, and yet unable fully to emancipate himself from Galen's physiology, he revised the whole field of anatomy by his own dissections. In neuroanatomy he struck a new high level in detail and precision, though with lesser success in the peripheral nervous system. He illustrated the brain partly in a sectional manner (a technical innovation), going far beyond existing knowledge. He clearly indicated the basal nuclei, hippocampus, fornix, internal capsule, pulvinar, colliculi, fourth ventricle, and many other details, with almost the accuracy of a modern atlas.

Eustachius (1550–74), a contemporary of Vesalius, has received less than just acclaim; his work, like Leonardo's, only became generally known long after his death. He left a brilliant depiction of the sympathetic nervous system (7.12), and he portrayed the cranial nerves more accurately than Vesalius and the pons (Varolii) than Varolius.

Vesalius' successors at Padua were less eminent, but exerted much influence on visiting scholars. Thus, Coiter of Montpellier (1534–76), a notable early comparative anatomist, studied under Fallopius, and he improved the work of Vesalius and Eustachius on the cranial nerves, describing the two roots of spinal nerves and distinguishing white and grey matter in the spinal cord. Fabricius, also a comparative anatomist, taught Harvey (1578–1657), whose celebrated discovery of the circulation was strangely combined with a veneration for Galen's views in other matters, sometimes almost servile. Nevertheless, Harvey rejected the flow of 'spirits' in hollow nerves, a break with dogma perhaps not unassociated with the influence of his contemporary, Bacon (1561–1626). Bacon's contempt for scholastic orthodoxy, and his inductive approach to experimentation and factual verification of hypothesis, have proved the first clear advance beyond the logic of Aristotle. This new scientific attitude, though a working philosophy rather than a practical technique, has perhaps influenced subsequent scientific endeavour as profoundly as Harvey's experimental genius. Thereafter the tempo of discovery has slowly augmented, with the focus upon humours in nerves or the blood, as avenues of control and communication, gradually transferring to the nervous system.



Until the times of Vesalius and Harvey the only techniques for study of the nervous system were dissection and the simplest experimentation, both observed with the unaided eye. No sudden changes occurred; but during the seventeenth and eighteenth centuries discoveries in parallel fields, especially in electrical phenomena and optics, have proved highly significant to nervous system investigation. The experiments of Gilbert (1540–1603) in electricity and magnetism foreshadowed the development of electrical stimulation of nerves by Galvani (1737–98) and Volta (1745–1827), which heralded the evolution of neurophysiology. Simple microscopes began to appear, enabling van Leeuwenhoek (1632–1723) to dispute the hollowness of nerves; the compound instruments which rapidly followed, though notably exploited by observers such as Hooke (1635–1703), were not applied extensively to neuroanatomy until the early nineteenth century.

Meanwhile, topographical neuroanatomy prospered, and such exponents as Willis (1621–75) and Vieussens (1641–1716) hardened the brain, either by soaking it in wine or by boiling. They were hence able to dissect it, an advance over the slicing methods of their predecessors, enabling them to achieve a new level of excellence. Willis in particular was a pioneer of macroscopic dissection of nerve fibre bundles in the central nervous system, the only technique available for such investigation for nearly two centuries after him. Naturally disposed towards experiment, he was also approaching modern concepts of reflex activity.

During the latter part of the eighteenth century the speculations of Willis, von Haller, Whytt and others regarding involuntary reactions to stimulation were beginning to emerge as realities in the experiments of the 'galvanists'. At the same time the compound microscope was coming into wider use; and during the first half of the nineteenth century the accessory supporting techniques of fixation, microtomy, and staining were also evolving. Neuroanatomists were turning from external features to internal structure, though the former diverged into a wide interest in comparative morphology. Many workers were becoming more specialized, and it is perhaps less confusing to consider further technical progress as a number of arbitrarily separated topics.

Comparative Anatomy and Embryology

Though Erasistratus is sometimes regarded as the first comparative neuroanatomist, the modern movement stems from the observations of Willis (1664); see also Cole (1944), Needham (1959). At first the accent was on functional rather than evolutionary concepts; and in this Willis laid the foundations of nineteenth-century preoccupation with localization of function, especially in the cerebral cortex. Gall (1758–1828) and his pupil, Spurzheim (1776–1832), though achieving a notoriety undeserved by the former through their erroneous theory of phrenology, nevertheless were initially responsible for the

II
I
III
IV
V
TAB. XVIII.

principle of cortical localization. In their massive publications (Gall and Spurzheim 1810–19) they much improved on Willis's comparative observations on cerebral gyri, and they also carried further his method of brain dissection. Tiedemann (1781–1861) was a pioneer in description of the human fetal brain, and Reil (1759–1813) concentrated on the development and comparative anatomy of the cerebellum and insula, advocating the technical value of combining such studies in functional interpretation (Tiedemann 1860; Reil 1807). Owen (1868) added the concept of brain weight and volume as a comparative technique, and he also linked the early developmental appearance of certain gyri with the regularity of their occurrence. Many others extended the series of animals studied, especially in respect of primates, and in this the advent of Darwinism was an additional spur. Throughout the nineteenth century a wealth of comparative and embryological observations were adduced in evidence of homologies in cortical pattern to support the polemics of the 'localizationists' and their opponents, a now almost forgotten controversy. All these contributions were based on macroscopic technique; but with Campbell, the Vogts and Brodmann (1909), at the end of the century and extending into the twentieth, microscopic investigation of the cortex on a comparative basis became established. The vast cytoarchitectonic investigations, familiar in the 'Brodmann maps' of many current texts, have never been equalled except by Conel's studies of developing cortex (1939–59).

With the great advances in neurohistology and neurophysiology in the late nineteenth and twentieth centuries, interest in topographical comparative neuroanatomy has somewhat waned. Nevertheless, with the new morphological techniques classical work such as that of Herrick (1931), of Larsell (1937) on the cerebellum, and Polyak (1957) on the visual system, continued to appear. The great compendia of comparative neuroanatomy compiled by Ariëns Kappers and his collaborators must also be mentioned (Kappers 1920–1; Kappers *et al.* 1936). (References to the work of others, including Tilney, Conolly, Bailey and von Bonin can be found in the recent text of Crosby *et al.* 1962.)

The linkage between embryology and comparative anatomy was early established, as already noted. Arnold (1842), for example, described the early development of the hippocampal gyrus in primates; His (1874) distinguished 'complete' fissures, which appear first, and secondary cortical sulci; and Broca (1878) supported his concept of a speech centre as much by such considerations as by functional data.

More significant, however, have been embryological studies at the microscopic level. His (1887) demonstrated stained preparations showing that axons grow from neuroblasts, thus providing positive evidence for the neuron doctrine, and in a sense foreshadowing the tissue culture studies of Harrison (1907). The work of His was confirmed by Held (1893), who nevertheless concluded that synaptic gaps, as we would call them today, disappeared during maturation of neurons—evidence against the individuality of nerve cells. Flechsig (1876) discovered that myelination proceeds—before and after birth—at different rates in various tracts, thus introducing a *myelogenetic technique* for investigation of fibre connexions.

Neurohistological Technique and Light Microscopy

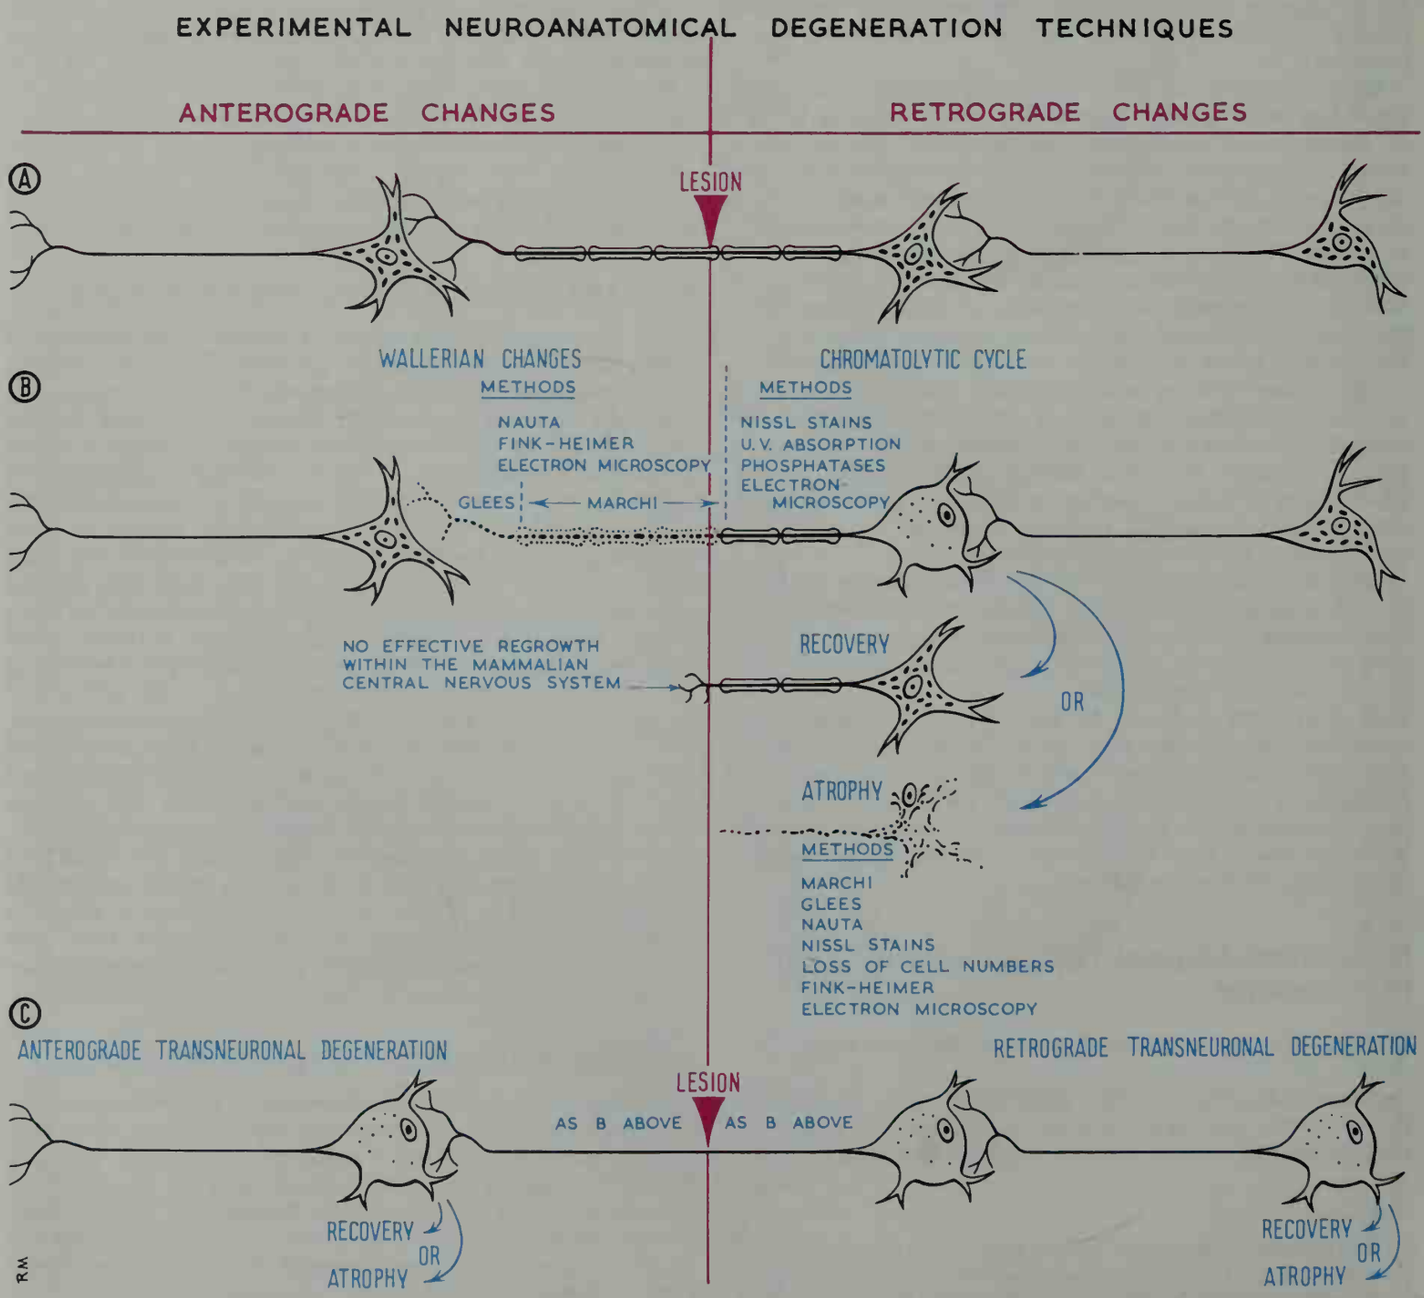
(*See* Clay and Court 1932; Brachet and Mirsky 1960; Clark 1961.)

Leeuwenhoek (1674) identified nerve fibres with a simple high-powered lens, and with a similar 'microscope' Swammerdam (1675) even dissected out the nervous system of the mayfly larva, a brilliant anticipation of microdissection. Jansen (1590) had already constructed the first compound microscope, put to practical but not biological use by Galileo. Kepler is also credited with a similar invention, carried into effect by Scheiner (1611). Huygens (*c.* 1684) introduced the compound eyepiece. Malpighi (1666) has been supposed to have been first to visualize nerve cells with a somewhat crude compound microscope, but a reconstruction of his observations with a similar instrument has neatly demolished this claim (Clarke and Bearn 1968). Fontana (1781) described nerve fibres clearly, but failed to distinguish axon from sheath. Further advances were in fact impossible without improvement in microscopy. Lister (1827) and Amici (1827) manufactured *achromatic* objectives; however, Lister's pioneer efforts were sustained by no British successor, the centre of further development passing to Germany, where Abbé, working for Carl Zeiss, was able to construct *apochromatic* objectives in 1886, using the newly discovered Jena glasses. He also improved the condenser and devised compensating eyepieces. Darkfield condensers (Wenham *c.*1853) and immersion objectives (Tolles 1874 and Abbé 1878) further accelerated the refinement of the late nineteenth-century microscope.

The immediate result of even achromatic objectives was a flood of descriptions of animal tissues. Botanical *cells* had been portrayed long before, of course, by Hooke (1665) and so named. Nerve cells, a discovery at one time accorded to Schwann when enunciating the cell theory with Schleiden in 1839, are now considered to have been first satisfactorily recognized by Ehrenberg (1833). However, there seems to be little doubt that Schwann first described the neurolemmal cell. These early achievements were rapidly surpassed with the new optical resources, but this progress rested equally upon development of adequate methods of preparation and staining of animal tissues.

PREPARATION OF MATERIAL FOR MICROSCOPY

Early microscopists used teased or squashed preparations of either fresh or, at most, partially preserved biological material. Since fixation and hardening are essential to adequate sectioning, especially of animal tissues, Reil's introduction of alcohol for this purpose in 1809 was an important advance. Hannover added chromic acid as a fixative in 1840; and Stilling (1842) used both methods, sometimes coupled with freezing, in accomplishing his classical work on the spinal cord (1846), cutting it both transversely and in longitudinal section. He also advocated serial sections, as did Virchow (1846), in describing and naming neuroglia. Formalin fixation was introduced much later by Blum (1893). Stilling and Wallach (1842) devised a simple hand microtome, improved by Welcher (1856); machines of increasing accuracy were invented and improved throughout the second half of the nineteenth century, still linked with names such as Jung, Thoma, Cambridge Rocker, etc. Von Gudden and Catsch (1875) were able to cut whole sections of the cerebral hemisphere, and Rutherford and Cathcart (1873) introduced the first freezing microtome. By the 1880s semi-automatic microtomes, such as the Cambridge Rocker, were capable of producing ribbons of thin serial sections from wax embedded material, paraffin wax having been introduced by Klebs in 1869. Embedding of tissue in collodion (Duval 1879), celloidin (Schiefferdecker 1882) and other materials followed, leading to such modern innovations as water-soluble waxes, freeze-drying, and cryostat techniques.



TISSUE STAINING METHODS IN NEUROANATOMY

It is a source of surprise and admiration to note how much was achieved by the early nineteenth-century microscopists without staining techniques, though it would be misleading to overlook the sporadic use of colouring methods from the beginnings of microscopy (Baker 1960; Gurr 1965; Pearse 1968). Nevertheless, Remak's early description of axons and their sheaths in 1836 was based on unstained embryonic material (Remak 1836), and under similar difficulties Purkinje, a year later, confirmed these observations and identified the cerebellar nerve cells named after him. Incidentally, Purkinje adopted acetic alcohol as a clearing agent and Canada balsam for permanent mounting of sections. It

7.12 The brain and autonomic nervous system depicted by Bartolomeo Eustachio (1550–74), a contemporary and rival of Vesalius (1514–64), from *Tabulae Anatomicae*, published posthumously in 1714 by Lancisi. The copperplates of Eustachio (or Eustachius) are not only anatomically more accurate than the woodcuts of Vesalius, but also technically superior. (By courtesy of the Trustees of the British Museum.)

is nowadays difficult to believe that Waller's study of degeneration in nerve fibres reported in 1850 was conducted on teased nerves, unfixed and unstained; or that Kühne's discovery of motor endings in 1862 followed mere treatment with weak hydrochloric acid to clarify the sarcoplasm.

The first neurohistological stain was probably the carmine and gold method of Gerlach (1858), which enabled him to advance a *reticular* or *net* theory of neuronal continuity. The controversy between the protagonists of this and the rival *neuron theory* reverberated down the rest of the nineteenth into the twentieth century. Though Faraday had discovered benzene in 1825, and Perkins had prepared the first aniline dye, mauveine, in 1856, the industrial development of dyes was quickly taken up in Germany, a by-product being a rapidly increasing range of such dyes available for histological use from 1862 onwards (*see* Conn 1948). Carmine staining was applied by Deiters (1865) in differentiating between dendrites and axons. Ranvier's (1871) classical delineation of nerve fibres and their nodes depended upon a silver impregnation of chromic acid fixed tissue; and Golgi (1878) further elaborated silver staining, thus rendering occasional whole neurons visible, from which preparations he described the cell types still known today by his name. (While Golgi's technique is usually regarded as applicable only to small volumes of nervous tissue, Golgi himself and some recent workers have stained whole human brains in this manner. *See* Kemali *et al.* 1977.) Golgi emphatically supported the reticular theory, but Ramon y Cajal (1908), who adopted Golgi's metallic impregnation methods and added his own refinements, was thus able to accumulate such an overpowering array of observations on neurons in all parts of the human nervous system, and in many other animals, that the neuron theory has prevailed. The accuracy and volume of this work was the chief factor in advancing the individuality of nerve cells, although the theory is often accorded to Waldeyer. Not until the advent of the electron microscope was it possible to adduce more convincing evidence in favour of Cajal's teaching; however, even as recently as 1933, a year before the appearance of the first electron microscope, he considered it necessary to re-emphasize his views. Cajal also used Nissl's methylene-blue method for staining 'chromatin granules' (*vide infra*). Ehrlich (1886), applying the same dye to living tissues and thus initiating vital staining, was thereby able to define peripheral nerve cell processes to their terminations; being an axonal stain, this technique has

7.13A–C Diagram of the sequelae of interruption of the fibres of central nervous system neurons. As shown, regeneration or atrophy may follow the response to injury, both in the neuron primarily damaged and in those affected transneuronally. Transneuronal effects may occasionally supervene in neurons more remotely associated with the damaged neuron. See text for further details.

proved most valuable, in various modifications, for the demonstration of peripheral non-myelinated autonomic nerve fibres.

Nissl (1892) discovered the *acute response* of a nerve cell body to damage of its axon, characterized by *chromatolysis*, a breakdown of the *Nissl* or *chromatin granules*, as well as other manifestations, such as swelling of the cell and eccentricity of its nucleus. (These, and other features of retrograde changes are described more fully elsewhere—pp. 861–863.) He thus provided further evidence of continuity of nerve cell and axon and also a most valuable means of delineating the arrangement of neurons. Weigert (1882), somewhat earlier, had elaborated a staining technique for *normal* myelin sheaths based on pretreatment with potassium bichromate, followed by acid fuchsin (haematoxylin is now more often used). It is interesting to note that he was already using collodion for embedding material, xylol for clearing, and balsam as a mounting medium. This innovation was quickly followed by Marchi's osmic acid method for staining *degenerating* myelin, for which it is specific and hence an early example of histochemical technique (Marchi and Algeri 1885–6). A few years before Nissl's description of the early response of neurons to damage, Gudden (1870) had studied the later sequelae of these changes, finding that the injured cells commonly atrophied and ultimately disappeared; he also noted that the changes were more rapid and marked in young animals.

Both Gudden and Nissl made considerable personal contributions using their own techniques. The former's original experiments were an investigation of thalamocortical connexions, which his pupil von Monakow (1882) carried further, also discovering the visual function of the lateral geniculate body. It is noteworthy that both problems have been reinvestigated by the same technique half a century later (Le Gros Clark and Penman 1934; Le Gros Clark 1936), an example of the continuing value of such degeneration techniques; these have continued in use throughout the twentieth century, and their application, together with certain other allied methods, is of such general importance in neuroanatomy that they must now be considered in more detail.

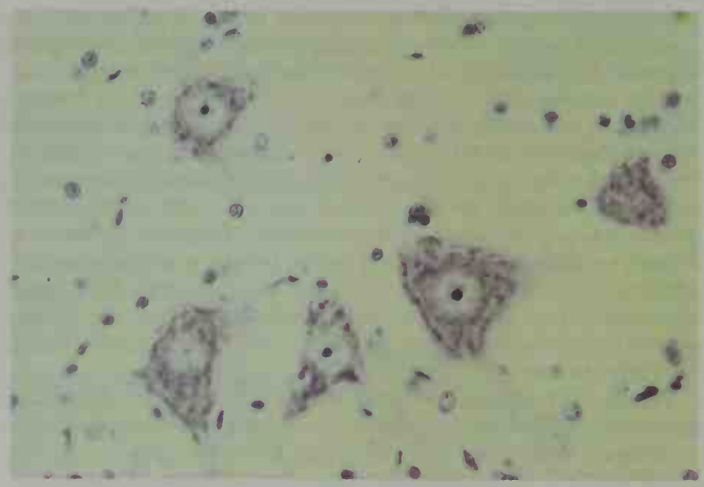
Neuron Tracing Techniques

The researches of Waller, Gudden, Golgi, Weigert, Marchi, Nissl and Cajal were all published within the last thirty years of the nineteenth century, except for Waller's basic observations in 1850. His demonstration that damage to nerve fibres induces microscopically identifiable changes proved a most fruitful starting point in this brilliant period and, indeed, in neuroanatomy and neuropathology in general. His immediate successors established the broad basis of neuronal morphology and the major techniques for an enormous volume of investigation into the organization of the nervous system. Modifications and some additions have followed, as we shall see, but their methodology remains substantially unchanged, persisting up to the present in parallel with subsequently evolved techniques in neurophysiology, histochemistry and electron microscopy (*vide infra*).

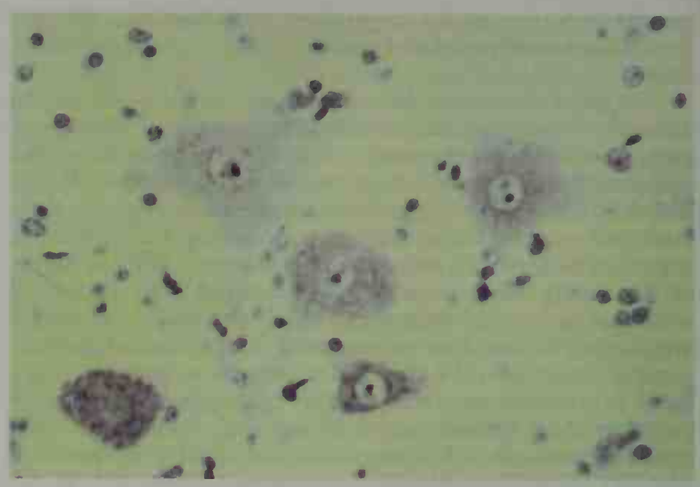
The essential features of the use of degeneration techniques in tracing out the arrangements of nerve cells and their neurites are shown in illustrations 7.13, 14.

When the cell body is actually ablated or damaged to such an extent that it dies, all its neurites, including the whole of the axon and its sheath of myelin, degenerate and finally disappear (for further details *see* p. 862), and during this period the changes described by Waller can be distinguished by Marchi staining of the degenerating myelin. The axon's terminal branchings, including their terminal synaptic buttons (*boutons terminaux*), are equally involved in their degenerative process, though this was not at first appreciated. Being devoid of myelin these degenerating terminals did not stain by Marchi's technique, and this often led to errors when interpreting their presumed destination. More recently, however, methods introduced by Glees (1946), and by Nauta and Gygax (1951), with various modifications by other workers, do stain these degenerating preterminal and terminal structures. More recently still, ultrastructural changes in *boutons terminaux* during degeneration have been utilized for fibre tracing.

However, as we shall see, there are many technical difficulties associated with the placing of small discrete experimental lesions within a mass of nervous tissue. Further, there is no known method of selectively ablating *cell bodies alone* within the central nervous system; in all experimental situations, their dendritic trees and the synaptic terminals from other functionally associated neuron groups, blood vessels, and often other structures, are involved simultaneously. In some respects a clearer experiment results when axonal processes are interrupted at some point along their course, and various terms have been introduced to indicate the different situations in which degenerative changes occur following such focal damage. These are merely summarized here.



Firstly, the effects confined to the neuron that has been damaged—those affecting that part of the axon, and associated structures, which has been detached from the parent cell, i.e. *distal* to the lesion, are termed *anterograde*; those affecting the dendritic tree, parent cell body and that part of the axon still attached to the cell body, i.e. *proximal* to the lesion, are *retrograde*. Secondly, changes may follow in neurons which have suffered no direct damage, but are functionally associated with the damaged cell. These are *transneuronal* (or *transynaptic*) changes, and they may be *primary* or *secondary*, etc. depending upon their degree of separation from the damaged cell, and further they may be *anterograde* or *retrograde*, depending upon their position relative to the damaged cell in a functional train of neurons. These varieties are detailed further in the following pages, and elsewhere in the present section.



Following a focal lesion of the axon, anterograde degeneration (of the Wallerian type involving again both the axon, its terminals, and myelin sheath) occurs distal to the lesion. The changes do not occur simultaneously at all points, but spread as a 'wave-front' distally from the lesion. After suitable time intervals they may be followed experimentally using the methods of Marchi, Glees, Nauta, Fink-Heimer, and histochemical and ultrastructural methods.

The proximal part of the fibre often does not show any changes when stained by Marchi's method, and for long it was believed that no degeneration occurred there although Cajal had described a process of retrograde degeneration of Wallerian type which extended backwards along the fibre, but only as far as the first node of Ranvier proximal to the site of damage. However, it has now been established that more extensive changes sometimes do occur in the fibre proximal to the injury, and that is when there occurs a *retrograde atrophy* of the nerve cell body in question (which is of course accompanied by degeneration of *all* its neurites). Such an atrophy of the cell soma is a later sequel of the *acute retrograde* (chromatolytic) *response* studied by Nissl (but as we shall see the latter is not followed in every case by the more chronic manifestations of atrophy). The degenerative changes in the nerve fibres are thus termed *retrograde* in the sense that they occur proximal to the lesion, but they proceed in a *centrifugal* direction, from the cell soma towards the lesion. Again, at suitable time intervals they may be studied using the methods of Marchi, Glees, Nauta and Fink-Heimer.

These various phenomena develop more rapidly and are more marked in degree in newborn or at least very young animals, as Gudden noted, whereas Nissl apparently did not. Brodal (1940), who has worked extensively with these methods, has introduced a so-called *modified Gudden technique*, which depends upon using very young experimental animals, in which both the acute and chronic types of retrograde change occur much more rapidly, the former being more usually relied upon.

The application of such methods, and the selection of a particular one in a given problem, require careful consideration; and the control of timing between infliction of a lesion and inspection of the consequent degeneration is critical. Moreover, workers in this field have reported much variation in the extent and rate of degenerative sequelae in different kinds of neurons and in the same cells in different species. Critiques of these experimental difficulties should be consulted (e.g. Glees 1961; Brodal 1969), as also the many publications of workers by whom these techniques have been employed.

7.14A–D A Large multipolar neuronal perikarya in the magnocellular part of the feline red nucleus, showing prominent Nissl's granules, bases of dendrites and axon hillocks. The nuclei are euchromatic and vesicular, with prominent nucleoli. The small nuclei scattered in the surrounding neuropil are characteristic of the various categories of neuroglial cells.

B A field similar to that depicted in A, but after previous contralateral hemisection of the spinal cord at the level of the fifth cervical segment, thereby severing the rubrospinal tract. The section shows characteristic chromatolytic retrograde changes in the cytoplasm of three large neurons. Two smaller neurons are unaffected.

C Transverse section through dorsal funiculi of feline cervical spinal cord, after unilateral dorsal column section at a more caudal level. Note anterograde Wallerian degeneration of ascending nerve fibres: degenerating myelin sheaths are stained black by Marchi technique. (Provided by Dr. E. W. Baxter, Dept. of Biology, Guy's Hospital Medical School.)

D A high-power light micrograph showing preterminal degeneration of afferent axons ending in relation to neurons of the red nucleus of a rat, after the previous placing of a cerebellar lesion. The preparation was stained by the Nauta-Gygax method. (Kindly supplied by Prof. K. E. Webster, King's College, University of London.)

The ultimate fate of neurons damaged deliberately for experimental purposes is not always the same, and the following remarks apply also to the long-term results of naturally occurring injury. As stated above, when the nerve cell is ablated or coagulated, or otherwise severely damaged as in the infliction of focal lesions (*vide infra*), the whole neuron, including all its processes, degenerates and disappears. However, where axonal injury is inflicted, the acute retrograde reaction which supervenes may be followed either by a gradual recovery extending over some weeks, or by chronic retrograde atrophy, a much slower process with ultimate disappearance of the cell and, of course, its processes. Quantitative aspects of these phenomena have been investigated in some respects by Turner (1943) and Bodian and Mellors (1945), amongst others. Where the nerve cell survives, its characteristic pattern of chromatin granules returns and the proximal, attached part of its axon recovers, whereas its severed part is finally absorbed, after passing through the changes of Wallerian degeneration. The time relations of the latter vary in different instances, and they may be very slow. In the spinal cord it has been possible to apply Marchi staining to identify degenerating tracts up to a year or so after injury (Smith 1951).

So far the retrograde and anterograde degenerative responses to injury *within a single neuron* have been considered. Early in the present century, however, it was recognized that experimentally induced degeneration in one set of neurons may be followed by similar changes in others, arranged in the same functional sequence, the phenomenon being termed *transneuronal* or *transynaptic degeneration*.

The best known example of *anterograde transneuronal degeneration* occurs in the visual pathway: selective lesions of the retina result in degeneration not only of the nerve fibres of the injured ganglion cells which travel thence to the lateral geniculate body, but also of the geniculate neurons with which these fibres form synapses. The process may extend even further, involving a second group of functionally associated neurons in the striate cortex. It is thus possible to speak of *primary* and *secondary* transneuronal degeneration. The potentiality of this finding for elegant experimentation has not been overlooked, but this kind of 'polysynaptic' degenerative response has not been discovered in more than a few instances. There are indications that it may be limited to situations where neurons receive their afferent impulses predominantly, if not exclusively, from a single source. However, ventral grey column cells in the spinal cord receive afferents from multiple sources, and yet it has been claimed that they exhibit transneuronal degeneration when appropriate dorsal spinal roots are cut; these claims have been severely criticized. However that

may be, the technique offers obvious possibilities in tracing pathways, and it may be more widely applicable than is so far expected.

Retrograde transneuronal degeneration has received less attention, though its occurrence in Gudden's cortical ablation experiments is now regarded as undoubted. The damage inflicted caused not only degeneration in anterior thalamic neurons, whose axons reach the cortex, but also in other thalamic nuclei now known to be in a primary and secondary functional relation to the anterior thalamus (Cowan 1970). In Gudden's investigations the destructive technique was surgical ablation, a method still used when applicable, and when no more accurate means is required. A number of other methods of making highly selective lesions have been devised.

SELECTIVE LESIONS AND STEREOTAXIS

In using fibre-tracing techniques an appropriately accurate method of killing nerve cells or dividing their fibres is essential. Simple division may suffice in peripheral nerves or in superficial central tracts; crushing or repeated injury has been advocated as more effective in the former. Superficial targets, such as cerebral or cerebellar cortex, can be damaged by ablation or by simple removal of pia mater, which naturally devascularizes a considerable depth of tissue. Most targets, however, are at some depth, and the surgical approach may invalidate some experiments by undesired damage to other regions. This difficulty has prompted alternative techniques, such as the introduction of fine electrodes, which can be used for stimulation as well as electrocoagulation, or of a fine probe capable of producing intense cold at its tip. Implantation of destructive substances, including alcohol, hydrocyanide, carbon dioxide snow, or radioactive yttrium, has also been practised. Irradiation by focused ultrasound (Warwick and Pond 1968) or proton beam (Malis *et al.* 1957) offers the advantage of causing damage within the nervous system without entering it, thus obviating even the usually trivial damage entailed by the passage of an electrode or probe. The latter complication becomes more serious when large or irregular structures, such as nuclei or ganglia, are to be destroyed, because repeated overlapping lesions must be made, requiring repeated insertions. The use of antibody-antigen reactions has been suggested, and it is claimed that the caudate nucleus has been selectively destroyed in this manner.

All the methods commonly employed to make selective lesions of the central nervous system, usually some part of the brain, entail the complication of *stereotaxis*—some means of aligning an electrode, cold probe, transducer, or the like with respect to the target selected (Carpenter and Whittier 1952). The usual method is to fix the head of the experimental animal in a rigid frame in relation to which the electrode, etc. can be adjusted in three planes according to the coordinates of a particular target. These coordinates are established by measurements of the position of the target structure in serial sections of the whole head prepared in three planes, or by the use of an X-ray guidance system, using such features as air-filled ventricles as reference points. Preliminary dissection down to the target for direct estimation of coordinates in preserved material has also been advocated. Since all such coordinate data vary a little from brain to brain, and with the method employed, the degree of accuracy obtainable is limited, but is acceptable for all but very small structures. Horsley and Clarke (1908) constructed the prototype stereotactic apparatus, and a considerable succession of modifications have improved on this, particularly under the stimulus of neurosurgery.

The Rise of Histochemistry, Electron Microscopy, and Neurophysiology

The morphological techniques so far discussed continue to be used and refined, and in parallel with them are electrophysiological methods which must also be mentioned.

With improving instrumentation in the early part of the twentieth century, the study of action potentials in nerve fibres has become increasingly accurate, and with continuous refinement in electrodes, smaller and smaller groups of fibres or nerve cells can be subjected to electrical recording. The technique of *evoked potentials* consists in controlled stimulation at one point with recording of the induced action potentials at another (Chang 1959). The stimulus may be applied at receptor organs and, for example, the recording terminal may be in the cerebral cortex, and the pathway may in fact involve a number of synapses. Another technique—*strychnine neuronography*—is less applied at the present time; strychnine solution applied to small areas of the cortex, for example, causes rapid firing in subjacent neurons, and the recording of distant responses can be correlated with the area stimulated (Dusser de Barenne *et al.* 1942).

These two kinds of approach to fibre tracing are often differentiated as anatomical and physiological, but in fact each inescapably contains an element of the other, and they often provide complementary advantages and an important check on each other. With either, whenever relatively lengthy pathways are under investigation, precise details of the intermediate route between the points of stimulation or destruction and the sites of consequent distant effects may require repeated experiment for full elucidation. The distance between such experimental terminals may be contracted or extended, or intermediate blockage at suspected sites may abolish a response and thus reveal the pathway situation at that level. A useful combined technique consists in the use of the same electrode to produce electrocoagulation in neurons to set in train degeneration along fibres from which electrophysiological activity has just been recorded.

By combination of data from all these various methods a most impressive volume of knowledge of the interconnexions of the parts of the central and peripheral nervous system has now accumulated; and by further application of the methods most likely to give accurate and reliable information, and by combining them where appropriate, this knowledge will doubtless continue to grow. Of late, however, attention has been directed most intensively towards the finer details of interneuronal connexions (e.g. Horridge 1968). By insertion of microelectrodes or micropipettes directly into individual neurons the activity of single cells has been recorded in a wide variety of situations in the central nervous system. By simultaneous recording from numbers of cells in small '*integrative units*' or '*microcircuits*' of interconnexion, and by combining the results of such experimentation with recent highly detailed studies of the morphology of the neurons involved and their synapses, a new era of analysis of nervous system function is beginning (e.g. Lissák 1967; Shepherd 1974; Rakic 1975; Schmitt *et al.* 1976). Earlier concepts of excitation, inhibition and facilitation are being expanded by disinhibition, disfacilitation, lateral, pre-, and post-synaptic inhibition, and the like, a somewhat inelegant neology, but perhaps necessary to the rapidly growing information on activity in the repetitive interneuronal patterns so characteristic of much of the central nervous system. The role of the synapse in these studies is basic, and in this regard the techniques of histochemistry and electron microscopy have mediated great progress.

PHYSIOLOGICAL TECHNIQUES FOR TRACING NERVE FIBRES

By the end of the nineteenth century microscopes and supporting histological techniques were well advanced. The general appearance of nerve cells and their fibres were established, their diverse types had been described in some detail, and the neuron theory was widely accepted. The gross and microscopic arrangement of the nervous system, central and peripheral, including its autonomic moiety, had been defined in much detail and in sufficiently explanatory functional terms to be highly useful in clinical diagnosis, even though understanding of the basic mechanisms might still be elementary. It is appropriate to note here the considerable contributions to neuroanatomy made by neurologists, both in the nineteenth century, when a combination of clinical and laboratory activities was more usual and perhaps easier, and in the twentieth, despite the effects of specialization and the increasing technical complexity of

experimentation. By this stage also, neurophysiological approaches were proving particularly successful in localization of function and reflex activity. The spectacular evolution of electronics had provided a continually increasing array of accurate instrumental techniques for the measurement of nerve fibre activities, the behaviour of synapses, and the electrical phenomena of integrated cerebral activity. The study of synapses has perhaps been even more potently stimulated by the discovery of transmitter substances (by Loewi, Dale, and others), such as acetylcholine and adrenalin, with immense physiological, biochemical and pharmacological consequences. In company with these brilliant advances morphological investigation has continued under the particular impetus of new light microscope techniques, new histochemical developments and the invention of the electron microscope.

DEVELOPMENTS IN LIGHT MICROSCOPY

General development of the light microscope has produced a highly flexible instrument with refined optics, and with such alternatives as dark-field illumination for examination of living cells in tissue culture, polarization accessories allowing the definition of birefringent substances such as myelin, and the addition of a host of auxiliary equipment, including varieties of moving stage, warmed stages for tissue culture, recording cameras for still, ciné and time-lapse photography, devices for micromeasurement including microdensitometry, microdissection and micro-injection.

The introduction of the phase contrast microscope of the Zernicke type in 1935, and of its congener, the interference microscope by Francis Smith in 1947, has ushered in a new era in the examination of living cells. Phase microscopy has become a normal adjunct of tissue culture, which has been extensively applied in the study of nerve cells and neuroglia (Geiger 1963; Murray 1965). Like the phase instrument, the interference microscope can be used to assess refractive index, even in different parts of the same cell, and the latter also makes possible measurements of concentration, water content and dry mass in living cells (Ross 1967).

Recently, incident illumination optics have been introduced as a method for studying myelinated nerve fibre populations *in vivo* by Williams and Hall (1970, 1971); the technique permits examination of the dynamics of the axon and its satellite cells under various experimental conditions such as osmotic stress, severance, varieties of trauma, and after the micro-injection of, for example, electron-dense tracers and substances which cause demyelination.

Ultraviolet microscopy offers two advantages—firstly, about twice the resolving power of the ordinary light microscope (now rendered less important by the advent of the electron microscope, especially since the latter's lowest magnification overlaps the highest in light microscopy) and, secondly, the selective absorption of particular frequencies in the ultraviolet spectrum by various substances and especially nucleoproteins. Caspersson (1936) has evolved a technique of ultraviolet microspectography applicable to single cells, and this has been widely applied in quantitative assessments of DNA and RNA. The amount, distribution and behaviour of these and other substances in various kinds of nerve cells have been studied extensively in normal, experimental and pathological situations (Hydén 1960).

NEUROHISTOCHEMISTRY

Phase, interference, and ultraviolet microscopy may be considered as adjuncts to histochemistry and, more especially, to cytochemistry. Histochemistry stretches back at least a century; Raspail, a botanist, published in this field as long ago as 1830; but like other innovations of the nineteenth century, histochemistry has developed slowly and by an accelerating multiplication of individual identification methods for particular biological compounds, whose distribution in tissues and at the intracellular level has been recorded in innumerable studies, some of outstanding functional significance (*see* Pearse 1968). A wide spectrum of such tests is available for nervous tissues and neurons both in normal and pathological states (Adams 1965). Of particular interest are the methods elaborated for the identification of transmitter substances and their associated enzymes, in nerve cells, fibres and synapses. These extend from the original chromaffin reaction of Henle (1865) and its modern modifications (Coupland 1965; *see* p. 1454) to the Gomori method (1943) and the more recently devised fluorescence techniques, including immunofluorescence (p. 819). The application of fluorescence techniques in neuroanatomy (Falck and Hillarp 1959; Falck 1962) have been recently surveyed (e.g. Fuxe *et al.* 1970; Fuxe and Jonsson 1974; see also Nieuwenhuys *et al.* 1978 for a convenient bibliography). Such methods have led to a new classification of nerve cells, and a useful, if inelegant, jargon. Thus, such techniques have allowed the mapping of the mammalian brain in terms of the distribution of noradrenergic (NA), dopaminergic (DA), and serotonergic (ST) neurons (see also p. 947).

In the more general field of neurohistology other comparatively recent innovations must be mentioned. New staining methods such as those of Bodian (1936) for nerve fibres, Glees (1946), Nauta (1950), and Fink-Heimer for terminal degeneration in experimentally divided axons, Einarson (1932) and Klüver (1953) for 'chromatin granules' (Klüver's method also stains axons)—all these and others augmented the neurohistologist's repertoire.

Of special interest, in view of the resurgence in the use of Golgi's technique, are its various modifications (e.g. Fox *et al.* 1951), which have been employed widely of late in working out the morphological interrelationships of small groups of neurons, particularly interneurons. The Golgi type of staining has an unexplained peculiarity in that only a fraction of the cells are actually stained, and this makes the unravelling of their intricacies practicable, and often allows the application of quantitative histological methods, including those of microreconstruction. Studies of this kind, carried out in a wide variety of vertebrates and invertebrates, have led to a considerable *rapprochement* between current electrophysiological and anatomical investigation of small-scale neuron networks and individual neurons (e.g. Eccles *et al.* 1967). An equally potent technique in drawing together workers in separated disciplines in neuroanatomical studies has been the advent of electron microscopy.

ELECTRON MICROSCOPY

Although practicable electron microscopes have been in use since the Ruska prototype in 1933, years elapsed before sufficiently thin sections of biological material could be reliably prepared. Pearse and Baker succeeded in doing this in 1948, using an adapted Spencer rotary microtome. Sjöstrand (1967) has described these early struggles and the emergence of the ultramicrotome in its modern varieties. It must also be emphasized that biological electron microscopy would have been equally impracticable without the introduction of glass and diamond knives to cut the hard embedding media required. From the 1950s all the basic requirements were met, and from then onwards biological preparations could be submitted to the increasingly high resolutions and magnifications of continuously improving electron microscopes, the use of which has transformed the morphological approach to cytology. Three decades of application have shown great improvement and innovation in supporting techniques. Heavy metal shadowing, replication methods, the production of homogenate films, heavy metal staining including negative contrast, autoradiography, densitometry, microreconstruction, cell fractionation methods depending upon differential centrifugation (of fundamental importance in neurochemistry), electron diffraction and electron phase contrast optics, freeze-fracture and freeze-etch methods, cytochemical staining, and many other techniques have enriched the basic potentialities of electron microscopy. Perhaps even more necessary has been the rapid improvement in the interpretation of the appearances of the greatly enlarged intracellular detail, and the growth of an experimental attitude and of quantitative methods in the use of electron microscopy; otherwise the singularly productive approximation of cytology, biochemistry and molecular biology, which is fast occurring, would have been improbable. In neuroanatomical research such bonds are

developing with much effect. Elucidation of the structure of the myelin sheath and of synapses have been notable achievements. With improvement in microtomes and in the orientation of material, it is becoming possible to counter the two main criticisms of electron microscopy—the small scale of sampling and the difficulty in equating some of the findings of light and electron microscopy. Techniques have thus been developed by which adjoining thick and thin sections of the same block can be prepared, stained by contrasting techniques, and examined using the light and the electron microscopes respectively. Even short runs of serial ultra-thin sections can be produced, with the possibility, for example, of tracing the full complexities of part of a nerve cell process using reconstruction techniques. A number of further developments are being elaborated or projected, and more than the most elementary potentialities of the scanning and high-voltage electron microscopes have yet to be exploited by neuroanatomists.

OTHER MODERN TECHNIQUES

The tracing of detailed neuronal circuitry, both central and peripheral, has received a renewed impetus during the last decade by the introduction of several new techniques. Two of these have proved to be particularly valuable: autoradiographic identification of labelled substances, absorbed by nerve cells and transported along their processes, and the retrograde transport of identifiable 'marker' substances (usually horseradish peroxidase). Both techniques may be regarded as dependent upon physiological activities, in contrast to the older 'degeneration' techniques, which involve the pathological reactions of neurons to deliberate injury. It is claimed that they are also more reliable (*see* Jones and Hartman 1978), but each has its peculiar advantages and disadvantages. The autoradiographic technique was introduced by Lasek (1968) and Hendrickson (1969) and was popularized by Cowan *et al.* (1972). It consists of the injection of radio-actively labelled amino acids or sugars around nerve cells, which take up these substances and transport them along their axons (usually combined in various macromolecules), where their presence is revealed by suitable autoradiographic technique and examined by light or electron microscopy (Rogers 1973, Hendrickson 1975). The method is *anterograde*, with respect to the axon, and transport extends to terminals, where the labelled molecules ultimately accumulate. The transport is relatively rapid, but the technique is much lengthened by the necessity of prolonged autoradiographic exposure. It has already been very widely applied; and while most studies using it have merely confirmed previous findings, it has also mediated a number of discoveries, such as the revelation of previously unidentified connexions (e.g. hypothalamo-spinal autonomic and olivo-cerebellar paths). It has been shown to produce transneuronal effects (e.g. in the visual system).

The horseradish peroxidase technique depends upon *retrograde* axonal transport, a phenomenon reported by Matsumoto (1920) and confirmed by Lubinska (1964) and others (p. 826). The usefulness of inducing a traceable material to pass along an axon, from its remote distribution to its cell of origin, is obvious, but it was not until 1971 that Kristenson and Olsson showed that labelled albumin and horseradish peroxidase could be used as markers in this manner. The LaVails (1972) quickly confirmed the use of horseradish peroxidase, and the technique has subsequently been used most extensively. It consists essentially in the injection of solutions of the enzyme into nervous tissues or in the immersion of their cut surfaces (e.g. a severed peripheral nerve) in such solutions. Mechanical application has been supplanted by iontophoretic injection in some cases, to reduce local damage. The material is taken up by axons, transported along them in residues and appears in their neuronal perikarya in identifiable form. The method is applicable to all types of nerve fibre and can be employed at light and electron microscopic levels. A large literature in regard to the technique itself has already accumulated (*see* reviews by Winer 1977, and Jones and Hartman 1978). It has been utilized in innumerable researches and its introduction has stimulated extensive efforts to find other suitable markers, such as fluorescent dyes, tetanus toxin, labelled cobalt, etc.

Some of the most exciting developments that have occurred in recent years in neuroanatomical research have been associated with the widespread application of standard immunological techniques to neurobiological problems. For example, immunohistochemical methods have resulted in the localization of neurotransmitters, neurotransmitter-related enzymes, pituitary hormones and their releasing factors and other nervous system-specific proteins with a spatial resolution frequently superior to that obtained with either customary staining or biochemical regional assays (*see* Jones and Hartman 1978). Basically these techniques involve the production and subsequent visualization of sites of antibody-antigen interaction within tissue sections (the quantity of antigen can in some cases be increased by varying the physiological or pharmacological status of the tissue prior to examination). As might be expected, there are a number of factors which can influence the final distribution of these sites, and therefore complicate interpretation of staining patterns. These may be grouped as follows: (i) the production and purification of specific antibodies (the preparation of pure antigen is difficult when tissue concentrations are low). (ii) Adequate tissue preparation, especially during fixation: most fixation regimes are designed to achieve the optimum compromise between preservation of morphology and antigenicity. The commonest fixative in use for this purpose is formaldehyde; other aldehydes, with their stronger cross-linking abilities have proved less popular, although a recent improvement involving periodate-lysine-paraformaldehyde has been reported (Nakane and Kawaoi 1974). (iii) Selection of an appropriate visual marker, which in neuroanatomical work is commonly either fluorescein isothiocyanate (FITC) or horseradish peroxidase (HRP). FITC emits a high yield of green fluorescence (517 nm) when excited with blue light (peak excitation 490–500 nm)—properties which in combination with modern fluorescence microscopes permit the examination of, for example, fine adrenergic fibres (Hartman 1973). The disadvantages are (*a*) the lack of permanence of the preparation, as a consequence of quenching in mountant or photodecomposition with time; and (*b*) fluorescent markers cannot be used in electron microscopy. HRP is used as a marker molecule in two completely different ways in the nervous system. As a marker in immunohistochemical studies it can be conjugated directly to antibodies by a number of bifunctional cross-linking reagents, although this results in a partial inactivation of peroxidase activity. A recent development, the peroxidase-antiperoxidase method (PAP) in which antibodies to HRP are bound to peroxidase without inactivating it, has had an enormous impact on immunohistochemistry, especially at the ultrastructural level (Sternberger 1974). The relatively large size of the PAP complex (*c.* 420,000 daltons) can, however, produce problems of penetration in certain situations (e.g., fine nerve terminals). A recent extension of the general method outlined above has involved the use of suitably tagged antigenic markers in the identification of different neurons and satellite cells, either in suspension after isolation from whole tissue or growing and differentiating in culture prior to fixation. Thus, *in vitro*, oligodendrocytes can be 'marked' with anti-galactocerebroside; astrocytes with anti-glial fibrillary acidic protein (GFAP); Schwann cells with anti-RAN I and certain neurons with anti-tetanus toxin (Raff *et al.* 1978). Moreover, antisera raised against certain components of the myelin sheath and against nerve growth factor are being used in studies of the factors controlling myelinogenesis and other ontogenetic and pathological mechanisms in the nervous system.

A number of other relevant techniques can be barely mentioned—autoradiography (Rogers 1967, 1973), ciné and time-lapse photography (Rose 1963), microreconstruction (Gaunt and Gaunt 1978), microphotometry, micromanipulation (Kopac 1960), neuron counting techniques (Konigsmark 1970; Corsellis *et al.* 1975), morphometric analysis (Weibel and Elias 1969), and the elaboration of models to provide functional analogues (Weiner and Schadé 1963). Enough has been said, however, to illustrate the ever-growing dependence of neuroanatomical investigations upon technical development. Despite widespread misapprehension, neuroanatomy—and indeed anatomy in

general—has at no stage been an entirely morphological, merely descriptive discipline, though it can descend, and frequently has so fallen, to this somewhat sterile level. However, there have always been those, such as Willis, Harvey, or Sherrington, who have disregarded the artificial separation of nervous structure and function. Unfortunately, levels of knowledge of one or the other have often been imbalanced. After a considerable period, early this century, of separation of disciplines concerned with morphology and function (perhaps chiefly due to the exigencies of teaching organization in medical schools), the consequent isolationism now shows signs of dissolution. This is particularly true of studies of the nervous system. Preoccupation with the minutiae of shape and of the nervous impulse have borne their separate fruit, and we can now pass on to more hopeful prospects. As morphologists become more experimental and the functionalists look more attentively at the arena of their experiments, instrumentation and outlooks are evincing an increasing similarity, and purposes a new cohesion. Doubtless we are still far from concepts of integrated brain activity; but, at simpler divisions or units of the whole, electrophysiological and anatomical inquiries into the behaviour of the individual neuron and synapse, and their associations in small functional networks, seem to afford a prospect of joint success. We may at least be much nearer to comprehending the 'miniaturized' basic units in central nervous mechanisms. It is to the individual elements at this level of organization that we must now turn our attention.

CYTOLOGY OF THE NERVOUS SYSTEM

The foregoing sections have been concerned with the organization and investigation of the nervous system. We shall now consider the cellular elements of the nervous tissue in more detail, since it is impossible to create a model of brain function without an appreciation of how the individual units work (Schmitt *et al.* 1967, 1970, 1977).

As already stated, nervous tissue is composed of two distinct sets of cells, the excitable cells or *neurons*, and the non-excitable cells which constitute the *neuroglia* and *ependyma* in the central nervous system, and the *Schwann cells* and associated elements in the periphery. Since our interest in terms of neural behaviour centres on the neurons, more space will be given to outlining their structure and behaviour.

The Neuron

Neurons, although diverse in appearance and size, have many characteristics in common. All possess a large surface area compared with most other cell types, and this surface is specialized for the reception, conduction and transmission of neural information by virtue of its molecular composition, and by the topographic specialization of the neuron. The branch-like extensions of its periphery are termed *neurites*, and these may be divided into receiving processes or *dendrites*, and efferent processes termed *axons*. Usually there are many dendrites but only one axon extending from each cell. The protoplasm massed around and including the nucleus of the cell is termed the *soma*, *perikaryon*, or *cell body*; the cytoplasm of this structure is characterized by the presence of numerous strongly basophilic inclusions, the *Nissl bodies* or *granules* (7.14). The soma is often angular in shape (7.15), the projection which leads to the axon being the *axon hillock*, and its bare continuation the *initial segment* of the axon. Sometimes the axon emerges from the base of one of the main dendrites rather than directly from the soma. From the other angles of the soma spring a number of main or *primary dendrites* which branch repeatedly to form a *dendritic tree*. Each axon may also possess side branches or *collaterals*, usually much finer than the main axonal process. Axons at their termination usually break up into several fine branches, the *axon terminals* or *telodendria*, which end in apposition, variously, with other neurons to form zones of interneuronal transmission or *synapses*, with effectors such as muscles (*neuromuscular junctions*) or with glands; adipose tissue also receives efferent terminals (*see* p. 851). The plasma membrane of the axon is known as the *axolemma* and its internal cytoplasm the *axoplasm*.

Neurons vary considerably in size, from microneurons with cell bodies 7 μm or less in diameter, to some of the largest cells in the body, e.g. spinal ganglion cell bodies 120 μm across. In some of the larger cells (e.g. Purkinje cells of the cerebellum, Betz cells of the cerebral cortex) the cell nuclei, which are proportionately large, are tetraploid in their chromosomal content (Herman and Lapham 1969). The size of the cell body reflects the need to sustain the large volume of cytoplasm present in dendrites and axon; in a large human motor neuron, the axon, which can be a metre long and possesses numerous branches, may be more than one hundred times the cell body in volume.

HISTOLOGICAL DEMONSTRATION OF NEURONS

As stated previously (p. 813), what we know of neuronal structure is dependent upon the special methods which have been elaborated to show various aspects of neuronal cytology, and it is useful to consider these methods further here. Although the standard methods of light microscope histology are valuable in showing their cell bodies, the neurites of neurons do not stain sufficiently well to allow them to be traced with any degree of confidence. Various types of impregnation of *blocks* of tissue with metallic salts, particularly those of silver, do, however, stain some or all parts of the cytoplasm. One of the most useful class of techniques, invented by Golgi (*see* p. 813), results in the precipitation of silver chromate or other metal salts within individual neurons, which can therefore be demonstrated in their entirety in thick sections; and, since only a small percentage of the total cell population is affected, they are visible as black spidery profiles against a clear background (7.15B). Although the fidelity of the method has in the past been questioned, electron microscopy supports the view that the results obtained with the Golgi techniques are an accurate representation in even the finest of light microscopic details, so that now there is a resurgence of interest in this means of investigation. However, there has, so far, been no critical evaluation of the distortion introduced by either of these preparative techniques. Recently, some other methods for demonstrating entire neuronal structure have been introduced, including horseradish peroxidase, cobalt nitrate, and various micro-injection methods (*see* p. 819).

Next, there are the various techniques of staining *sections* with silver salts, some of which are specific for the neurofibrils within neurons (Gray and Guillery 1966), and others which seem to stain the entire cytoplasm (7.15E). In this category are the ammoniacal silver nitrate methods of Bielschowsky and their subsequent modifications, the silver proteinate methods of Bodian, and the various silver nitrate techniques such as that of Holmes. The block staining methods of Cajal also give good results by a similar process. Various modifications of the silver reactions have also been used to demonstrate anterograde degeneration of axons (the Nauta methods) and of their terminals (such as the techniques of Glees) in sections, by chemically suppressing the staining of normal as opposed to degenerating axons (7.14, see also p. 817). More recently, important modifications of these degeneration techniques for use with the electron microscope (e.g. the Fink-Heimer method) have been introduced, but these are being superseded by the horseradish peroxidase methods for anterograde analysis.

Numerous methods have been developed to demonstrate the sheaths of myelinated fibres (*vide infra*, p. 844), some based on osmium staining, and some on haematoxylin and allied stains such as Luxol fast blue (7.15). A modification employing chromium salts has also been developed to demonstrate *degenerating* myelin sheaths (the method of Marchi) although this

is now less widely used because of various difficulties of interpretation (p. 838). Added to these, there are modifications of normal cytological stains which demonstrate various organelles within the cytoplasm. The most useful of these, the Nissl stains, are basic substances which bind strongly to the nucleic acids which are abundant in neuronal nuclei and cytoplasm. Such stains as cresyl fast violet (7.14) and toluidine blue are widely employed by neuroanatomists for this reason. A number of stains also demonstrate mitochondria, particularly in axon terminals, and modifications show the *degeneration of axon terminals* after experimental trauma.

Electron microscopy has in many cases revolutionized our concepts of neuronal structure or, in some instances, has determined which of several alternative models is the correct one. However, since this discipline is restricted to the examination of ultra-thin sections, three-dimensional reconstruction of nervous tissue is laborious and limited in scope. It is therefore of great importance to correlate light and electron microscopy to obtain an understanding of neuronal organization.

All of the above methods involve the examination of dead material, but much may also be learnt from studies of neurons stained by supra-vital methods. Methylene blue was found by early neuroanatomists to stain the entire cytoplasm of neurons, giving a picture of individual cells as striking as those obtained with the Golgi methods. Because methylene blue is a vital stain, however, its use is restricted largely to thin or small whole tissue situations such as the peripheral and embryonic nervous systems, where penetration and staining are rapid. Many other techniques are also available for specific purposes.

GENERAL STRUCTURE OF NEURONS

Neurons can be described in several ways according to the patterns of their neurites, their physiological action, the transmitter which they release and so on (Hydén 1967; Bourne 1968). Of these various descriptions, only the first is generally possible, since our understanding of the physiological and biochemical properties of neurons is limited to relatively few instances, whereas the morphology of many neuron populations is well established. Even within the field of general structure, several types of classification are possible, mostly based on the patterns of ramification of the neurites. As mentioned previously (p. 805) a commonly used scheme distinguishes: (1) *unipolar neurons*, in which the cell body has a single extension giving rise to both dendritic and axonal branches, examples being dorsal root ganglion cells (sometimes termed *pseudo-unipolar* because this form is arrived at secondarily in development), and granule cells of the olfactory bulb; (2) *bipolar neurons*, with an extension at each end of the cell body, for example retinal bipolar cells, and cells of the cochlear and vestibular ganglia; (3) *multipolar neurons*, with several extensions of the cell body; most cells of the central nervous system are of this last type. Although this scheme of classification (7.15) is useful for descriptive purposes, it appears to have limited physiological significance. Of more importance is the classification of central neurons into relatively large, Golgi type I neurons which have long axons connecting different parts of the nervous system (Cajal 1911), and small Golgi type II neurons (microneurons) in which the axon is short and terminates in the neighbourhood of the cell body, or else is entirely absent (7.15). The Golgi type II neuron is often present in inhibitory situations, an example being the periglomerular cells of the olfactory bulb (p. 992). In a special category of microneurons, lacking an obvious axon, nervous conduction is apparently possible in either direction along their dendrite-like processes. Such neurons have long been known in the retina (*amacrine cells*), where they lie in synaptic contact with ganglion and other cells (p. 1171), but their presence is also indicated in other parts of the central nervous system, including the olfactory bulb (granule cells) and, possibly, the lateral geniculate body. It is probable that they constitute a characteristic element of all the main sensory pathways. In some situations, at least, microneuron cell processes make *reciprocal synapses* with adjacent dendrites, so that *dendrodendritic transmission* occurs (*see* p. 806).

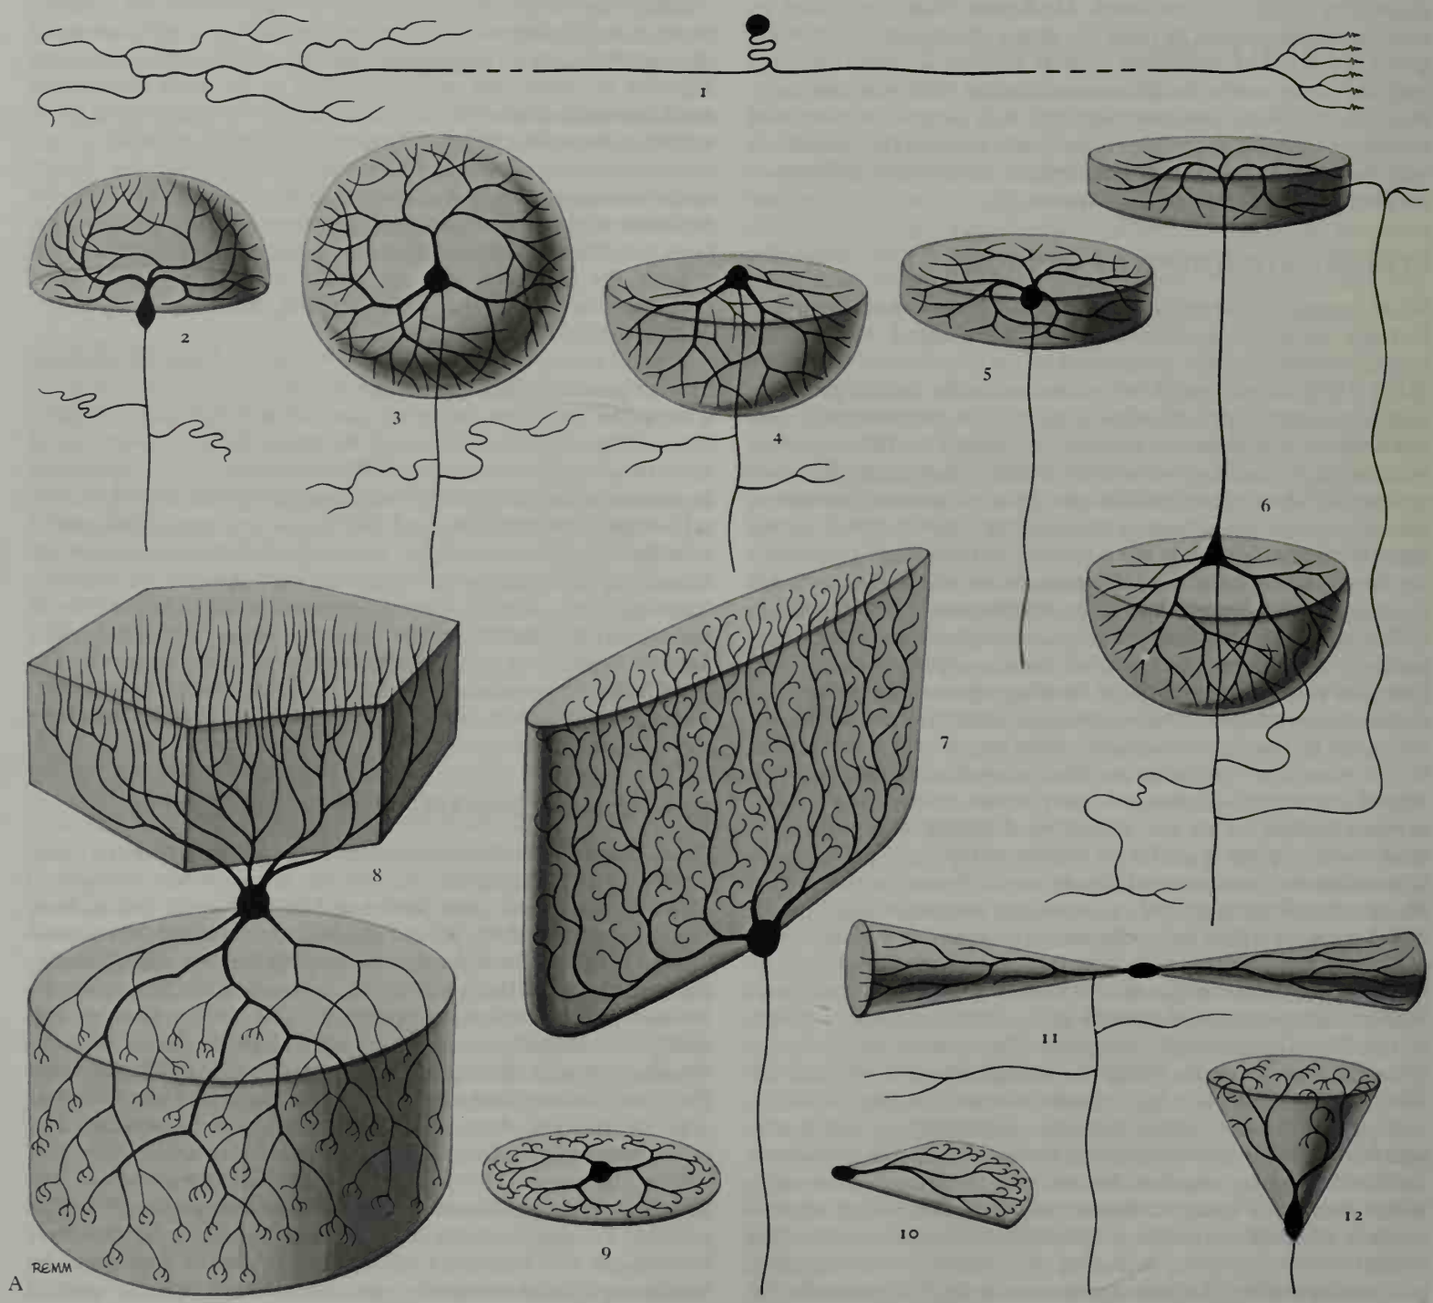
The small inhibitory neurons appear responsible for an important type of interaction between neurons, such as those of the sensory projection pathways, in which maximally excited cells can inhibit the activity of less excited, adjacent neurons, by means of inhibitory interneurons, thus 'sharpening' the sensory patterns at various levels in the pathway (7.8 and p. 808), a process termed *lateral inhibition* (*see* Horridge 1968, and pp. 808, 889).

Central neurons can also be classified according to the branching patterns and shape of their dendritic fields (7.15). Those with dendrites extending equally in all directions away from the cell body, to fill a roughly spherical volume with their smaller branches, are termed *stellate cells* (7.15), a type common in the cerebral cortex, and in certain nuclei of the brainstem and spinal cord, amongst other locations. In *pyramidal cells*, the cell body is pyramidal or conical in shape, and *basal dendrites* emerge from the angles made by the base and the walls of the pyramid to fill a roughly hemispherical volume (7.15); an *apical dendrite* emerging from the apex of the cell may also be present to give a second dendritic field at some distance from the cell body, as in the pyramidal cells of the cerebral cortex (7.15). Spindle-shaped cell bodies with dendrites emerging at one or both ends are termed *fusiform*.

Many variations of these basic patterns exist, of course, throughout the nervous system, depending upon the pattern of afferent fibres, their synaptic sites, and the mechanical constraints imposed by other cells and so on. One of the most remarkable dendritic fields is that of the cerebellar Purkinje cell (p. 919), in which a primary dendrite emerges apically and branches to form a complex two-dimensional fan-like array (7.15, 79, 80). *Glomerular neurons* are also known, in which there may be relatively few dendrites with highly convoluted branches at their tips (7.15, 79, 81) where most synaptic contact occurs, as in the mitral and tufted cells of the olfactory bulb (p. 992), in the lateral geniculate nucleus, in certain 'relay' nuclei of the thalamus (p. 957), and in the cerebellum (p. 924).

Several attempts have been made to classify dendritic patterns by their geometry, but most of these schemes, although useful for descriptive purposes, seem to have limited functional significance. More important seems to be the mathematical analysis of the branching patterns of dendrites in terms of the frequency, angles and dimensions of the branches, the spatial distribution of cell surface and volume, and the frequency, type, and spatial location of synaptic endings, since all of these parameters are known to be significant in the electrical activity of neurons. Although such studies are still in their infancy, a number of important contributions to the field have already been made. The use of computers to collate such information holds out considerable promise for the future. Other biometric parameters, such as the ratio between nuclear and cytoplasmic volume have also been examined.

STRUCTURAL PARAMETERS OF DENDRITES



When dendritic fields are examined, as for instance with the Golgi methods, the dendritic branching is seen to be largely dichotomous (Sholl 1956; Aitken and Bridger 1961; Gelfan *et al.* 1970). Where dendrites spread and branch symmetrically around the cell body, the *total number* of dendritic branches is, of course, dependent upon the number of primary dendrites and the number of sub-orders of branches. The *surface area* of cell membrane associated with the *dendrites* can be calculated from simple, although laborious, measurements of the diameters and lengths of the branches, and this can be compared with the *surface area* of the *cell body*. In spinal cord motor neurons and interneurons, up to 80 per cent of the total neuronal surface area (excepting the axon) is associated with the dendrites, emphasizing their important role as a receptive area for afferent stimuli (see also p. 883). Various methods of describing the dendritic tree have been used; the frequency of branching can be expressed by imagining a series of equally-spaced concentric spheres centred on the cell body; as the dendrites emerge and branch, the number of dendritic segments passing through the surface of each imaginary sphere can be counted and expressed as a function of distance from the cell body. In neurons of the cerebral cortex and spinal cord, the number of branches rises quickly to a maximum,

and then tails off asymptotically or logarithmically, with increasing distance from the base of the primary dendrite (Sholl 1956). Counts of the thorn-like extensions of the dendrite surfaces, the *dendritic spines*—an important index of numbers of incoming synapses (p. 826)—show that in some types of neuron there are often many thousands equally spaced over much of the dendritic tree (Gelfan and Rapisarda 1964; Gelfan *et al.* 1970). Thus it follows that the number of synapses probably first increases, and then decreases asymptotically with distance from the cell body in the same manner as the number of dendritic branches. Careful measurements indicate that different populations of neurons, although showing the same general mode, have their own peculiar relationships between cell body and dendritic surface areas, volumes, spine counts, and so on (Lindsay and Scheibel 1974).

The importance of these parameters, of course, lies in the numbers of afferent synapses made with the cell, their position, and the spreading patterns of electrical disturbance at the cell membrane which follow their activation (Rall 1977). A vital feature is the relative distribution of excitatory and inhibitory synapses, but, as yet, this can only be estimated from electron micrographic studies, which are often statistically invalid (*see*, however, p. 922). Microelectrode studies are a possible means of analysis of dendritic action, but in most cases the dendrites are too small to be monitored individually, and elaborate mathematical techniques are necessary to extract any meaning from the records. There are, however, some functional observations indicating the general significance of dendritic branching patterns; for example when neonatal mice are made thyroid hormone-deficient to simulate the condition of cretinism in man, they show behavioural retardation, and the dendritic trees of their cerebral cortical neurons are also smaller, with fewer branches, than those in control animals (Eayrs 1955).

PHYSIOLOGICAL PROPERTIES OF NEURONS

Neurons, as we have seen (p. 805), are characterized by their ability to receive, conduct and transmit *information*, which is

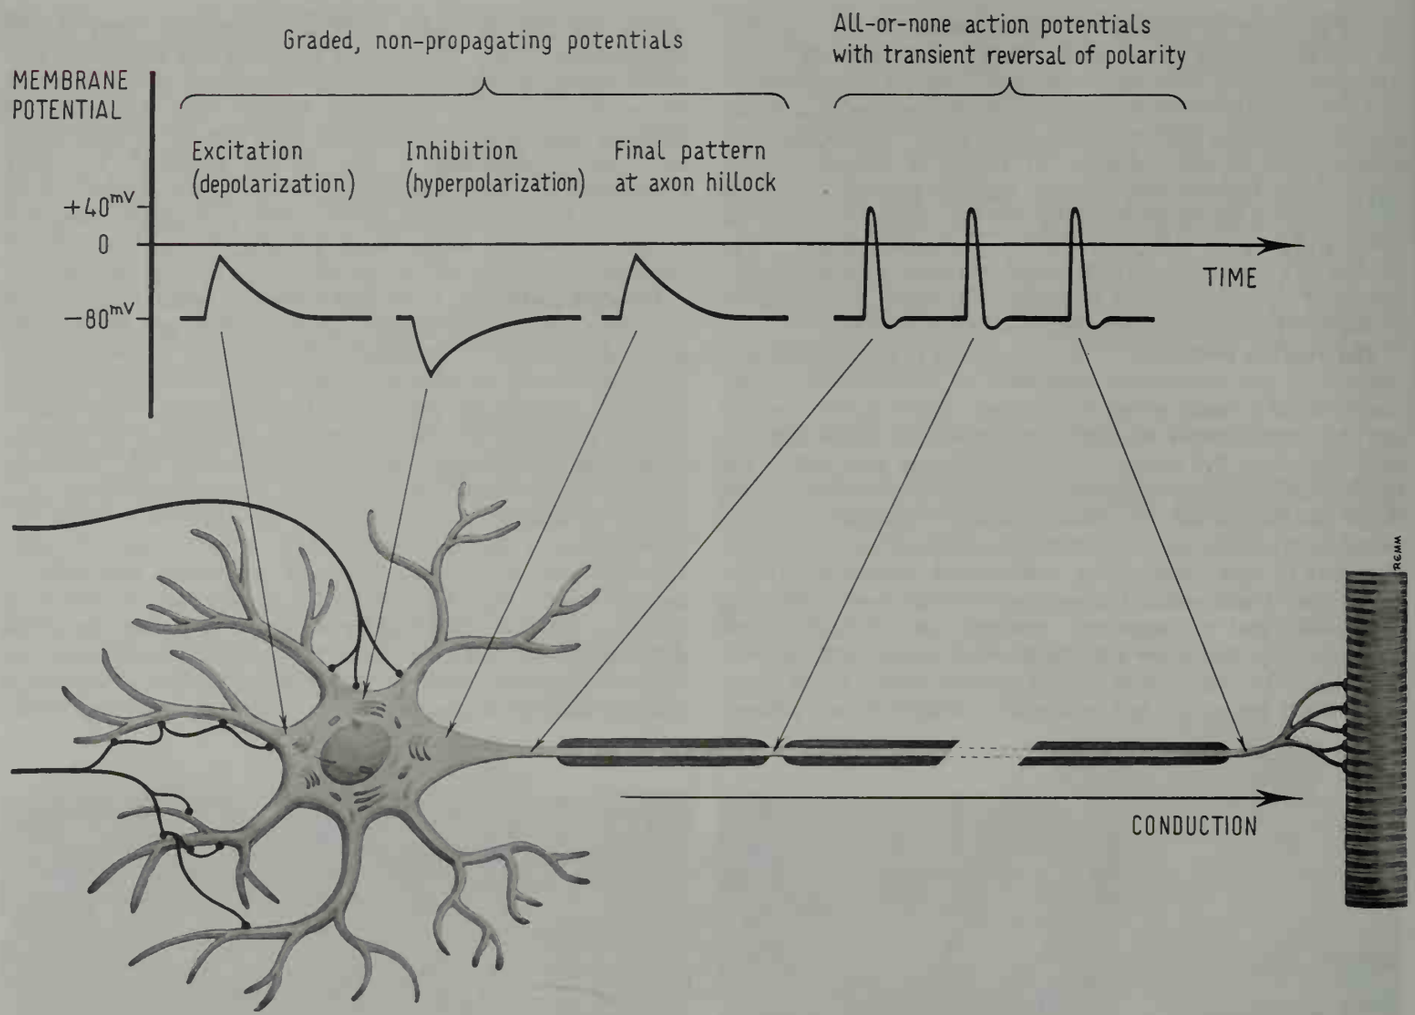
7.15A–E A Schema showing pattern variations of neuronal geometry: (1) unipolar, sensory ganglionic neuron; (2) bipolar neuron; (3) stellate (isodendritic) neuron, with (4), (5), and (11) which are modifications of this pattern; (6) pyramidal neuron with an apical and a series of basal dendrites, and recurrent axon collaterals, from the cerebral cortex; (7) Purkinje neuron from the cerebellar cortex; (8) Golgi neuron from the cerebellar cortex; (9) and (10) amacrine cells lacking axons; (12) glomerular neuron (mitral cell) from the olfactory bulb, showing recurved dendritic tips.

coded in terms of transient electro-chemical changes in their plasma membranes (Katz 1966; Kuffler and Nicholls 1977). These changes are associated with rapid fluxes of ions in and out of the cytoplasm, which occur against the background of a steady electrical potential difference maintained across this surface. The measurement of these changes by means of various electrophysiological instruments, and their analysis, provide a means of understanding the structure of the nervous system in functional terms, and progress in these two fields is coming more and more to depend on a close working relationship between them. A detailed survey of electrophysiology is beyond the scope of the present account and only a brief summary will be attempted.

The resting potential (7.16) of a neuron is in many respects similar to the membrane potential of non-excitable cells, consisting of a steady potential difference of about 80 mV which can be measured across the plasma membrane, the inside negative with respect to the outside. This bioelectrical potential is the result of differences in concentration of various anions and cations inside and outside the cell, which is further dependent upon the permeability properties of the external membrane, and the active transport of ions, particularly sodium and potassium, by the membrane. These various factors result in a high concentration of potassium, and of negatively charged, non-diffusible ions (proteins, etc), and a low concentration of sodium and chloride ions, *inside* the cell, relative to their concentrations in the tissue fluid which bathes the cell externally. Calcium is also present within the cell at much lower concentrations than in the extracellular fluids. The resting potential can change in two distinct ways, giving rise to *graded potentials* or *action potentials* respectively. Graded potentials involve the membrane of *dendrites* and neuron *cell bodies*, and consist of fluctuating increases or decreases in the resting potential, i.e. their membranes are either relatively *hyperpolarized* or *depolarized*. In contrast, the action potential involves a transient complete reversal of polarity across the membrane of *axons* (and also of some large dendrites which resemble axons in their structure).

Graded potential variations may be either *excitatory* or *inhibitory*. When excitatory, there occurs an increase in permeability of the membrane to sodium ions, which therefore flow down their concentration gradient to enter the cell, and thereby progressively *depolarize* the membrane. This sudden influx results from the transient opening of special ionic channels present in certain membrane proteins (*sodium* and *potassium gates*). The size and time course of the depolarization at a particular membrane locus, to which an effective stimulus has been applied, is related (logarithmically) to the stimulus strength. Furthermore, surrounding zones of membrane also suffer a depolarization, but with decreasing amplitude, at increasing distances from the initiating locus. Thus, the larger the initial depolarization, the greater the spread of effect to surrounding areas of membrane. Such a mechanism allows the *summation* of effect of multiple excitatory stimuli applied at numerous points

B A high-power light micrograph showing part of a pyramidal neuron from the cerebral cortex of a rat, prepared by the rapid method of Golgi. The bases of several dendrites covered with dendritic spines, and a thin axon (left) are visible. (Preparation kindly supplied by Dr. A. R. Lieberman of University College, London.)



C A low-power light micrograph of groups of interweaving axons from the medulla oblongata of a cat, stained by the Holmes' silver method. (Preparations C–E kindly supplied by Dr. E. L. Rees of the Anatomy Dept., Guy's Hospital Medical School, London.)

D A group of neuronal perikarya (purple) amongst bundles of myelinated fibres (blue), from the brainstem of a rat. Stained by the cresyl fast violet-Luxol fast blue method.

E A section through the mesencephalic nucleus of the trigeminal nerve (rat), stained with the Holmes' silver nitrate method to show large unipolar neurons from one of which a dendro-axonal process is emerging.

7.16 A diagram showing the types of change in electrical potential which can be recorded across the cell membrane of a motor neuron at the points indicated by the arrows. Excitatory and inhibitory synapses on the surfaces of the dendrites and soma cause local graded changes of potential which summate at the axon hillock, and may initiate a series of all-or-none action potentials, which in their turn are conducted along the axon to the effector terminals.

over the receiving surface of the neuron. Inhibitory stimuli, thought to act by increasing the inflow of negatively charged chloride ions, therefore tend to increase the membrane potential (*hyperpolarization*), and thus they oppose or subtract from, the *total excitatory state* of the neuron.

The action potential, **nerve impulse** or **spike potential** in contrast, is characterized by a brief *reversal* of polarity caused by the sudden influx of sodium ions, followed by a return to the resting potential as potassium ions flow out; these processes take about 5 msecs in all (Hodgkin and Huxley 1952). For any system, the *amplitude* and *duration* of each successive action potential is identical, no matter how large the stimulus is above a certain *threshold value*, so the response is an *all-or-none* event. The wave of excitation associated with the action potential spreads away from the point of initiation, but, unlike the graded potential, its size and time course do not alter, so the wave sweeps rapidly over the membrane at a constant rate. The action potential is therefore said to be *propagated* and *non-decremental*. After a region of membrane has been stimulated, however, there is an irreducible *refractory period* during which another action potential cannot be elicited, thus fixing a maximum frequency of their formation. When a series of action potentials is generated, they are rapidly conducted along the neurite, maintaining their original frequency pattern precisely. This phenomenon is the basis of nervous communication, which is therefore said to be *frequency-coded*.

The graded and action potentials are related to one another at specific points on the neuronal surface. For example, in a motor neuron, the graded potentials of the dendrites and soma sweep over the axon hillock to initiate action potentials at the *initial segment* of the axon. The greater the graded depolarization of the soma, the more frequent the action potentials, so that the *state of excitation* of the cell is reflected by the *frequency pattern* of the *volleys of action potentials* which flow along its axon.

When an action potential reaches the axon terminals, it causes the release of a discrete amount of *neurotransmitter substance* which further changes the excitability of the receiving cell, either another neuron, a muscle cell, or some other element. A closely grouped series of action potentials (*spike trains* or *volleys*) naturally causes a greater effect than single ones, since extracellular enzyme action, or other processes, usually limits the time during which the neurotransmitter can act.

Although the most common cell region for the change from graded to action potential to occur is the initial segment of the axon, in many peripheral receptors with an axon-like dendrite (for example cutaneous sensory neurons), it occurs in a region close to the sensory ending, often the first node of Ranvier, in myelinated fibres.

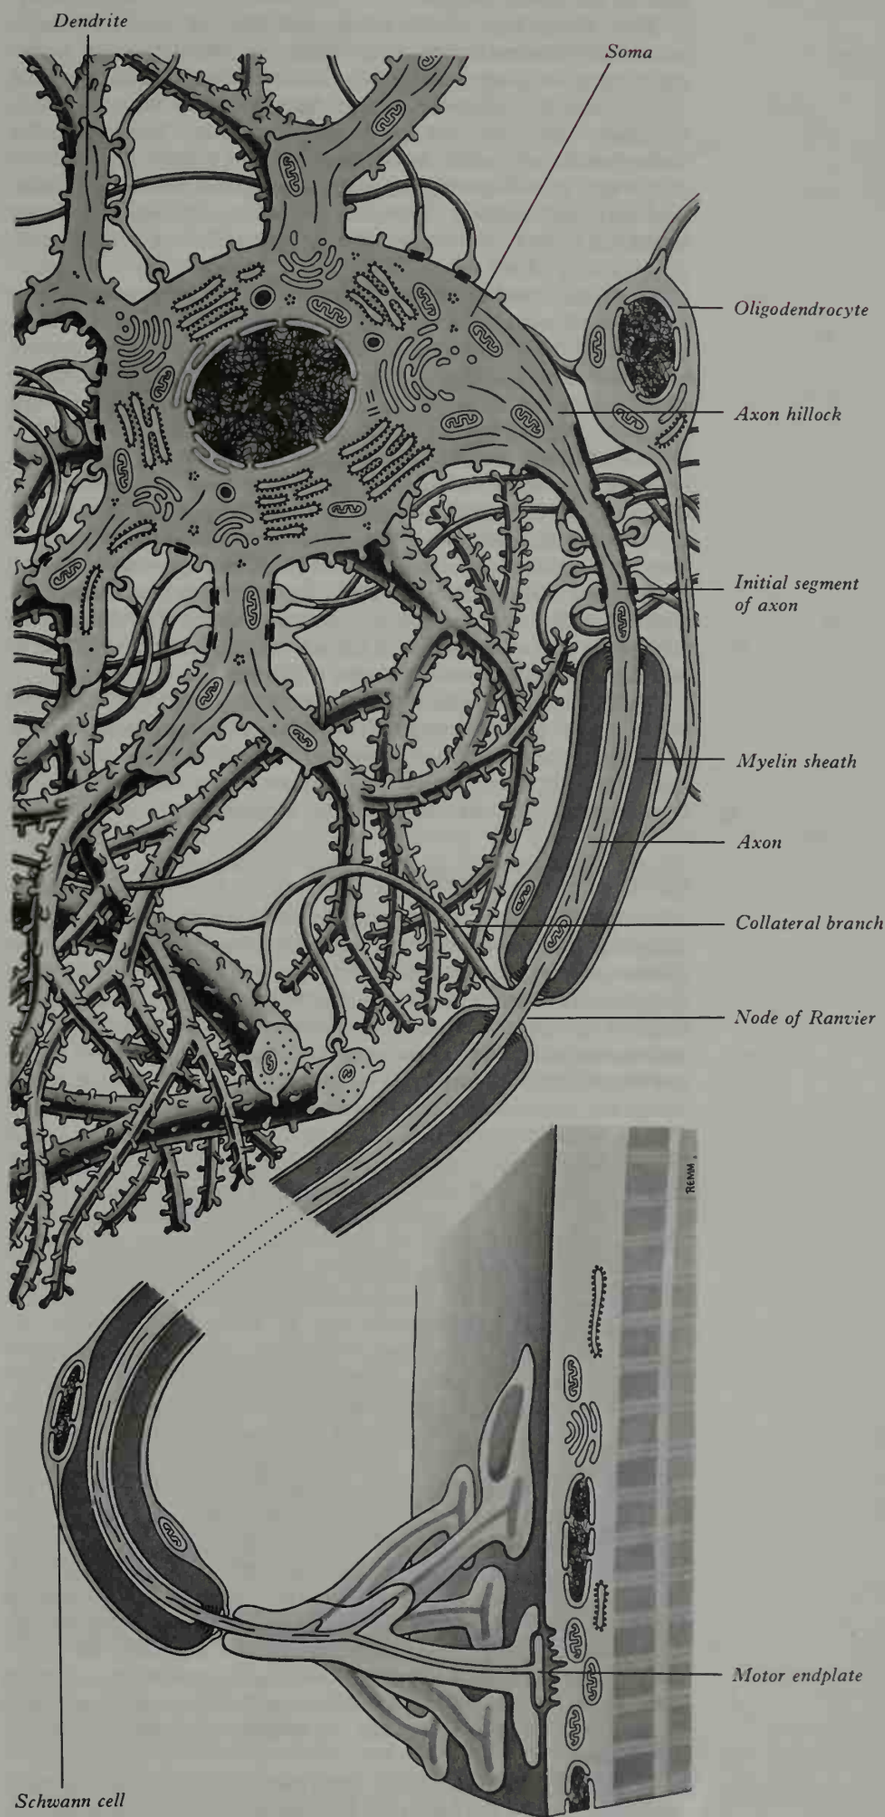
In amacrine cells (p. 1171) and some other very small neurons lacking true axons *all* electrical activities may be of the graded type, and such cells are able to spread these changes in any direction depending on the point of stimulation. In cells with an axon, however, conduction occurs under physiological conditions in one direction only, that is, from the dendrites and cell body to the axon (*orthodromic conduction*); although when artificially stimulated at the periphery, axons can conduct in the opposite direction (*antidromic conduction*), and electrical changes then invade the cell body.

SIGNIFICANCE OF NEURONAL MORPHOLOGY

Because of the mode of synaptic excitation and decremental conduction of the dendrites and perikarya, the shape of these

structures and the distribution of excitatory and inhibitory synapses over their surfaces, undoubtedly play a vital part in determining the relation between the input and output of a neuron. This provides a cogent reason for analysing the geometry of neurons in as precise a manner as possible, in order to understand their role in different physiological processes.

ULTRASTRUCTURE OF NEURONS



Since the pioneering studies of Palay and Palade (1955), and of de Robertis and Bennett (1955), much information on neuronal ultrastructure has been amassed (*see*, for example, Peters *et al.* 1976; Palay and Chan-Palay 1977). Following the terminology of light microscopy, it is useful to distinguish between those regions of the nervous system consisting mainly of the cell bodies of neurons, or of regular arrays of their axons which constitute relatively discrete *nuclear cell masses* and *fibre tracts* respectively, and those parts made up of complex meshworks of axon terminals, dendrites and neuroglial processes which form the *neuropil* of the nervous system (e.g. Peters *et al.* 1970). The different components of the neurons will now be considered in detail.

The soma consists of cytoplasm rich in granular and agranular endoplasmic reticulum (7.17, 18) with attached and free polyribosome clusters, often forming large aggregations; these are visible with the light microscope, by virtue of their constituent RNA, as basophilic *Nissl* or *chromatin bodies* or *granules*. These are more obvious in highly active cells, such as the motor neurons of the anterior grey column of the spinal cord, where *stacks* of granular endoplasmic reticulum occur (7.18).

The *nucleus* is usually large, rounded and quite pale, that is, euchromatic, with one or more prominent *nucleoli*. All of these features are typical of cells actively engaged in protein synthesis, as too is the presence of numerous mitochondria as a source of energy, available also for other cellular activities. *Lysosomes* are another prominent cell component, as are also stacks of agranular cytomembranes comprising the *Golgi complex* which often form several distinct groups in different parts of the cell body. A Golgi complex-associated endoplasmic reticulum in which lysosomal enzymes are collected is also a prominent feature of many neurons. *Neurofilaments* and *microtubules* are present in abundance, bundles of the former corresponding to the 'neurofibrils' of light microscopists. Microtubules and neurofilaments extend into and throughout the lengths of **dendrites** and **axons**, the relative proportion of these two components varying with the type of neuron and the type of cell process involved. In general, dendrites are richer in microtubules than are axons, which may be almost completely filled with neurofilaments; neither microtubules nor neurofilaments appear to be continuous from the cell body to the tips of its neurites, and although bundles of them diverge at points of neurite branching, individual tubules and filaments do not branch. Actin microfilaments have also been described in neurons, as indeed in most cells (*see*, for example, Lasek and Hoffman 1976).

Centrioles, formerly believed to be absent from mature neurons, have been described in every neuronal type so far investigated, and may be associated with the generation or maintenance of the microtubular apparatus. In some neurons, centrioles and ciliary projections from the cell surface have been reported; although cilia appear to be common on the surface of neuroblasts, they have also been found in mature cells; their significance, except at some special sensory terminals, is obscure.

Various other inclusions are also commonly present in the cytoplasm of neurons. *Pigment granules* of various types characterize certain parts of the brain (Barden 1969); the substantia nigra (p. 936), for example, has a *neuromelanin* whose presence is probably related to the catecholamine-synthesizing ability of these neurons, these neurotransmitters being closely related chemically to the pigment. In the locus ceruleus, likewise, a similar pigment, rich in copper, gives a bluish colour to the neurons. Other neurons are unusually rich in certain metals, zinc for example in the hippocampus, and iron in the oculomotor nucleus. These metals may be part of the prosthetic groups of various special enzymes. As neurons age, all of them tend to accumulate granules of a yellowish pigment termed *lipofuscin*

7.17 A schematic drawing of the ultrastructure of a motor neuron, showing part of its dendritic field (above left); the dendrites are studded with spines which are contacted by different types of synaptic terminal. The cytoplasm of the neuronal soma contains stacks of rough endoplasmic reticulum, and other organelles. See text for a detailed description.

(senility pigment), which becomes particularly prominent in the cells of the spinal ganglia.

The dendrites share many features of the cell body, containing microtubules, neurofilaments, mitochondria, a few lysosomes, and, to a lesser extent, ribosomes and agranular endoplasmic reticulum (7.18, 20). **Axons** are similar, except that normally they do not contain ribosomes. The agranular endoplasmic reticulum in the neurites often takes the form of perforated transverse septa, or longitudinally orientated tubules and spherical vesicles. Various types of vesicle are also found clustered close to the points of neurotransmission to other cells (*vide infra*, p. 829).

As already mentioned, several of the features of neurons can be interpreted as indicating a high level of protein synthesis, prompting the question, For what activity is this protein destined? Maintenance and repair of cytoplasmic proteins are activities in which all living cells engage, and in view of the relatively huge volume of cytoplasm in the cell body and extensive neurites of many neurons, it is perhaps not surprising that the rate of protein synthesis is also high. However, a sizable proportion of the protein synthesized may also be involved in the elaboration of the transmitter materials released at nerve endings, and also in various cellular activities associated with the reception of stimuli at dendritic and cell body surfaces. Cholinesterase, for example, is present at the surface of many neurons, which are also rich in other enzymes associated with the active transport of ions, such as sodium and potassium stimulated ATP-ase.

Although the machinery of protein synthesis, that is, RNA and ribosomes, is found throughout the cell body and in the dendrites, these materials are usually absent from axons. This raises the question of how transmitter substances and other materials are transported to the extremities of the neuron.

AXOPLASMIC FLOW

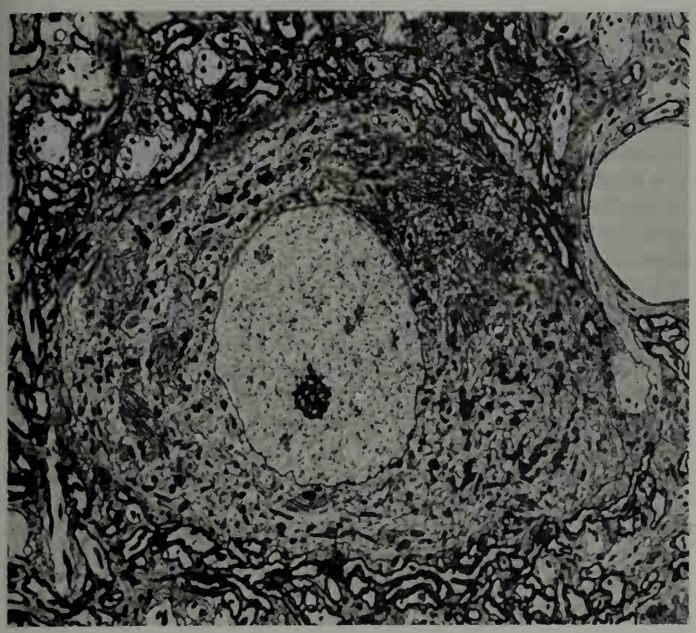
It has for some time been appreciated that the cytoplasm of nerve cells, like that of other cells, is in continual motion; in tissue culture, streaming movements of particulate matter and vesicles along axons in both directions can be observed. A considerable body of evidence from several sources now shows that a similar movement occurs in the axons of living neurons, resulting in the net transport of materials along axons from the cell body to the terminals, with some lesser movement also in the other direction (Weiss 1970). Experiments which involve following the progress of radioactive substances (for example, from the retina along the visual pathway), and other investigations involving the ligature and subsequent structural analysis of central tracts and peripheral nerves (Kapeller and Mayor 1967), have shown that *two types of transport* can be detected, one slow and the other relatively fast. The first type is a *bulk flow of axoplasm* including mitochondria, lysosomes and vesicles at a rate of about 1–3 mm a day, constituting the *slow transport*; the second, *rapid transport*, carries selected proteins and other materials at the rate of about 100 mm a day, and in the neurosecretory pathway of the hypothalamohypophyseal tract (p. 969), at the maximum recorded speed of 2,800 mm a day. This rapid flow can be eliminated by treating the nerve trunk locally with colchicine, indicating that microtubules are associated with the phenomenon (see also p. 970). It has also been shown ultrastructurally, in lampreys, that vesicles with side projections line up along the outside margins of microtubules, suggesting that they may be transported along axons by shearing forces generated between the projections and the microtubules. Other investigators have pointed out the presence of cross-connexions between adjacent microtubules, and proposed them as a tentative basis for wave-like oscillations, which possibly generate a motile force for streaming movements of the cytoplasm.

Whatever the mechanism, several problems arise. For example, what happens to the materials transported to the periphery—do they pass out of the neuron, and if so, into what tissue compartment? Ligature experiments show that there is a build-up of vesicles on *both* sides of the ligature, so that any mechanism must account for *bi-directional movement* of cytoplasmic organelles. Many unsolved questions remain to be answered in this field.

Morphology of Synapses

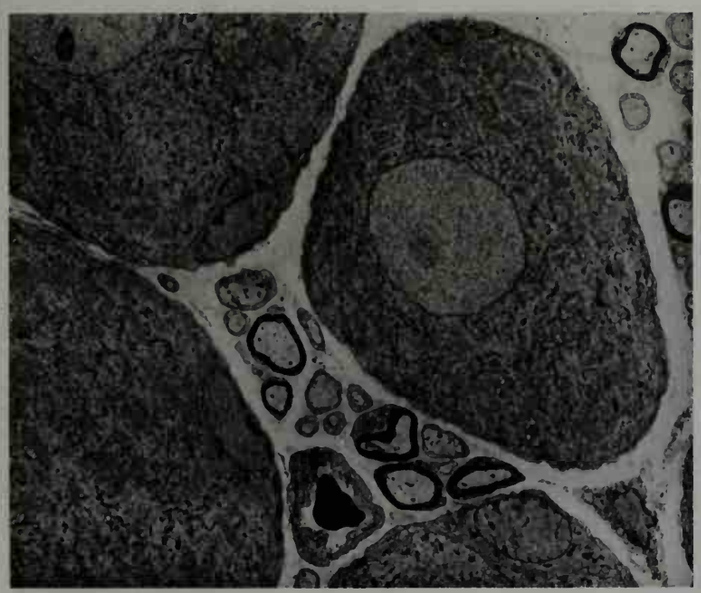
The concept that neural pathways are interrupted at specific junctional points, was derived first from the physiological observation that there is an irreducible delay period inherent in reflex responses to sensory stimuli, and that neural conduction occurs only in certain directions (Sherrington 1947; Eccles 1964). When it was established histologically that the central nervous system consisted of large numbers of individual neurons, rather than a continuous syncytial network, it became possible to attempt the localization of the junctional zones or synapses morphologically. Studies with the silver impregnation methods of Golgi (*vide supra*, p. 820) showed various structural specializations at axon terminals in the central nervous system, and other methods demonstrated rather similar peripheral endings in muscles (7.19A, B, 20, 26). Later studies with the electron microscope, correlated with a considerable body of physiological and pharmacological knowledge, have helped to establish the morphological basis of synapses (*see* 7.19A–C, 20, 21), and their molecular organization. Since individual chemical synapses conduct only in one direction, some type of asymmetry might be expected in their structure; and, being regions of apposition between adjacent neurons, they may involve the junction of almost any parts of the two neuronal surfaces. The most common type of synaptic junction (7. 19A, B, 20) is that between an axon and a dendrite or a soma, the afferent fibre being expanded to form a small bulb or *bouton*; this may either be the terminal expansion of an axonal branch (*bouton terminal*), or it may be one of a series of expansions which form a row of bead-like endings, each of which makes synaptic contact (*bouton de passage*). Boutons may synapse with: (1) *dendritic spines* or with the *flat surface* of a *dendrite*; (2) the *spines* or *flat surface* of the *soma*; (3) the *initial segment* of an *axon*; (4) the *boutons* of other *axons*. The patterns of axon termination in different populations of neurons vary considerably; a single axon may synapse with only one neuron, for example the climbing fibres ending on cerebellar Purkinje cells (p. 921), or more commonly, with a number of cells, the parallel fibres of the cerebellum being an extreme instance of this type (p. 922). An axon may synapse primarily with the dendritic tree or it may enwrap and arborize around the soma. Afferent axons of different origins may synapse only with certain parts of the neuron: for example, in the pyramidal cells of the visual cortex, optic radiation afferents synapse chiefly with the basal segments of the apical dendrite. (See also the account of the differential distribution of afferent terminals on the pyramidal cells of the cornu ammonis on p. 1000.)

In *synaptic glomeruli* groups of axons make contact with the dendrites of one or more neurons in localized regions encapsulated by neuroglial cells (7.21); often complex interactions take place which will be further described below (p. 829).



SYNAPTIC SPINES

Thorn-like extensions of dendrites and other parts of the neuron surface (7.15B, 17, 19A, B, C) are termed *spines* or *gemmules*; they form the receptive points of contact with many of the incoming boutons, and may take several forms. Most frequently they are slender extensions (7.15B, 17, 19A, B) not more than about 2 μm long, with one or more expansions at their free ends, but they can also be short and stubby, branched, and bulbous. Their fine structure and distribution will be described below.



ULTRASTRUCTURE OF SYNAPSES

Ultrastructurally, chemical synapses can be defined as regions of structural specialization between two or more neurons, which possess some type of asymmetrical organization (7.19A, B, C, 20). They can be classified in various ways, for example by the type of neuronal processes involved and the direction of transmission. Thus synapses may be *axodendritic* (most common), *axosomatic* (also quite common), and less commonly, *axoaxonic*, *dendroaxonic*, *dendrodendritic*, *somatodendritic*, or *somatosomatic* (*see* Shepherd 1974; Gray 1974).

Axodendritic and axosomatic synapses are found in all regions

A

B

of the central nervous system and in autonomic ganglia. Axoaxonic synapses occur between the boutons of two axon terminals (p. 806) and also between axon terminals and the initial segments of other axons (7.19B, C, 20). The other types of synapse appear to be restricted to regions of complex interaction between the larger neurons of sensory pathways and microneurons.

For clarity, the **axodendritic arrangement** will first be described in some detail (7.19, 20), since considerable effort has been made by various investigators to understand its structure, e.g., Gray (1959, 1961, 1969, 1974); Uchizono (1965); Pappas and Purpura (1972); Shepherd (1974); Rakic (1975); Jones (1978). Each synapse involves the apposition of a *presynaptic bouton* or *synaptic bag* with a postsynaptic process from which it is separated by a *synaptic cleft*. On both sides of this cleft there are zones of dense cytoplasm, usually broken on the presynaptic side into several groups, and on the postsynaptic side often extended into a filamentous meshwork, the *subsynaptic web*. The cleft shows indications of fine transverse filaments. The presynaptic expansion is typified by numerous small membranous *synaptic vesicles* clustered in groups against the edge of the synaptic cleft and often, in a particular sectional profile, filling the whole bouton; mitochondria, membranous sacs and occasional lysosomes are also present. Recently it has been shown that after pretreatment with albumen, fixed boutons may demonstrate numerous microtubules stemming from the attendant axon and extending in a regular manner close to the presynaptic membrane or attaching to the presynaptic dendrites (Gray 1975). Each microtubule is surrounded by a cluster of synaptic vesicles connected to it by thin filaments; although it is not understood why these details are revealed by the rather unusual method of preparation, it is feasible that the complex of structures represents a means of conveying transmitters close to the presynaptic membrane, to which they may attach and fuse, releasing their contents at specific sites (*'synaptopores'*) into the synaptic cleft when the bouton is depolarized. Membrane added by this fusion of vesicles with the presynaptic surface is taken back into the bouton for recycling in the form of endocytic vesicles at the lateral margins of this structure (Heuser and Reese 1975).

Considerable cytochemical investigation has also revealed interesting details of presynaptic organization (*see*, for example, the review by Pfenninger and Rees 1976), mainly of the 'type I' synapse (*vide infra*). Staining with ethanolic phosphotungstic acid has shown a hexagonal grid pattern to occur on the cytoplasmic side of the presynaptic membrane, probably consisting of proteinaceous pillars guiding the vesicles to attachment points on the membrane (7.19A). Various other methods, such as the bismuth iodide staining technique coupled with enzyme digestion, have also demonstrated glycoproteins of various types in the synaptic cleft and postsynaptic proteins within the neighbouring dendrite. Freeze-fracture techniques have further shown the presence of rings of membrane particles within the presynaptic membrane, corresponding to vesicle attachment sites, and also of numerous particles in the postsynaptic membrane, believed to be related to receptors for neurotransmitter substances which are responsible for activating the postsynaptic structures electrically (Akert *et al.* 1972).

In some sites, the neurofilaments of the afferent axon enter the bouton and form a loop which takes a variety of forms visible under the light microscope with silver stains. On the postsynaptic side there are frequently membranous structures within the cytoplasm, such as the parallel cisternae which constitute the *spine apparatus* of some mammalian dendritic spines. Glial cell processes commonly enwrap these various structures, but they do not extend into the synaptic cleft. The synaptic surface of the bouton is flat where it ends on the smooth surface of a dendrite or soma, but where postsynaptic spines are involved it may be highly curved to enwrap the spine or several spines belonging to adjacent neurons (7.19A, B, 20). In some situations the dendrite surface

(Specimens 7.18A–C kindly provided by Dr. A. R. Lieberman of University College, London.)

itself forms a large spike, which interdigitates with the surface of the bouton. Conversely, dendritic expansions may be invaginated by one or more axonal terminals.

FUNCTIONAL CLASSIFICATION OF SYNAPSES

Since we know that synapses may be either inhibitory or excitatory and that different transmitters are released in their locality, it is important to look for corresponding structural differences between synapses. These can be classed morphologically on the basis of the shape of their synaptic vesicles and the arrangement of their pre- and post-synaptic cytoplasmic densities, into a number of distinct types. Thus, synapses which are rich in *catecholamines* (noradrenalin, adrenalin, dopamine), contain large (40–60 nm) *dense-cored vesicles* (7.20), similar to those of chromaffin cells in the adrenal medulla, and their action in some sites is inhibitory, whilst in others it is excitatory. *Neurosecretory endings* such as those of the posterior pituitary contain relatively huge (50–200 nm) dense-cored vesicles of an irregular shape (7.20). Of the other types of central synapse, it was first recognized by Gray (1961) in osmium-fixed material that two classes could be distinguished—a *type I* in which the zone of subsynaptic dense cytoplasm is much thicker than that on the presynaptic side, and a *type II* in which the two zones are more symmetrical but thinner (7.19). The widths of the synaptic clefts are also different, being about 30 nm in type I synapses against 20 nm in type II synapses. With the advent of aldehyde perfusion as a method of fixation, these two types of synapse were found to be associated with two distinct classes of synaptic vesicles, type I endings containing small spherical vesicles about 50 nm in diameter, and type II boutons showing a variety of flattened forms (7.20). Where the electrophysiology was known, as in the cerebellum, *type I synapses* could be correlated with *excitation* and *type II endings* with *inhibition* (Uchizono 1965). Other reports, however, indicate that the situation is more complicated than this simple classification implies, since it is possible to distinguish between large (25 × 60 nm) and small (15 × 40 nm) flattened vesicles (Pinching and Powell 1971), and also between discoidal and cigar-shaped forms (Dennison 1971). Irregular (*pleomorphic*) shapes are also reported. Other studies have shown that in fresh specimens all vesicles may be spherical, but that some flatten on exposure to the buffers used in the preparative procedures

7.19A The general organization of an excitatory synapse (asymmetrical, Gray type I) showing a synaptic bouton (left) cut away to show presynaptic structures, and an associated dendritic spine (right).

(Bodian 1970). Different synaptic endings also show *mixed populations* of flat and spherical vesicles of varying proportions, depending upon the osmotic strength of the fixative. Although these various appearances are undoubtedly artefactual, they nevertheless point to real differences in the chemistry of the synapses. There have been several attempts at classifying different forms of synaptic boutons in different regions of the central nervous system, according to such criteria as vesicle shape and size, distribution of pre- and post-synaptic cytoplasmic thickenings, the overall size of the bouton, presence of mitochondria, and so forth. One commonly used notation (Guillery 1969; Partlow *et al.* 1977) designates the type I synapse of Gray as a round vesicle-asymmetrical thickening (R.A.) class, and Gray's type II as flat vesicle-symmetrical thickening (F.S.) class; various subdivisions of these categories have also been suggested (*see*, for example, Robson and Hall 1977). Whilst these schemes have some descriptive value, our knowledge of the transmitters present at the various types of synapse, and of their functional status, is so slender that any serious effort beyond a crude classification would appear to be premature. Mixed populations of small, clear vesicles and large, dense-cored ones are also commonly found; in some cases such synapses have been correlated with the presence of the peptide transmitter substance 'P', of serotonin, or of the enkephalins (Beaudet and Descarries 1979; Pickel *et al.* 1979); (*see* also below).

Some central synapses apparently lack the specialized contact zones mentioned above, and seem to be formed by areas of release of transmitter in varicosities of nonmyelinated axons, so that synaptic action may in these cases be somewhat diffuse and could affect several neighbouring structures, as, for example, described in the aminergic pathways of the basal nuclei (*see* also p. 948).

It is also interesting that freeze fracture studies of type II synapses have failed to demonstrate the numerous pre- and post-synaptic intramembrane particles typical of the type I variety, suggesting that there may be fundamental differences in the method of release and of action of the transmitter on the postsynaptic membrane (Landis *et al.* 1974).

The junction between the retinal receptors and bipolar neurons, and between cochlear hair cells or vestibular sensory cells and their afferent endings is also marked by a synapse-like structure; this differs from the usual pattern in that the vesicles are clustered around an internal cytoplasmic rodlet, rather than being situated at the margin of the synaptic cleft (Boycott and Kolb 1973; Flock 1971).

NEUROCHEMICAL TRANSMISSION

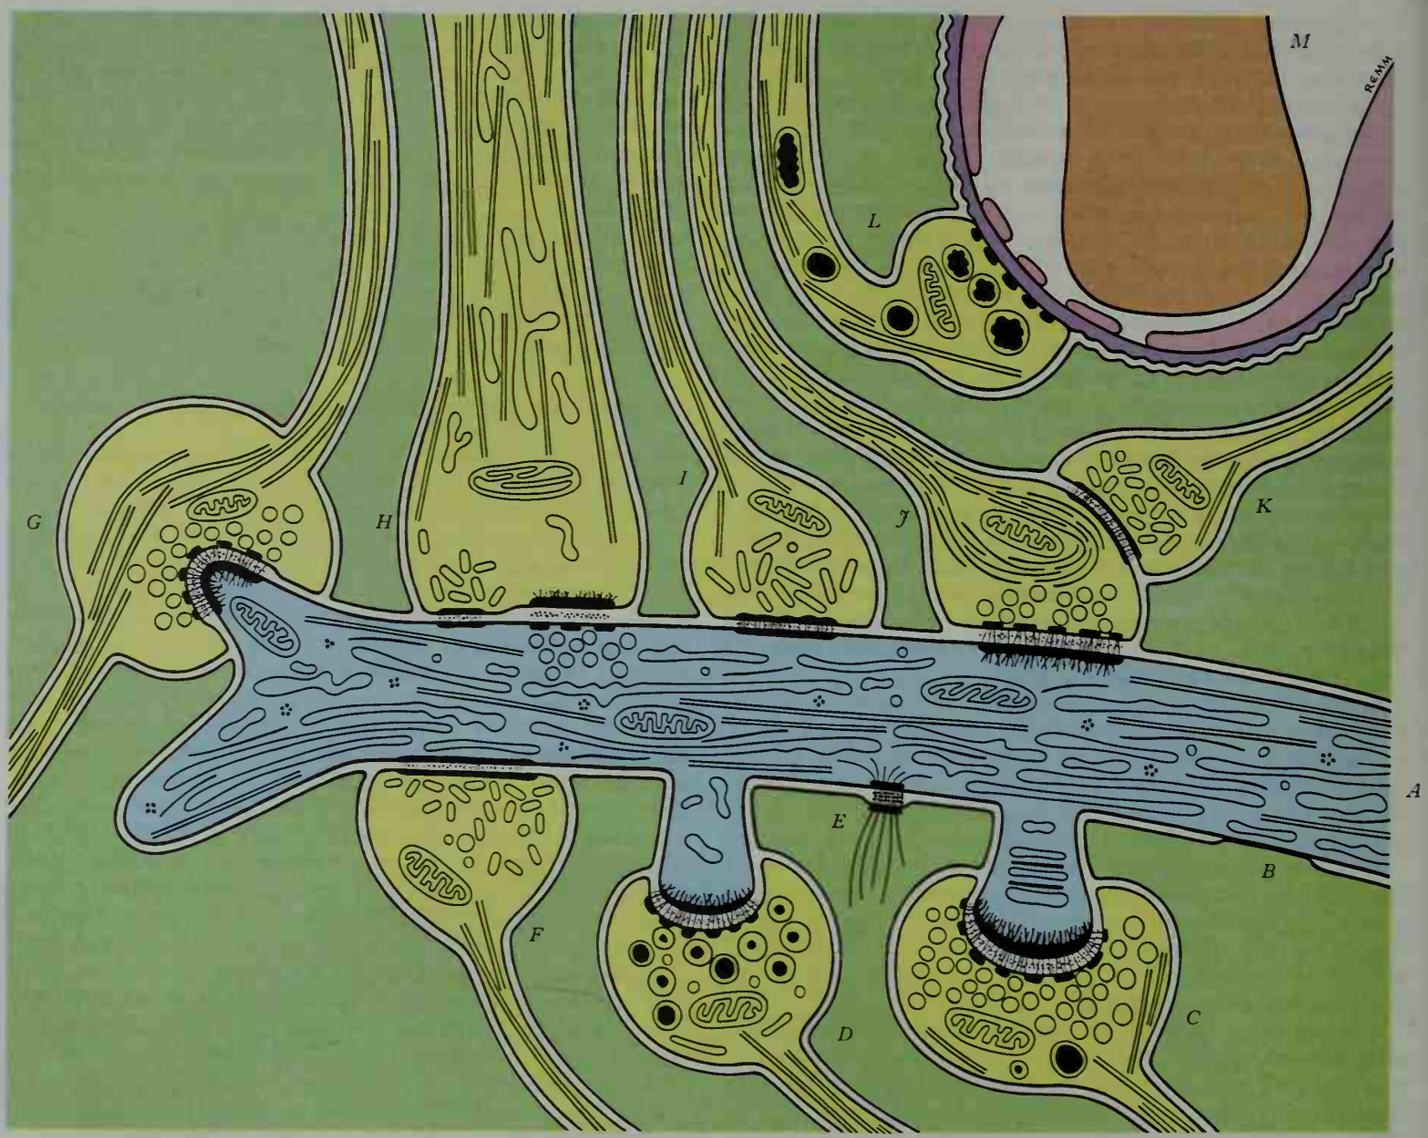
Transmission at all of the synapses described above is *neurochemical*, involving the release of *transmitters* associated with, or contained within, the synaptic vesicles, into the synaptic cleft. Here, the transmitter causes changes in potential at the postsynaptic surface, tending to depolarize it in the case of excitatory synapses, or to hyperpolarize the membrane in inhibitory ones. The cue for transmitter release is the depolarization of the presynaptic membrane by the arrival of a nerve impulse, and the consequent release of calcium ions in the cytoplasm of the terminal.

Synaptic bags (*'synaptosomes'*) can be separated by cell fractionation techniques from brain homogenates, and further subfractionated into various components. Where acetylcholine is the transmitter, enzymes capable of synthesizing this substance from its precursor, choline, are present in synaptosomes, and the transmitter is stored in association with the synaptic vesicles. Catecholamines, and other possible transmitters, have been demonstrated in the same way in synaptosomes (*vide infra*).

ELECTRICAL SYNAPSES

Although in mammals chemical transmission is usual, in lower vertebrates, and in several groups of invertebrates, electrically acting synapses are abundant in certain pathways where speed or synchrony of action is important. Examples are the 'spoon' endings in the chick ciliary ganglion, 'club' endings on the giant Mauthner cells of the medulla in bony fishes, electromotor synapses in electrogenic fishes, and the giant fibre 'escape' systems of crayfish and earthworms. In structure and physiology, these synapses are essentially the same as the electrical junctions in cardiac muscle (p. 517), and non-striated muscle (p. 520), and are much more rapid than chemical synapses. Some of the invertebrate types can operate equally well in either direction, though usually the transmission is undirectional.

More recently, similar junctions have been shown in mammals at various sites, including the superior olivary and vestibular nuclei, cerebellar and cerebral cortices, although electrophysiological corroboration of their transmission properties are available in only a few cases (*see*, for example, Gwyn *et al.* 1977).



ORGANIZATION OF SYNAPTIC GROUPS

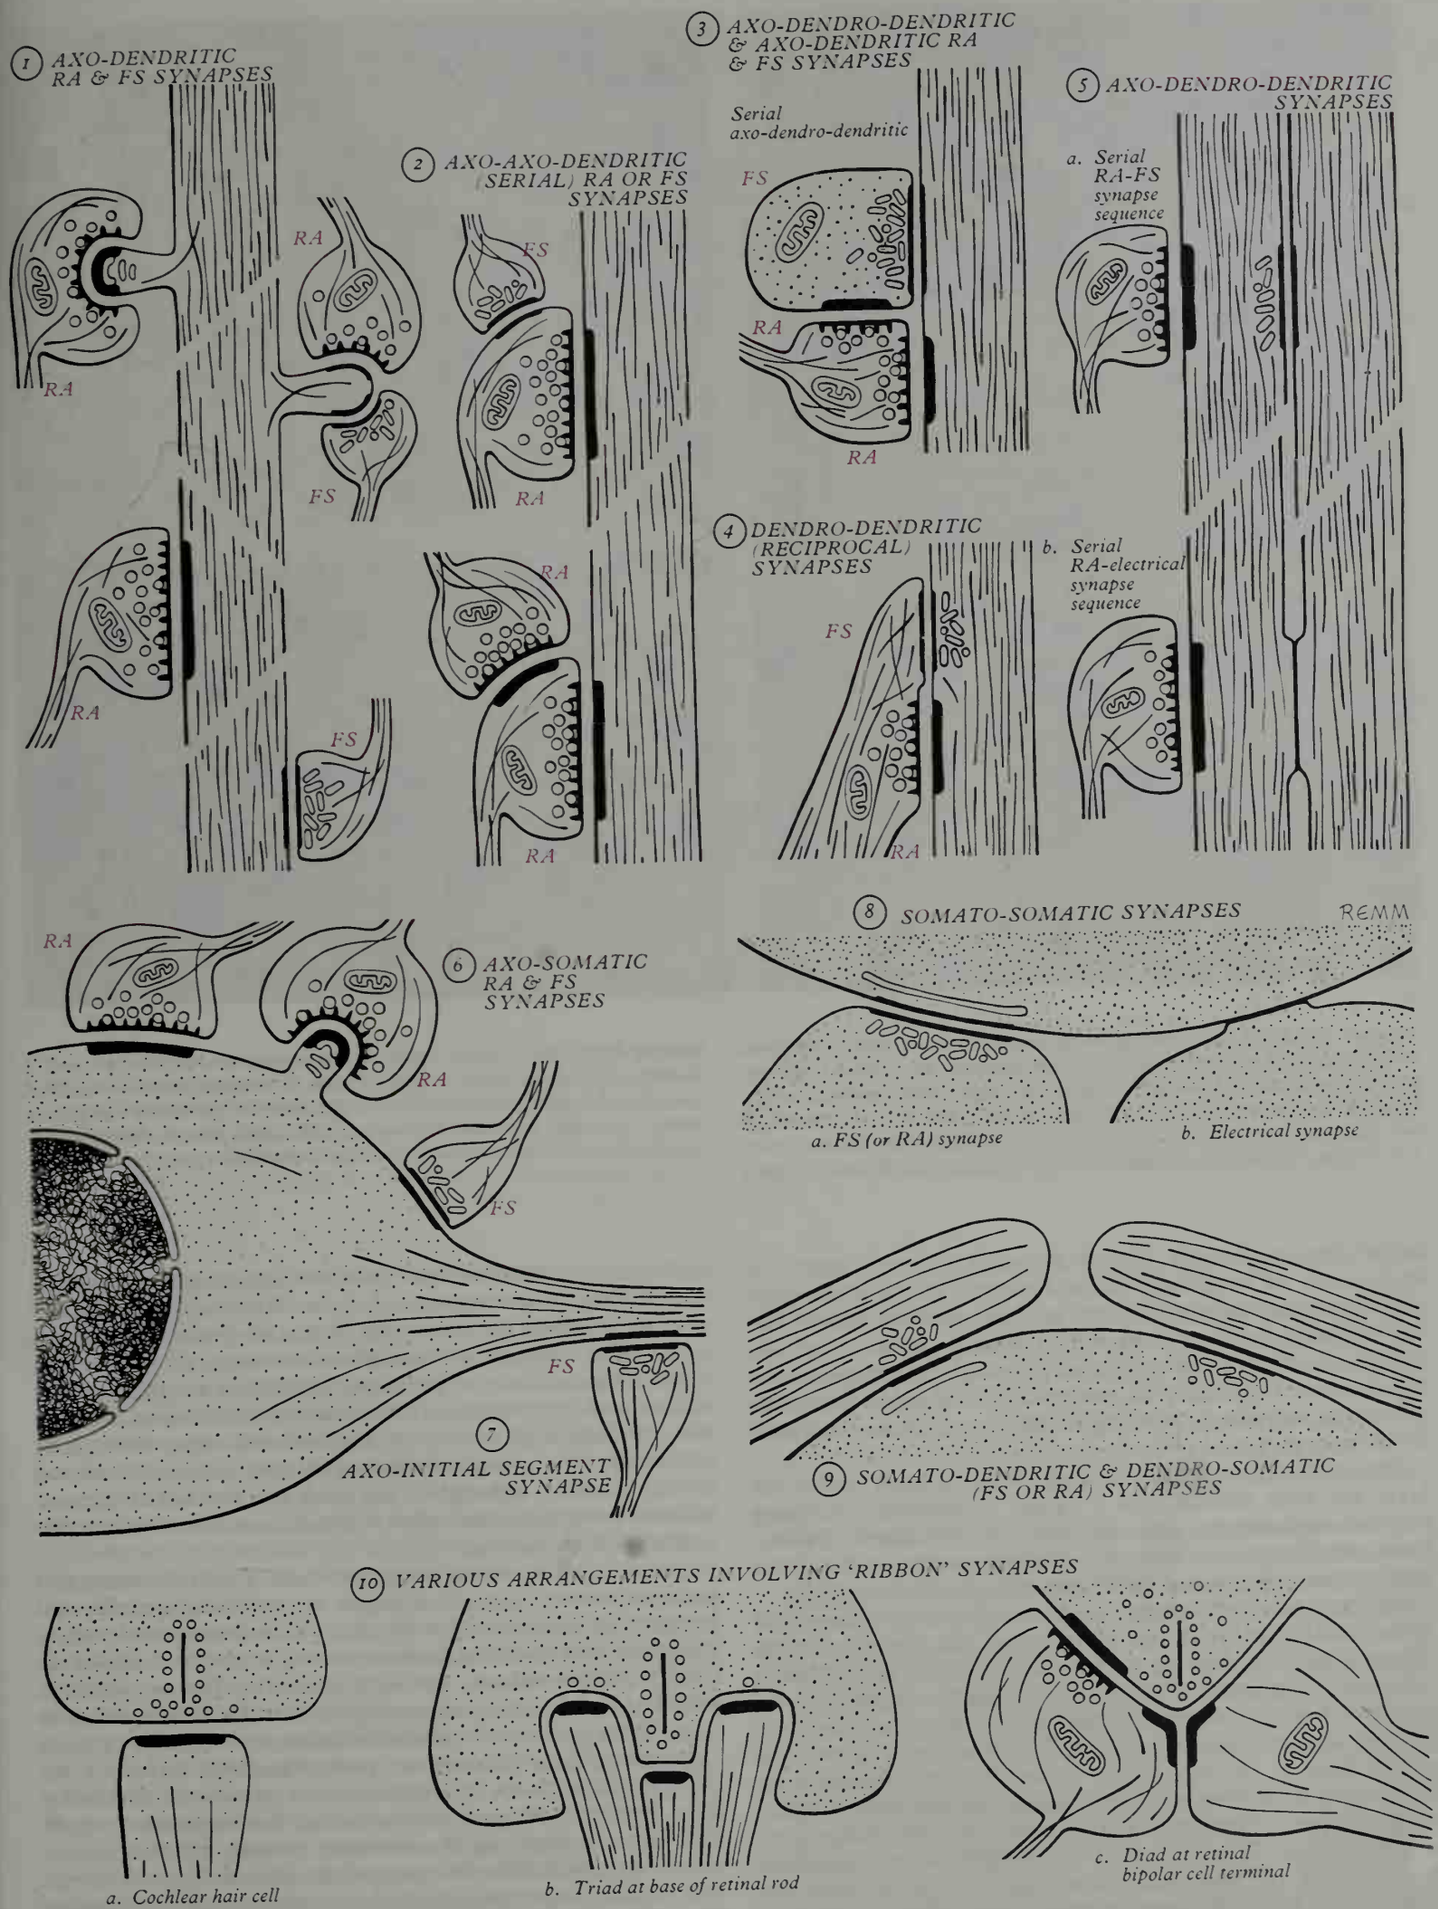
The way in which synaptic endings affect other neurons is partly dependent on their detailed arrangement on the cell surface, and their interrelations with other synapses. At *serial synapses* (7.19B, C, 20E), boutons end on other boutons, to affect their ability to respond to an afferent volley of nerve impulses; this could be the basis of *presynaptic inhibition* observed physiologically in the spinal cord, although of course it could also be responsible for *presynaptic facilitation*, depending upon the types of synapse involved. In *reciprocal synapses* (7. 19C, 20F) found initially in the olfactory bulb and in the lateral geniculate body, and subsequently in many other sites, transmission between two processes can occur in either direction by way of staggered synaptic zones placed on each side of the synaptic cleft. Commonly the zones appear to be excitatory in one direction and inhibitory in the other; they are believed to be the basis of lateral inhibition, at least at the first of these sites (Rall *et al.* 1966; Shepherd 1974, 1978). Other arrangements involving serial synapses at axonal or dendritic junctions have been described; some of these are depicted in illustration 7.19C (*see* also Gray 1974; Colonnier 1974; Shepherd 1974, 1978).

In **synaptic glomeruli** (7.20, 21) several boutons may synapse with dendrites, and with each other, in localized regions of the neuropil which are usually encapsulated by layers of glial cells (Szentágothai 1970). Sometimes, where microneurons are involved, the synaptic relationships are quite complex, involving both excitatory and inhibitory interactions between many cell processes; these may occupy extensive zones or **synaptic clusters**. In **synaptic** or **neuropil cartridges**, a local region of a dendrite is enclosed partially by a glial sheath to isolate a cylindrical zone of synaptic endings both on spines and the smooth dendritic surface between spines (7.21B). Glial cells may also be so situated as to isolate or allow juxtaposition between various groups of interacting cells in various ways which may be of some physiological importance. Although much is known about the arrangement of synapses in limited areas of the nervous system, much remains to be learnt about the disposition of different types of synapse on the surfaces of neurons. It has been suggested, for example, that inhibitory synapses might be particularly effective in blocking excitation if situated on the flat surfaces of the stems of dendrites, and on the soma and initial segment of the axon, where they could block excitation caused by other types of endings occurring on the spines of dendrites or other more peripheral positions, an example being the terminals of the basket cell axon which synapse with the 'pre-axon' of the Purkinje cell (p. 921).

DEVELOPMENT AND PLASTICITY OF SYNAPSES

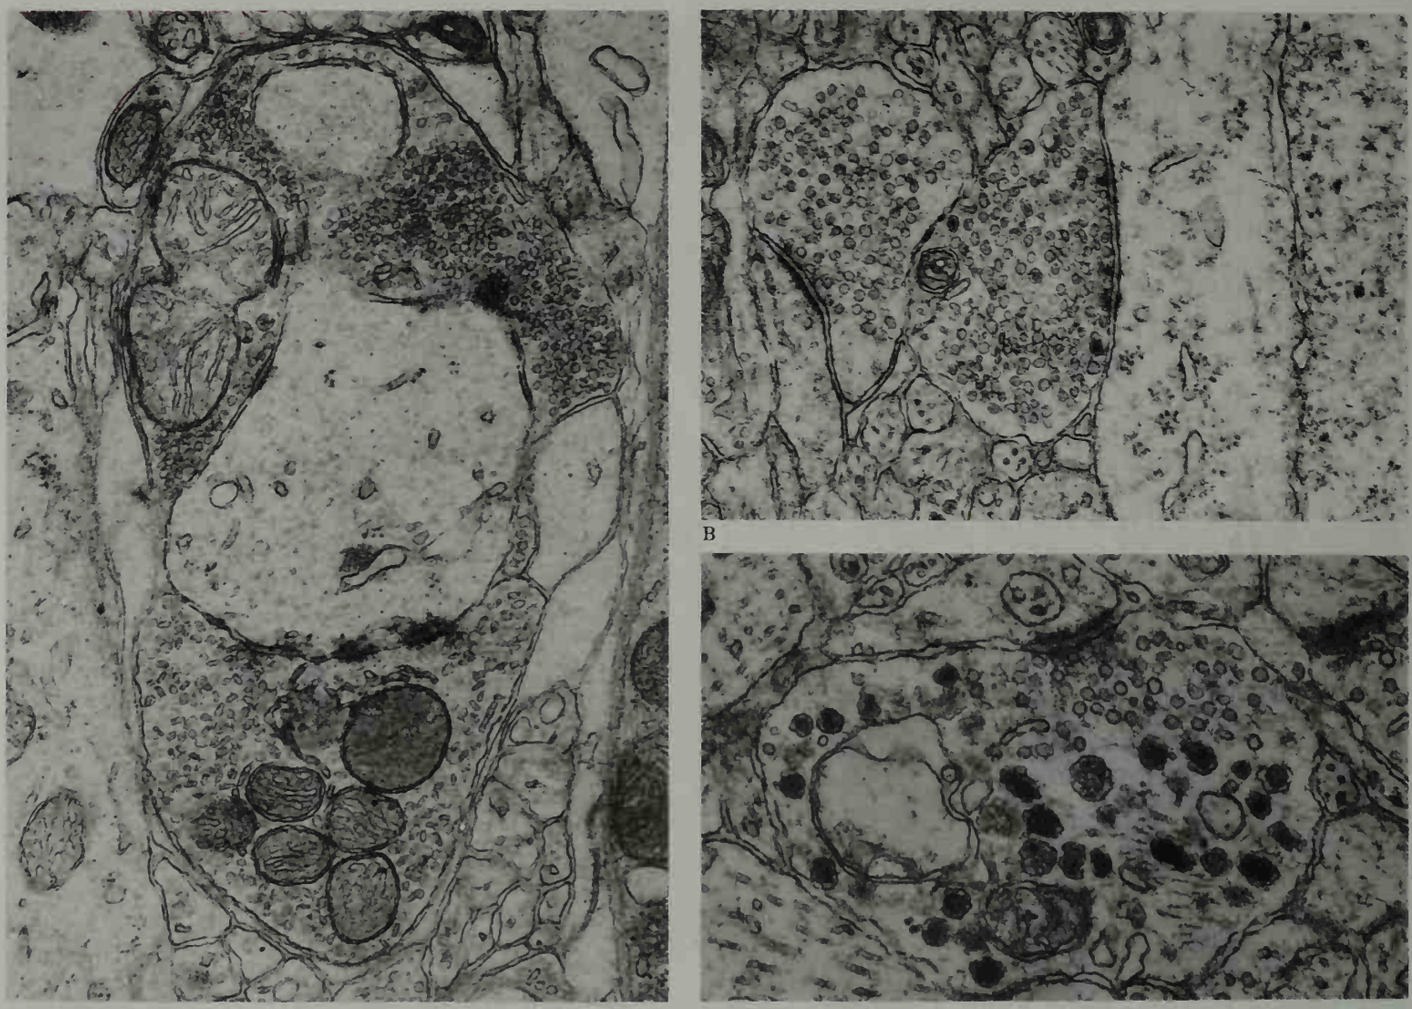
When first formed embryonically, synapses are recognizable by inconspicuous zones of density on each side of the synaptic cleft, and they only gradually mature into their fully differentiated structure (Bodian 1970; Pfenninger and Rees 1976). Similar profiles are often seen in postnatal nervous systems, prompting the suggestion that synapses may be labile structures capable of being recruited for transmission, and perhaps dispersing when redundant. A change such as this is implicit in some theories of memory, which require synapses to be subject to modification according to the frequency of their use, thus establishing

7.19B A scheme of the ultrastructural morphology of synapses, showing various junctional structures, grouped around a dendrite (A). The tight junction (B) and the desmosome (E) are without synaptic significance. Excitatory synaptic boutons are shown (C, G) containing small spherical translucent vesicles. D: a bouton with dense-cored, catecholamine-containing vesicles; F: an inhibitory synapse containing small flattened vesicles; H: a reciprocal synaptic structure between two dendritic profiles, inhibitory towards dendrite A and excitatory in the opposite direction; I: an inhibitory synapse containing large flattened vesicles. J and K: two serial synapses; J is excitatory to the dendrite; K is inhibitory to J. L: a neurosecretory ending adjacent to a vascular channel (M), surrounded by a fenestrated endothelium. All the boutons in this diagram are of the terminal type, except G which is a *bouton de passage*.



preferential conduction pathways in the brain. Unfortunately, what little evidence is available from training experiments, and from artificial stimulation, either does not support this hypothesis, or is equivocal. Neurophysiological recording of cortical neurons, however, suggests that synapses may become less easy to excite with repeated use, and they may change size. However, perhaps it is not necessary to postulate structural changes on this scale, since an increase of molecular receptor sites on the postsynaptic membrane, for example, would have the same effect as a change in the size of the presynaptic *bouton*. It is interesting that a somewhat controversial body of evidence has accumulated, suggesting that long-term memory formation is associated with increased protein synthesis; any change in the proteins associated with the synapse, even of receptor proteins, might require such an increase (*vide infra*).

There is, however, much evidence that during early postnatal development there is a considerable increase in the number of synapses, correlated with a parallel increase in dendritic spines, and that this phenomenon is dependent upon the degree of neural activity. This is seen particularly well in the visual cortex in young animals made temporarily blind in one eye, when the dendritic spines of related cortical neurons show greatly impaired development (Rothblat and Schwarz 1979).



NEUROTRANSMITTERS

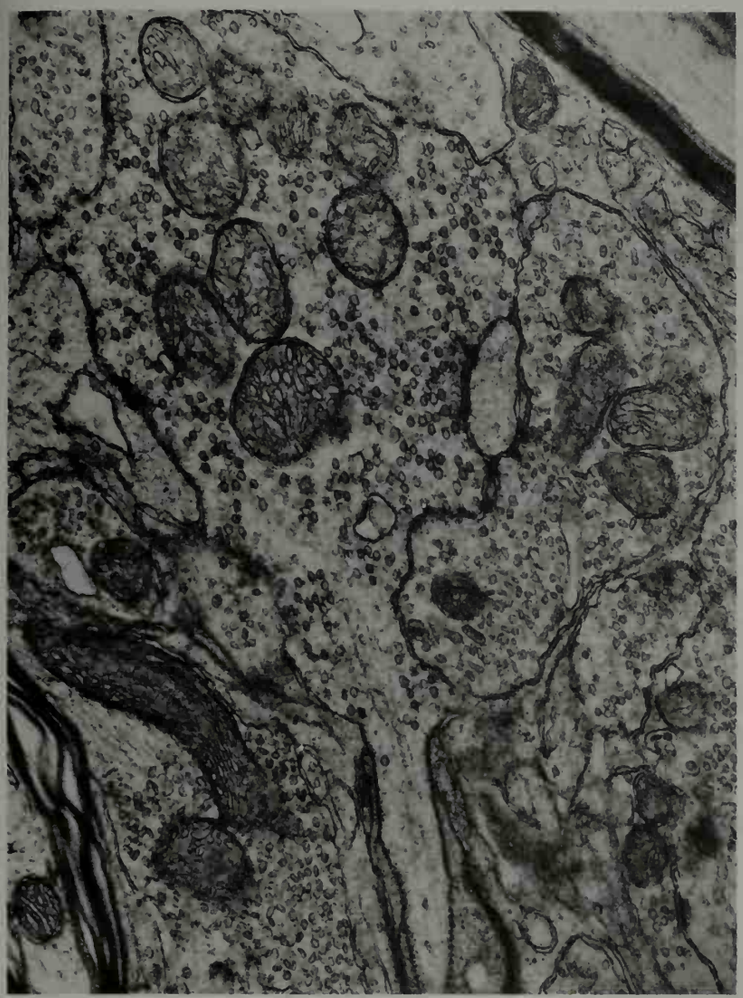
Up to the present time the major classes of transmitter substance, which have been authenticated as such and extensively examined, are *acetylcholine*, various *monoamines*, the catecholamines *noradrenalin* and *dopamine*, the indoleamine *5-hydroxytryptamine* (serotonin), and the amino acid *gamma aminobutyric acid*, or GABA (*see* the reviews by Krnjevic 1974; Snyder and Bennett 1976; Burgen and Mitchell 1978). The physiological effects of these vary considerably from one site to another and are beyond the scope of the present account. However, their common characteristics are that they are released from nerve endings when a nerve impulse arrives, and that they affect the resting potential of the cells which they influence, either to raise or lower it, for only a limited period of time. With acetylcholine, this temporal restriction is achieved by enzymic destruction of transmitter in the synaptic cleft, and the enzyme *acetylcholinesterase* can be demonstrated by various means, including cytochemical localization, in that region. With the catecholamines, as with other possible transmitters (*vide infra*), the transmitter is taken back into the nerve ending, to be stored for subsequent use, so terminating its extracellular action.

The mechanism of action of neurotransmitters is not yet fully

7.19C A diagram illustrating various types of simple and multiple arrangements of synapse involving 'asymmetrical' synapses with rounded vesicles (R.A.), 'symmetrical' synapses with flattened vesicles (F.S.), and electrical synapses. For further details, see text.

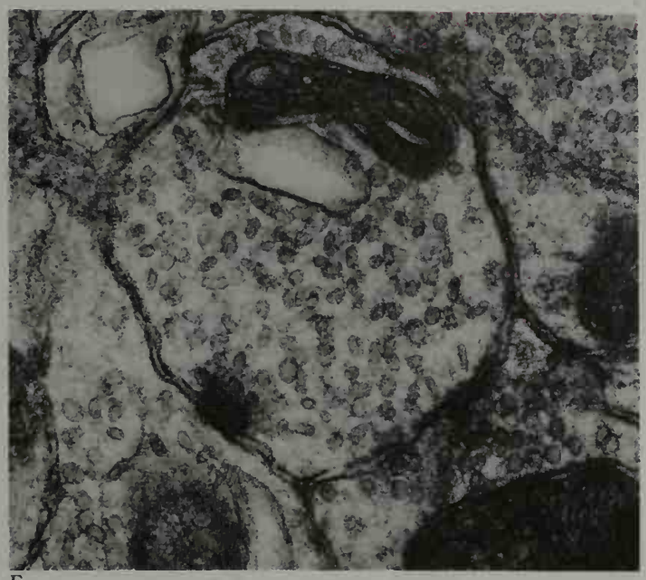
One of them (above) contains round vesicles, and the other (below) contains flattened vesicles of the small type. A number of pre- and post-synaptic thickenings mark the specialized zones of contact. B Two types of synaptic structures are shown; one of them (left), a type I synapse between an axon terminal containing round vesicles, and a dendritic spine, the other (right), a type II synapse between an axon terminal containing pleomorphic vesicles, and the surface of a neuronal soma. C A type I synapse containing both small, round, clear vesicles, and also large dense-cored vesicles of the neurosecretory type.

understood, and most of our knowledge comes from investigations of peripheral motor endings. In the cholinergic endings in muscle, the subsynaptic sarcolemma of the muscle cells bears special *receptor molecules*, proteins, which bind the transmitter strongly, and presumably initiate the changes in the membrane which alter its permeability to ions. A similar mechanism appears to exist with other transmitters, although details may vary.



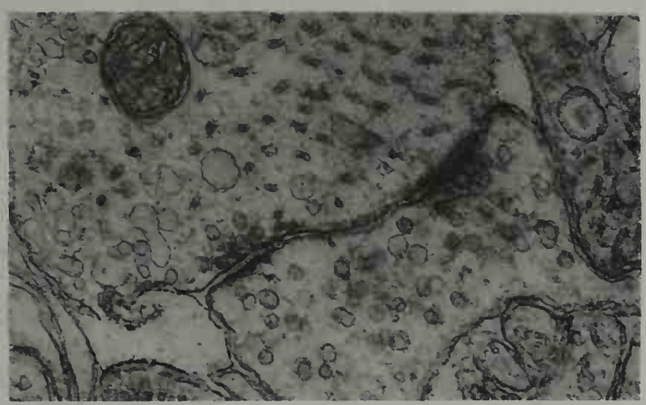
The distribution of particular neurotransmitters within the brain has been studied with a variety of methods, including pharmacological techniques, radioactive tracer methods, fluorescence microscopy with respect to the monoamines and recently choline acetyl transferase, cytochemical localization and so on.

Although relatively few neurotransmitters have been identified unequivocally, many of the synapses of the central nervous system appear to operate by means of other transmitters of unknown chemistry. Numerous substances which can be extracted from the nervous system are known to have profound pharmacological effects at synapses, but have not so far satisfied all the classical pharmacological criteria for neurotransmitters. Some of these agents are present in relatively large concentration in specific parts of the brain, and are known to be synthesized and metabolized locally. They may be precursors or breakdown products of transmitters, rather than actual transmitters themselves; however, some of them have been localized in synaptic endings, and are taken up from extracellular media in the same manner as catecholamines.



Morphological and pharmacological evidence points to a multiplicity of transmitters within the central nervous system; why so many are needed is not clear, but obviously much remains to be learnt about the physiology of central synapses which will have a direct bearing upon concepts of nervous organization. One simplifying concept, first formulated by Dale *et al.* (1936), is that each neuron synthesizes only one transmitter substance, which is then released at all of its axon terminals including those of its collaterals. This concept has been upheld in many peripheral and central locations, although in the latter it is perhaps at variance with the occasional observation of mixed populations of synaptic vesicles within boutons.

Acetylcholine is present at the terminals of somatic motor and parasympathetic axons, at synapses in autonomic ganglia, and centrally has been located in the corpus striatum, some ascending pathways, and in the collaterals of motor neuron endings on inhibitory interneurons, the Renshaw cells. (For an extensive review of the 'cholinergic nervous system' *see* De Feudis 1974.) In most of the sites mentioned acetylcholine is thought to exert an excitatory effect, although at parasympathetic terminals inhibitory actions may, in some instances, also occur depending upon the type of receptor site acted upon. In effector terminals, as probably elsewhere in the nervous system, acetylcholine is associated structurally with synaptic vesicles of the small (40–50 nm), round, clear type, and with the presence of acetylcholinesterase in the neighbouring synaptic gap.



Gamma aminobutyric acid (GABA) is an important transmitter which has a postsynaptic inhibitory (hyperpolarizing) action on many central neurons, although in the spinal cord it also may

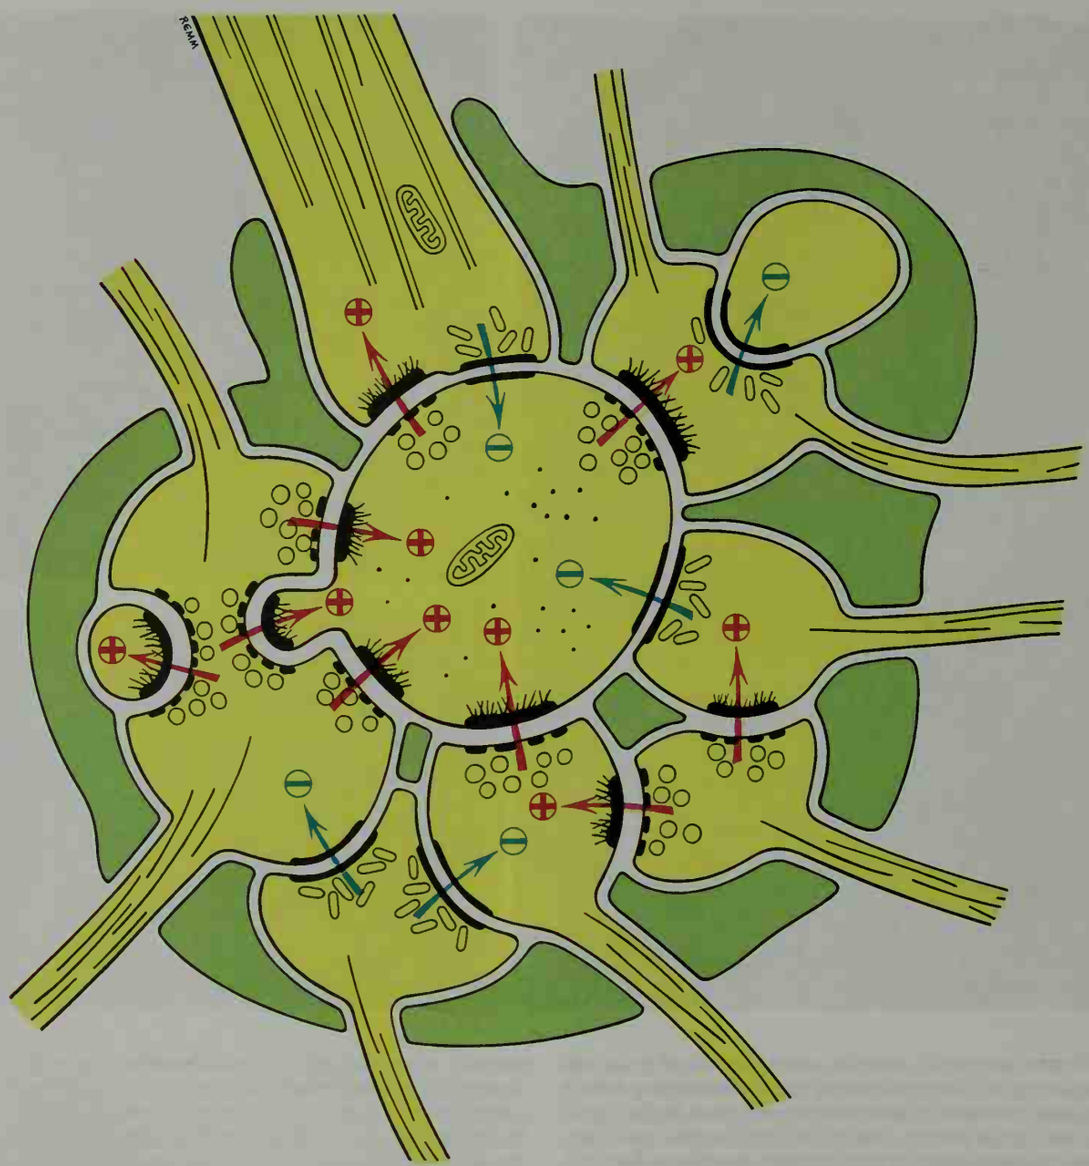
D This shows a large terminal bouton of an optic nerve afferent fibre, which is making contact with a number of postsynaptic processes, in the dorsal lateral geniculate nucleus of the rat. One of the postsynaptic processes (right), also receives a synaptic contact from a bouton containing flattened vesicles. E Three neuronal processes in serial contact. On the lower right, a process, containing round vesicles, synapses with a second process (centre) containing flattened vesicles; in turn the latter makes contact with a third process (lower left): specimen from the dorsal lateral geniculate nucleus of the rat. F This demonstrates reciprocal synapses between two neuronal processes in the olfactory bulb of the rat. (7.20A, D and E provided by Dr. A. R. Lieberman of University College, London.)

cause presynaptic inhibition by depolarization of the axon terminals of excitatory fibres. Its action has been particularly well established at the terminals of the cerebellar Purkinje neurons synapsing in the lateral vestibular nucleus.

Glycine is another probable inhibitory transmitter, and is found abundantly in the spinal cord and brainstem where it appears to act by increasing chloride conductance, thus hyperpolarizing the postsynaptic membrane. Various studies have suggested that it is contained in the flattened vesicles of the type II synapse (*vide supra*). Other amino acids which have been proposed as central neurotransmitters because of their presence and known pharmacological actions are *glutamic* and *aspartic acids*, both excitatory in the spinal cord, and *taurine*, which has an inhibitory effect.

The *monoamines* form a class of substances widely distributed in the nervous system. These include chemicals having excitatory effects in the central nervous system, namely, *noradrenalin* (a catecholamine), *5-hydroxytryptamine* or *serotonin* (an indoleamine), and *histamine*; *dopamine* (also a catecholamine) is an inhibitory substance. Of these putative transmitters there is considerable evidence that noradrenalin, serotonin, and dopamine are major central nervous transmitters; noradrenalin is, of course, also the classical transmitter at peripheral sympathetic nerve endings, where its precise action depends upon the type of receptor site present in the innervated cell surface.

The precise structure of synapses associated with the monoamines is not yet fully understood, although noradrenalin and dopamine are known to be present where moderate-sized or large dense-cored vesicles abound. Serotonin has been correlated with clear rounded vesicle populations, often mixed with dense-cored vesicles (Beaudet and Descarries 1979).



Recently, another class of possible transmitters has been discovered in the brain, all of them having polypeptide chains of 5 or more amino acid residues. These include *substance P*, an undecapeptide, which occurs extensively in the axon terminals of primary sensory neurons, amongst other sites, where excitatory synapses are known to contain mixed dense-cored and small clear vesicles at 'asymmetrical' junctions (Hökfelt 1977; Pickel *et al.* 1979).

The *enkephalins* are pentapeptides which have various inhibitory actions resembling those of morphine when injected into the brain and have been shown to bind to '*opiate receptor sites*' widely distributed in the spinal cord and brain, particularly throughout many of the subdivisions of the so-called limbic system (*see* p. 990). Synapses rich in the enkephalins apparently resemble those containing substance P (Pickel *et al.* 1979).

The *endorphins* have somewhat longer molecules, derived from the pituitary peptide *β-lipotropin*, but have certain actions similar to those of the enkephalins.

Finally, the *purine* derivative *adenosine triphosphate* has been suggested as an important transmitter in a group of peripheral ('*purinergic*') postganglionic autonomic neurons supplying gut musculature and various other tissues (Burnstock 1975), the terminals of such cells containing large dense-cored vesicles (for further comments *see* p. 520).

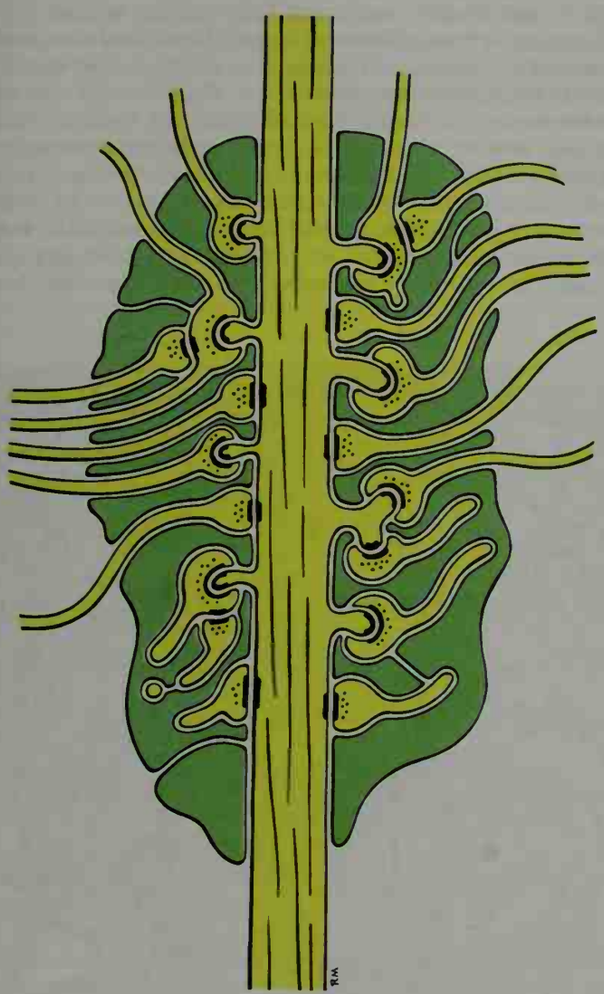
It should be borne in mind that not all of these substances may be actual transmitters themselves, but may instead be metabolites

7.21A and B Specialized multiple groups of synaptic contacts. A A synaptic glomerulus, showing various arrangements of synapses grouped around a centrally placed terminal dendritic expansion, seen in cross-section. Both excitatory (+) and inhibitory (−) synapses are shown; the direction of transmission is indicated by arrows (red for excitation, blue for inhibition). A glial capsule surrounds the whole complex.

of transmitters; alternatively, they may exert their effects in a general, diffuse manner, thus modulating the firing patterns of large numbers of neurons.

(For information concerning the distribution of a number of these substances in the mammalian brain and a general discussion consult the section on 'The Reticular Formation', pp. 943–953.)

Neuroglia



In addition to neurons, several varieties of non-excitable cells are present in the nervous system (de Robertis and Carrera 1965), forming a major component in its total composition (7.22, 23). In the central nervous system these are the *glial cell types* in the parenchyma of the brain and spinal cord, and the *ependymal cells* lining their internal cavities. In the ganglia of the spinal nerve roots and autonomic nervous system, are the *capsular cells* which surround the cell bodies in those masses and peripherally the *Schwann cells* ensheathing the axons (*see* p. 843), terminal *lemmal cells* surrounding sensory capsules, *teloglial cells* ensheathing motor terminals, and the *supporting cells* of the sensory epithelia. Although the precise roles of the various cell types is not yet clear, their importance in the activities of the nervous system is becoming more and more obvious. One barrier to study has been their small size and variable appearance as seen with the special staining methods necessary to demonstrate them with light microscopy. Combined electron and light microscopic studies have helped to clarify some of these details, and a picture is gradually emerging, at least of their appearances.

NEUROGLIAL CELL TYPES

In the central nervous system the chief non-nervous cells are the glial cell types (7.22, 23). These vary in numbers and type from one part of the nervous system to another, but two basic classes have long been distinguished (del Rio Hortega 1924) by their size and embryonic origin, namely: *macroglia*, relatively large cells derived from the neural plate, and the smaller *microglia*, stemming from the mesodermal tissues surrounding the nervous system, which they enter at a relatively late stage of development (*see* pp. 157, 861).

The *macroglia* (7.22, 23) comprises three cell types, the *astrocytes* (*astroglial cells*), the *oligodendrocytes* (*oligodendroglial cells*) and the *glioblasts*.

Special methods have to be used to demonstrate different neuroglial cells, since only their nuclei are made visible by the commonly used histological stains, and these lack obvious distinguishing features. Apart from various metallic stains, which are capricious in their results, the recent use of 0·5–2·0 μm epoxyresin sections stained for light microscopy, and correlated with electron microscope studies, have enabled clear distinctions

B A synaptic cartridge, with synapses grouped around a segment of a dendrite, and enclosed within a glial capsule (green).

to be made routinely, at least in some mammalian species (Ling *et al.* 1973).

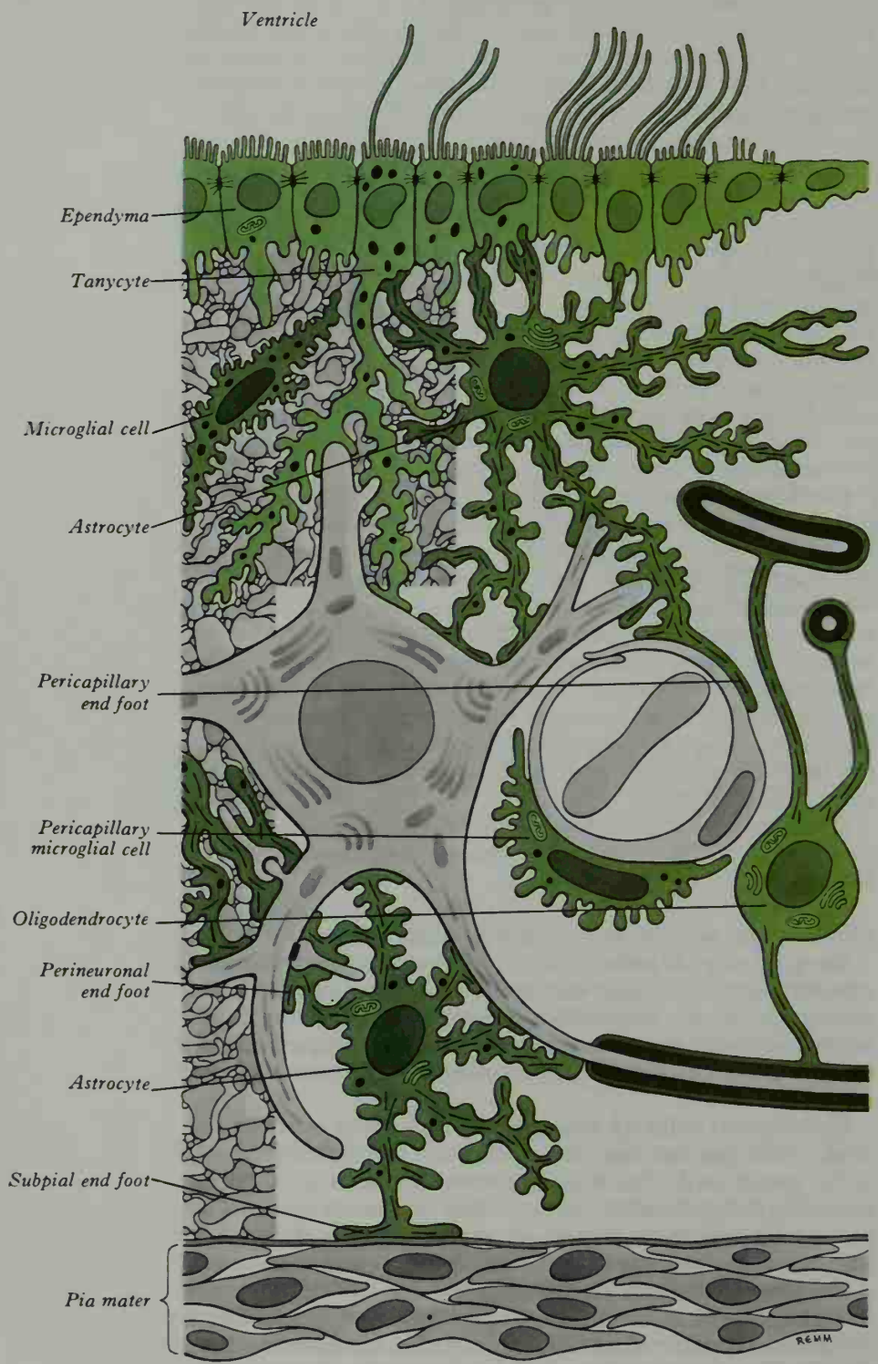
Astrocytes possess small cell bodies (the nucleus is about 8 μm in diameter in man) with ramifying dendrite-like extensions. These cells can be further divided into star-like *protoplasmic astrocytes* with broad symmetrically spreading processes, confined to the grey matter, and *fibrous astrocytes* situated chiefly in the white matter, with asymmetrically spreading processes ramifying amongst the nerve fibres. The cytoplasmic processes of astrocytes carry fine, foliate extensions which partly engulf and separate neurons and their neurites, and often end in plate-like expansions on blood vessels, ependyma (*vide infra*), and on the pial surface of the central nervous system. Ultrastructurally, the cells are typified by a somewhat pale nucleus lined by a narrow rim of heterochromatin (7.23), a pale cytoplasm which is rich in glycogen, lysosomes (corresponding to the *granules* or *gliosomes* of earlier light microscopy), Golgi complexes, and in fibrous astrocytes, bundles of filaments extending throughout the cell processes (Mori and Leblond 1970). Glial filaments have received considerable attention recently because of their notable contribution to the total protein content of the brain. The 'glial fibrillary acidic protein' composing much of each filament, appears to be similar to that of tonofibrils, intermediate filaments, and similar structures elsewhere; it is likely that the astrocytic filaments are skeletal in function (*see* Schacher *et al.* 1977). Desmosomes and gap junctions (*see* pp. 5–6) form special contact zones between individual astrocytes, and sometimes between astrocytes and neurons. Cells with these features may take a number of different forms, and it appears likely, on the basis of isotopic labelling studies, that astrocytes, which are able to divide in mature animals, pass after mitosis through a series of structural transformations before finally disintegrating. In areas of brain injury they proliferate (gliosis), and also act as phagocytes to clear cellular débris.

Oligodendrocytes (7.22, 23), as their name implies, have fewer cell processes, and occur in two distinct areas, namely as *intrafascicular* cells in myelinated tracts, and as *perineuronal* oligodendrocytes where their processes come into apposition with the surfaces of the somata of neurons.

Since the advent of electron microscopy, the earlier suggestion that these cells may be connected with myelin sheaths has been amply confirmed (*see* Bunge 1968); indeed it is evident that they are responsible for laying down myelin and that these cells are the central nervous counterpart of the peripheral myelinating Schwann cell. There are some interesting differences between central and peripheral myelin, however, including a distinctive chemical composition (*see* Gregson 1975), and a different relationship between the axon and myelinating cell: the oligodendrocyte may enclose several neighbouring axons in separate myelin sheaths, whereas Schwann cells of myelinated peripheral nerve fibres are each associated with only one axon. Ultrastructurally, these cells are characterized by a rounded nucleus and a cytoplasm rich in mitochondria, microtubules and glycogen. As with astrocytes, there is a spectrum of appearances, ranging from cells with relatively large euchromatic nuclei and a pale cytoplasm to those with heterochromatic nuclei and a dense cytoplasm. Tritium labelling, again, shows that oligodendrocytes can proliferate in normal *mature* animals, and that they pass through stages of maturation and degeneration.

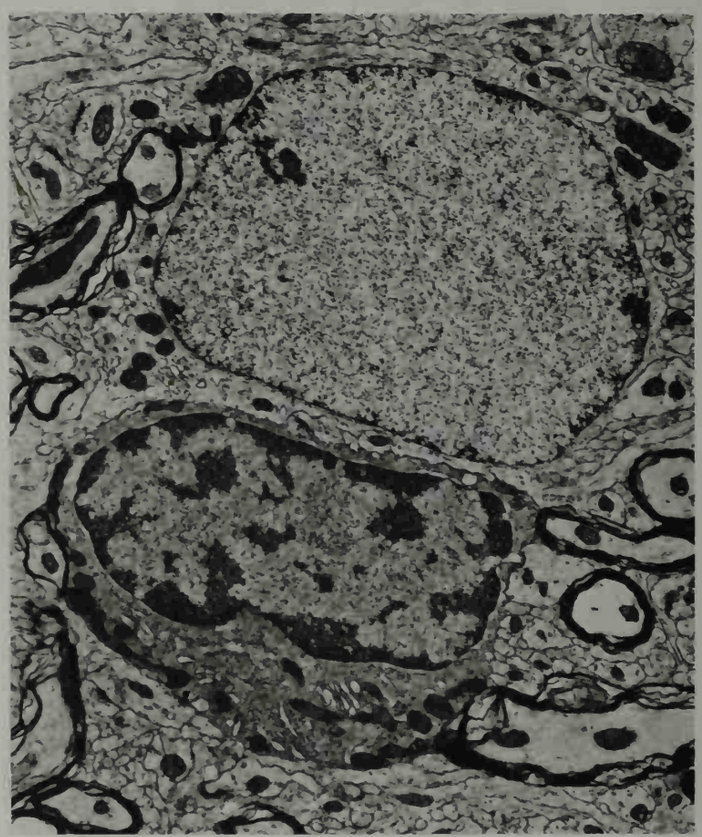
Glioblasts are embryonic or postnatal stem cells capable of differentiating into macroglial cells. They have structural features typical of such cellular elements, namely a pale nucleus and cytoplasm, free ribosomes, and in general a rather rounded shape. They are particularly numerous, even in adults, in a diffuse layer beneath the ependyma (the sub-ependymal zone). It is not known whether, in adults, such glioblasts are multipotent, i.e. able to form either astrocytes or oligodendrocytes, or if individual glioblasts for each cell line exist. However, they appear to be an important source of macroglial cells formed by mitotic division throughout postnatal life as well as in the fetus (Mori and Leblond 1970; Ling *et al.* 1973).

Pituicytes of the neurohypophysis are similar to astrocytes in some respects, except that their processes end mostly on the endothelial cells of vascular sinuses.



Müller cells of the retina (p. 1171) also have many features in common with astrocytes, and are of a similar origin.

Bergmann glial cells of the cerebellum (p. 921) have a special structure; their cell bodies and nuclei are situated in a row some distance below the pial surface. A single apical process passes superficially and then branches into terminal pial expansions. In many respects they have the appearance of a rather primitive glial cell type.



Ependymal cells are arranged as an epithelial layer one cell thick which lines the ventricles of the brain and the central canal of the spinal cord. The cells vary from squamous to columnar according to their locality. At the surface they are in contact with each other by gap junctions and occasional desmosomes, and their free faces bear numerous microvilli and cilia which are often motile, their movements contributing to the flow of cerebrospinal fluid. Ultrastructurally (Brightman and Palay 1963; Bleier 1977) the nucleus is rather heterochromatic, with an indented outline; the cytoplasm is rich in mitochondria, lysosomes, microtubules and microfilaments (7.22, 23). Secretion bodies are also sometimes present. Great regional variations in surface specializations occur in the ventricular linings of the brain, some areas being heavily ciliated, others being lined by microvilli or by secretory structures (Scott *et al.* 1974). In embryonic nervous systems, and in lower vertebrates, ependymal cells possess one or more long, radially orientated processes which may branch and give off short side extensions, and are termed *tanycytes*, *ependymal*

astrocytes, or *ependymoglial cells*. Later, in most, but not all regions of mammalian brains, the basal process is absorbed and a rapidly increasing number of functional roles are being ascribed to them (*see*, for example, pp. 1442, 1443; **8**.197). Some authorities consider these cells as important in providing 'guides' for early neuroblast migration (*vide infra*).

The functions of glial and ependymal cells in general appear to be numerous although not fully explored (*see* Kuffler and Nicholls 1976): (1) Undoubtedly they act mechanically as a supporting component of the nervous system, and their various filaments, microtubules, and surface contact zones fit them for this task. (2) They act as insulators, separating neurons and their processes from each other, or grouping interacting regions, and limiting the spread of ions from neurons during electrical activity. Electrical activity. Certainly changes in external potassium, such as may occur when neighbouring axons are active, cause GABA release (Iversen and Kelly 1975) and this may have some kind of modulating action on local synaptic processes (*see* discussion by Kuffler and Nicholls 1976). (5) Oligodendrocytes form and maintain the myelin sheaths of the larger neuronal processes of the central nervous system, in a manner similar to that of the Schwann cell in the periphery. (6) Ependymal and related cells are associated with secretion into, and uptake and transport from, the cerebrospinal fluid; these functions have been explored in regions associated with the hypophysis cerebri where they may be involved in transport of hormone-controlling factors in the median eminence and hypophysial stalk (*see* Bleier 1977). (7) We can speculate that macroglial cells may play an important part in determining levels of physiological activity in the neuronal populations which they infiltrate by regulating the metabolic and ionic environment of the neuronal population. Although there is no evidence that glial cells supply ions to neurons during their studies of glial cells in leeches, where they are particularly large, show that they can act in this way, and further that they lack the ability to conduct surface depolarizations for any distance (Nicholls and Kuffler 1964). (3) They can act defensively by phagocytosis of foreign material or cell débris, and can provide a means of limited repair to form glial scar tissue, or to fill the gaps left by degenerated neurons. (4) They take up and store neurotransmitters released from neighbouring synapses and in some cases may metabolize them; in this manner the transmitters in the extracellular spaces are removed from their sites of action, as seen for example, by autoradiographic studies of gamma aminobutyric acid uptake by glial cells (Schon and Kelly 1974). Such transmitters may also be released again from glial cells, although this possibility has yet to be shown in normal neural

7.22 A schema showing the types of non-neuronal cells in the central nervous system. The ependymal and glial cells are shown in green. The ependyma includes examples of ciliated and non-ciliated cells, and one tanycyte, with a centrally directed basal process. Two astrocytes are shown apposed to a neuronal soma and dendrites; one (above) also contacts a capillary, the other (below) expands on the pial surface. An oligodendrocyte (middle right) provides myelin sheaths for two axons. Two flattened microglial cells, one adjacent to a capillary (middle right), and the other within the neuropil at the top left, are also illustrated.

7.23 An electron micrograph of two neuroglial cells situated amongst myelinated and non-myelinated nerve fibres, in the rat thalamus. An oligodendrocyte containing numerous mitochondria, a well-developed endoplasmic reticulum, and an indented nucleus is shown below; a larger astrocyte with a vesicular nucleus and scanty cytoplasm, is demonstrated above. (Kindly provided by Dr. A. R. Lieberman of University College, London.)

activity, alterations in the metabolism of glial cells may have profound effects on the ionic environment of neurons and therefore on their patterns of excitability (*see* Kuffler and Nicholls 1976). Such alterations may be involved experimentally where anions such as chloride, applied topically to the brain surface, cause spreading electrical changes, the *spreading depression of Leao* (p. 1023); it is conceivable that various metabolic changes within the brain may effect changes of electrical behaviour in its various parts by this means, either as a normal biological mechanism, or as a pathological one. Pathological disturbances of glial function may equally result in profound disturbances of neuronal function. (8) It was first suggested in the last century by Golgi that macroglial cells because of their contacts with blood vessels and ventricular surfaces as well as with neurons, could provide an intracellular route for nutrient diffusion from the vascular system and cerebrospinal fluid to the neuronal population. Whilst such an idea has its attractions, particularly in the case of neuronal processes remote from their cell bodies, there is little firm evidence in favour of this view. Against this theory we may adduce the lack of any consistent or frequent neuroglial connexion between nutrient supply and neuronal surface, the availability of reasonably rapid intercellular diffusion pathways from the ventricles and central canal to neurons, and the ability of material to pass from cell bodies to axon terminals by axonal flow mechanisms. It would appear, therefore, that whilst glial nutrient pathways cannot be excluded, they do not need to be invoked to explain neuronal nutrition.

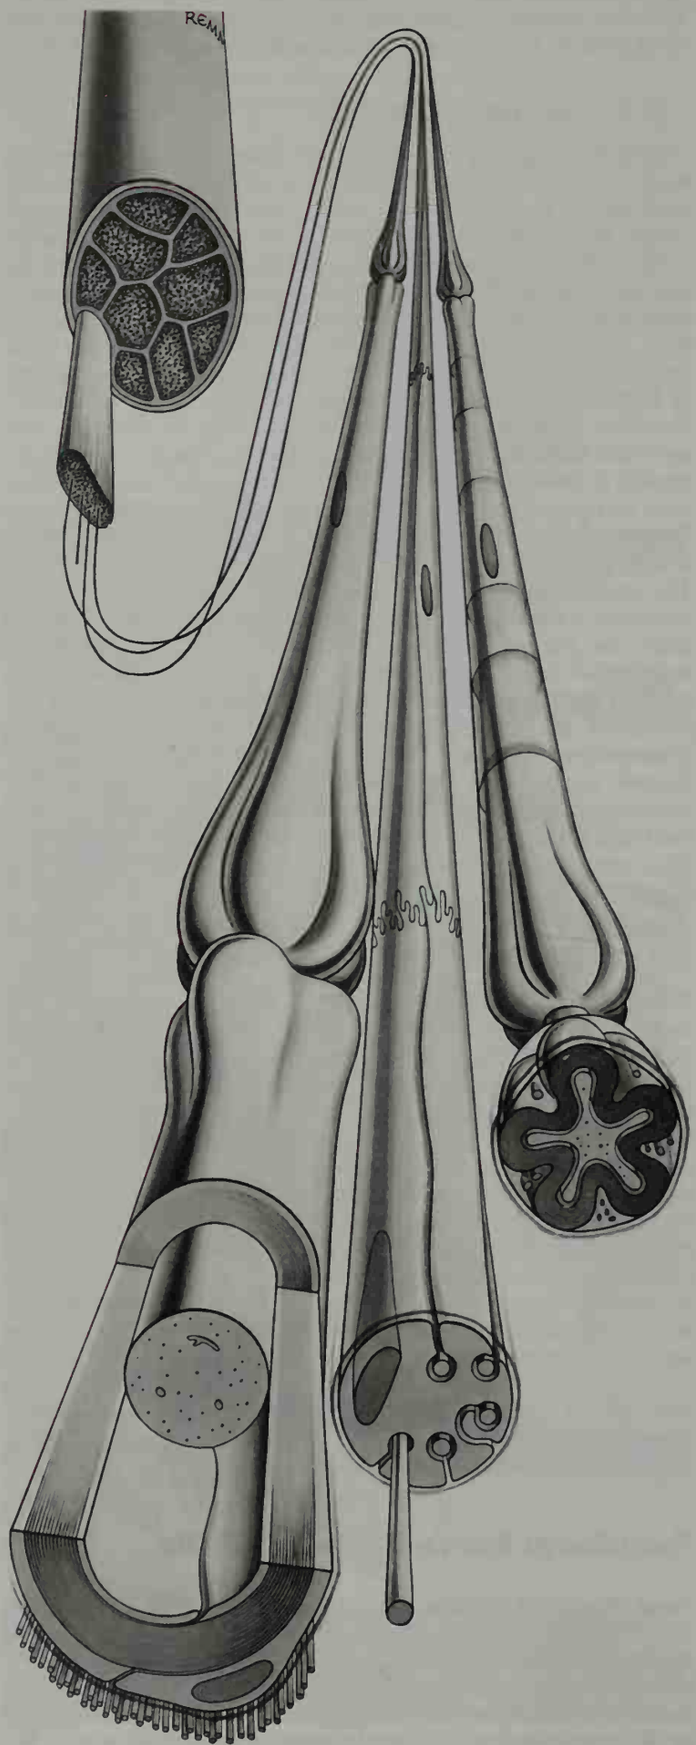
Microglia

The microglial cells (7.22) are the smallest of the glial elements, and have flattened outlines, with fine, rather short, dendritic processes inserted between neurons, or applied to the external surfaces of capillaries. Ultrastructurally, the cells contain rather heterochromatic, flattened or indented nuclei and, beside the usual organelles, large numbers of lysosomes. These features are identical with those of connective tissue macrophages, which indeed they are thought to be. Recent experimental studies with labelled bone marrow or circulating monocytes have shown that these blood cells migrate as macrophages into damaged or degenerating areas of the central nervous system to phagocytose and eliminate cellular débris, and are then indistinguishable from indigenous microglial cells which are activated to carry out a similar role. Indeed, macrophages may remain afterwards as sedentary microglial cells, although the majority of this type of cell apparently migrate into the brain and spinal cord during late fetal and early postnatal life (Imamoto and Leblond 1977, 1978; Ling 1978). However, it should be mentioned that some authors still regard the microglial cell as being derived from neural plate tissue in the same way as other neuroglial cells.

ORIGINS OF NEUROGLIA AND EPENDYMA

Early schemes of cellular differentiation in the neural tube such as that of His envisaged germinal cells giving rise, *simultaneously*, to *neuroblasts* and to glial stem cells or *spongioblasts*, which differentiate further into glioblasts and ependymoglial cells. Glioblasts subsequently differentiate into astrocytes and oligodendrocytes and the ependymoglial cells into mature ependymal elements (p. 1037). With the coming of autoradiographic methods of analysis, this scheme was modified in the sequence of events (*vide infra*), the germinal (matrix) cells *first* giving rise to neuroblasts, and *later* to the other cell elements (p. 860). As the matrix cell of later stages can only form non-nervous elements, it corresponds in principle to the spongioblast. However, it has been established that astrocytes and oligodendrocytes are also able to multiply once they have reached their position in the parenchyma of the nervous system (p. 860), even in mature animals. Ultrastructurally, the maturation of the glial and ependymal cells is marked by a gradual increase of intracellular membranes, to which ribosomes become attached, an increasing density of the nucleus and eventually the laying down of characteristic organelles such as filaments and microtubules (Mori and Leblond 1970; Vaughan and Peters 1974; Sturrock 1974, 1975, 1976). These events accompany the cell migration and the contacting of the neuronal and vascular structures with which they establish their particular functional relationships. Microglia migrate in from the meninges, along the blood vessels, during embryonic development; they also appear able to divide in postnatal life.

THE BLOOD-BRAIN BARRIER



In early investigations of the brain it was noticed that certain dyes, when injected into the circulatory system, failed to stain the parenchyma of the brain and spinal cord, although they passed easily into non-nervous tissues. Many subsequent studies confirmed that access from the circulation to the extracellular space of the central nervous system is severely limited for many substances, as though a physiological barrier existed at this junction. The structural nature of this '*blood-brain barrier*' has been the subject of much debate in view of its importance in the therapy of nervous disorders, anaesthesia, and so on (Davson 1970). However, many materials when injected into the *ventricles* can enter the brain with ease, indicating that the barrier is probably present at the level of the capillary. Experiments with peroxidase as an ultrastructural colloidal tracer (Brightman and Reese 1969; Brightman *et al.* 1970) show that diffusion can occur quite freely in the interstices between the cells of the central nervous system. The tracer passes from the ventricles, through the intercellular junctions of the ependymal layer, and across the nervous tissues to reach the pial surface. Diffusion is, however, stopped at the endothelial lining of capillaries, and it appears that central nervous capillaries are unusually impermeable to *large molecules* by virtue of their well-formed tight junctions and lack of fenestrations. Likewise, diffusion of substances through the choroid plexus from the vascular system is restricted by the impermeability of both vascular endothelial and choroid epithelial junctions, so that the cerebrospinal fluid contains only those materials secreted selectively by the choroidal epithelium (Cserr 1971).

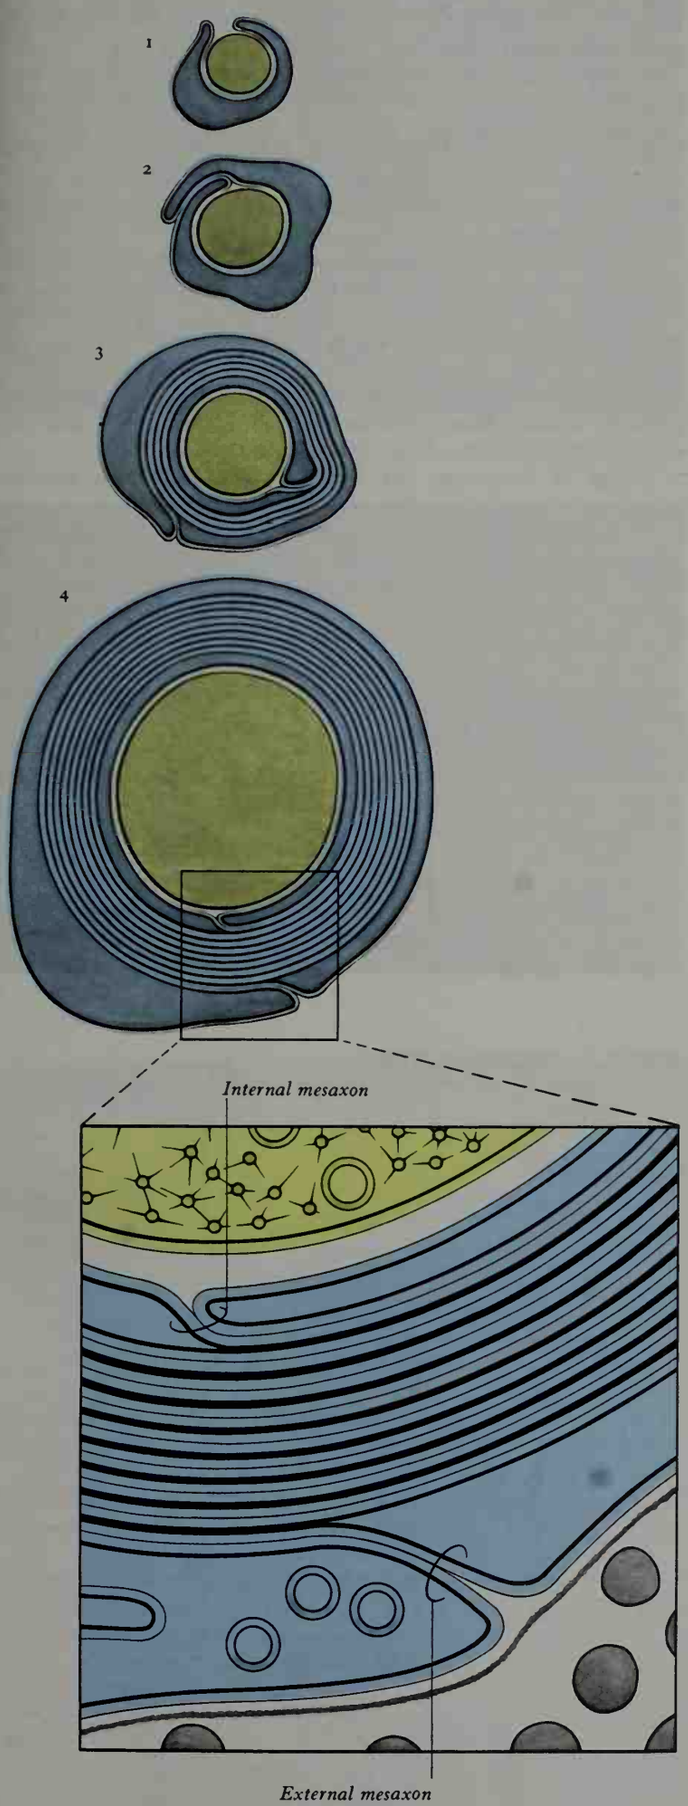
EXTRACELLULAR SPACE IN THE BRAIN

When considering the movements of water and solutes in any tissue it is convenient to think of the system in terms of a number of functional barriers which create a series of physiological compartments, namely the capillary bed, the lymphatic drainage, the intracellular space and the extracellular space (Davson 1970). The central nervous system lacks an intrinsic lymphatic drainage and the position is therefore simplified. At one time it was considered that large extracellular spaces were present between the cell processes, on the basis of light microscopy; but fine structural studies soon showed that the central nervous parenchyma consists of a complex three-dimensional meshwork of neurons and their processes, glial cells and capillaries, all apparently tightly packed with little more than a 20 nm gap between their surfaces. However, tracer studies show that in spite of the narrow spaces between cells, there is relatively rapid diffusion of substances from the ventricles and central canal through the nervous tissue, and a similar rapid diffusion of *small* molecules from intrinsic blood vessels (*vide supra*).

Peripheral Nerve Fibres

As in the central nervous tracts, two types of nerve fibre exist in the peripheral nervous system, namely myelinated and non-myelinated fibres. Peripherally, however, they are ensheathed by the *cells of Schwann* instead of the central oligodendrocytes. Both central and peripheral nerve fibres present a number of difficulties to the neurohistologist, either because of their small size in the case of non-myelinated fibres, or because the sheaths of myelinated fibres are severely disrupted by the lipid solvents employed for histological preparation. A number of special methods have been devised to overcome these problems; with myelin sheaths these are based chiefly on means of fixing and staining the myelin either in teased material which demonstrates individual fibres, or in blocks of tissue which can be later processed and sectioned in the usual way. The osmium-based

7.24A This diagram shows some structural features of peripheral nerve fibres. A nerve trunk (top left) is cut away to expose a single fasciculus, from which three fibres are indicated in detail. These include two myelinated axons, one on each side of a group of non-myelinated axons enclosed within a Schwann cell sheath. The myelinated fibre on the left has been cut away at various points to demonstrate the relationship between the axon, the Schwann cell, and its sheath of myelin.



methods are particularly valuable in this respect, either used as osmium tetroxide in aqueous solution, or with chromate and haematoxylin solutions, both methods fixing and staining the sheaths simultaneously. Other methods include the use of frozen sections stained with lipid-soluble dyes, examination of material prepared by any of these methods by polarization, phase or interference microscopy, and observation of freshly teased or living nerves *in situ* by various means including incident light techniques. The extension of time-lapse cinemicrography, and videotape recording techniques in conjunction with closed-circuit television, to this field of investigation have aided the analysis of living nerve fibres (Williams and Hall 1970, 1971*a* and *b*). The various means of demonstrating central neurons already described (p. 820), have also been valuable in demonstrating peripheral nerve fibres including non-myelinated ones; as with other parts of the nervous system, electron microscopy has contributed greatly to our understanding of peripheral nerve structure.

Structure of the Peripheral Nervous System

The peripheral nervous system comprises the cerebrospinal and autonomic systems of nerves and their associated ganglia, containing nerve cell somata, together with the cellular and connective tissue elements which ensheathe them. All these structures, of course, lie peripheral to the pial envelope which covers the central nervous system, through which the central and peripheral nerve fibres are continuous at many points; but the histology of the two contrasts in a number of ways, and that of the peripheral structures will now be considered (7.24, 25, 26, 27, 28).

The sensory ganglia of dorsal roots of spinal nerves (7.25), and corresponding ganglia on the trunks of the trigeminal, facial, glossopharyngeal and vagal cranial nerves, are ensheathed by periganglionic connective tissue which is similar to perineurium in composition (p. 1052). The neurons are *unipolar*, possessing spherical or ovoid somata of varying size, and these are aggregated in groups, interspersed with fasciculi of myelinated and non-myelinated nerve fibres. The fine structure of neuronal cytoplasm is described elsewhere (p. 825) and will not be pursued further here, but it should be noted that a single non-myelinated neurite (sometimes termed a 'dendro-axonal' process) leaves each cell soma. It often follows a highly convoluted course near the parent soma before bifurcating at a T-junction to become continuous with the central and peripheral processes of the sensory nerve fibre. In the case of myelinated fibres, such a junction occurs at a node of Ranvier (p. 845). The peripheral process terminates in a sensory ending and since it conducts towards the cell body it is functionally an *elongated dendrite*, but it possesses all the structural and physiological characteristics of a *peripheral axon* and, following common usage, will be so termed in this account. Each unipolar cell body is closely enveloped by a *nucleated capsule* consisting of flattened, epithelioid *capsular cells*, also variously termed *amphicytes* or *satellite cells*. (It should be noted that the name satellite cell is used in a number of different ways. Some authors use the term for small rounded extracapsular ganglionic cells, others include ganglionic capsular cells and Schwann cells, and yet others include all non-neuronal cells both central and peripheral which are perineuronal in position. Further, the name is also applied to cells associated with the surfaces of striated muscle fibres—p. 513). The cytoplasm of the capsular cells in many ways resembles that of Schwann cells (*vide infra*), and their deep surfaces are irregular, interdigitating with reciprocal irregularities on the surface of the subjacent nerve cell body. The layer of capsular cells is continuous with a layer of similar cells which encloses the convoluted part (*initial glomerulus*) of the dendro-axonal process, and this, in turn, is continuous with the Schwann cell layer of the peripheral and central processes of the nerve fibre. Outside these cell layers lies a delicate vascular connective tissue which is continuous with the endoneurium of the peripheral nerve and nerve root.

Sensory ganglionic neurons are not confined to the discrete ganglia of the cerebrospinal nerves, but either singly or in small

7.24B A diagram showing the development and organization of the myelin sheath of a peripheral nerve fibre. In stages 1–4 myelin formed by a Schwann cell (blue) progressively envelops the growing axon (yellow), to form the final pattern of spirally disposed myelin lamellae: see enlarged detail at the base of the diagram.

7.24C An electron micrograph of a myelinated peripheral nerve fibre, showing an axon containing neurofilaments, microtubules and mitochondria, surrounded by a myelin sheath, enclosed in turn by Schwann cell cytoplasm and endoneurial spaces. Magnification × 25,000.

groups, they often occupy '*heterotopic*' positions either peripheral to the ganglia.

The autonomic ganglia have a different structure, since their cell bodies are multipolar, with dendritic trees which receive synapses from incoming preganglionic visceral motor fibres, and sections show a mixed neuropil of afferent and efferent fibres, dendrites, synapses and cell bodies (*see* p. 1124).

The nerve trunks and their principal branches are composed of roughly parallel bundles of nerve fibres including efferent and afferent axons, their ensheathing Schwann cells, which in some cases elaborate *myelin sheaths*, surrounded by connective tissue sheaths at different levels of organization. The fibres are grouped together within the trunk in a number of *fasciculi* each of which may contain from relatively few to many hundreds of nerve fibres. The size, number and pattern of the fasciculi vary greatly in different nerves and at different points along the length of a nerve. The number of fasciculi increases and their size decreases some distance before there is macroscopic evidence of *branching* of a nerve trunk. Similarly, where the nerve is subjected to considerable increases of pressure, as when passing deep to a fibrous retinaculum, the fasciculi are again increased in number and reduced in size; further, their volume of associated connective tissue and their vascularity also increase. Consequently, the nerve shows a pink, fusiform dilatation of contour at this point, which is sometimes termed a *pseudoganglion* or *gangliform enlargement*.

A dense irregular connective tissue sheath, the *epineurium*, surrounds the whole trunk, and a similar but less fibrous *perineurium* encloses each fasciculus, within which the spaces between nerve fibres are penetrated by a loose delicate connective tissue network, the *endoneurium*. These connective tissue sheaths serve as convenient planes of access for the vasculature of peripheral nerves, the capillary bed and associated lymphatics running in the main parallel to the nerve fibres in the endoneurial spaces, but short oblique cross-connexions pass between them.

The epineurium is a collagenous adventitial coat with little regular organization (Thomas 1963); the perineurium in contrast has a regular structure of highly flattened laminae of fibroblasts alternating with fine collagenous sheets running in various directions. Macrophages are also present. The fibroblasts, surrounded by dense intercellular material, form junctional complexes and it appears from tracer experiments that these limit the diffusion of large molecules across the sheath (Waggener and

Beggs 1967). The fibroblasts also show numerous pinocytotic vesicles, an indication of active transport mechanisms.

THE CLASSIFICATION OF PERIPHERAL NERVE FIBRES

Several schemes of classification have been proposed for peripheral nerve fibres, based on relative conduction velocities, functional nature of fibres, total fibre diameter and other considerations. Of these, two are in common use (*see* accompanying table); the first scheme, proposed initially by Erlanger and Gasser (1937) in relation to the different conduction speeds in frog nerves, divides fibres into three major categories, designated A, B and C, corresponding to three peaks in the distribution of velocities. The group A fibres could be further divided into three subgroups termed α, β, and γ; B group fibres are preganglionic autonomic efferents, and C fibres are non-myelinated. Since total diameter and conduction velocities are in most fibres roughly proportional to each other (in mylinated fibres conduction, expressed in metres per second is approximately six times the fibre diameter in micrometers), the group Aα fibres are both the widest and the most rapidly conducting, and the C fibres the narrowest and slowest. In mammals it was found that Aβ fibres were negligible, but also that a subclass of non-autonomic fibres similar in conduction speeds to B fibres exists; these are termed Aδ fibres.

In the Erlanger and Gasser scheme, the *afferent (sensory) fibres* are confined to the Aα, Aδ, and C groups. The largest of these (the Aα fibres) include the axons of the encapsulated cutaneous, joint and muscle receptors and some large alimentary or related interoceptors. The Aδ fibres belong to various nociceptors, including those of the dental pulp, of skin, and of various other connective tissue sites, and the C fibres have thermoreceptive, nociceptive and interoceptive functions.

The somatic efferent (motor) fibres include Aα, Aβ, and Aγ fibres. The Aα fibres innervate extrafusal muscle only, being up to 22 μm in diameter and conducting at a maximum of 120 m/sec. The fibres to the 'fast' twitch muscle are slightly larger than those to 'slow' muscle. The Aβ fibres are restricted to collaterals of Aα fibres, forming plate endings on intrafusal muscle fibres, and the Aγ fibres are exclusively fusimotor nerves to plate and trail endings on intrafusal muscle fibres (*vide infra*).

Autonomic efferents comprise the preganglionic B fibres and postganglionic sympathetic and parasympathetic axons of the C (non-myelinated) group.

As can be seen, this scheme can be applied to all fibres of spinal nerve trunks and all cranial ones except perhaps olfactory nerve fibres which form a uniquely small diameter and slow conducting fibre population.

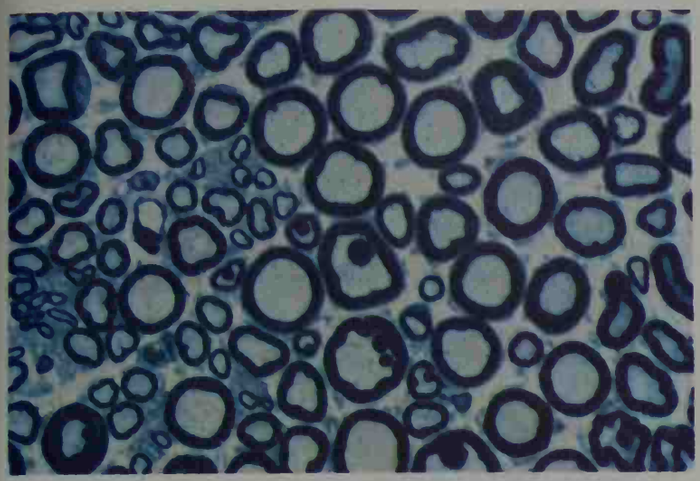
Another type of classification, proposed for use in designating the afferent fibres of somatic muscles, was instituted by Lloyd in 1943. In this scheme, the myelinated fibres are divided into three groups, I, II, and III, the non-myelinated fibres forming group IV.

Group I fibres are large in diameter (12–22 μm), and include the primary sensory fibres of muscle spindles (Group Ia) and the slightly smaller fibres of the Golgi tendon organs (Ib).

Group II comprises the fibres of the secondary sensory terminals of muscle spindles, with diameters of about 6–12 μm.

Group III fibres, 1–6 μm in diameter, have free endings in the connective tissue sheaths surrounding and within muscles, and appear to be nociceptive, related to the experience of 'pressure-pain' in externally stimulated muscles. The paciniform endings of muscle sheaths may also contribute fibres to this class.

Group IV includes non-myelinated fibres below 1·5 μm again with 'free' endings in muscle sheaths and interiors, chiefly with nociceptive functions.



For a full discussion of the sensory nerves of muscle, the reader is referred to the excellent reviews by Matthews (1973), Barker (1974), and Hunt (1974).

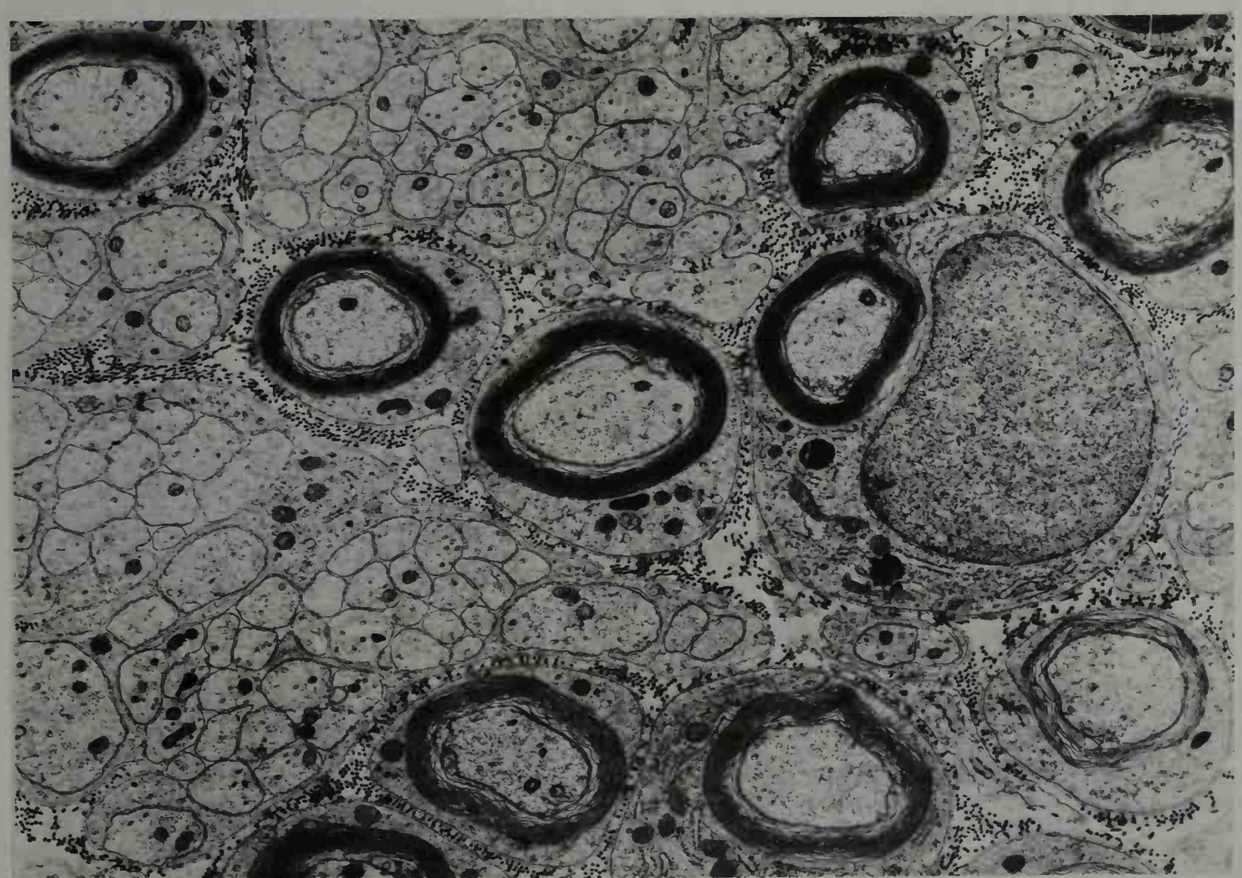
Whilst such general forms of classification have proved of great assistance in neurophysiology, it must be emphasized that caution should be exercised before assuming that a single structural parameter, such as total fibre diameter, measured at one point along a nerve trunk, adequately categorizes the nerve fibre population along the length of the nerve. Likewise, many of the

CLASSIFICATION OF PERIPHERAL NERVE FIBRES

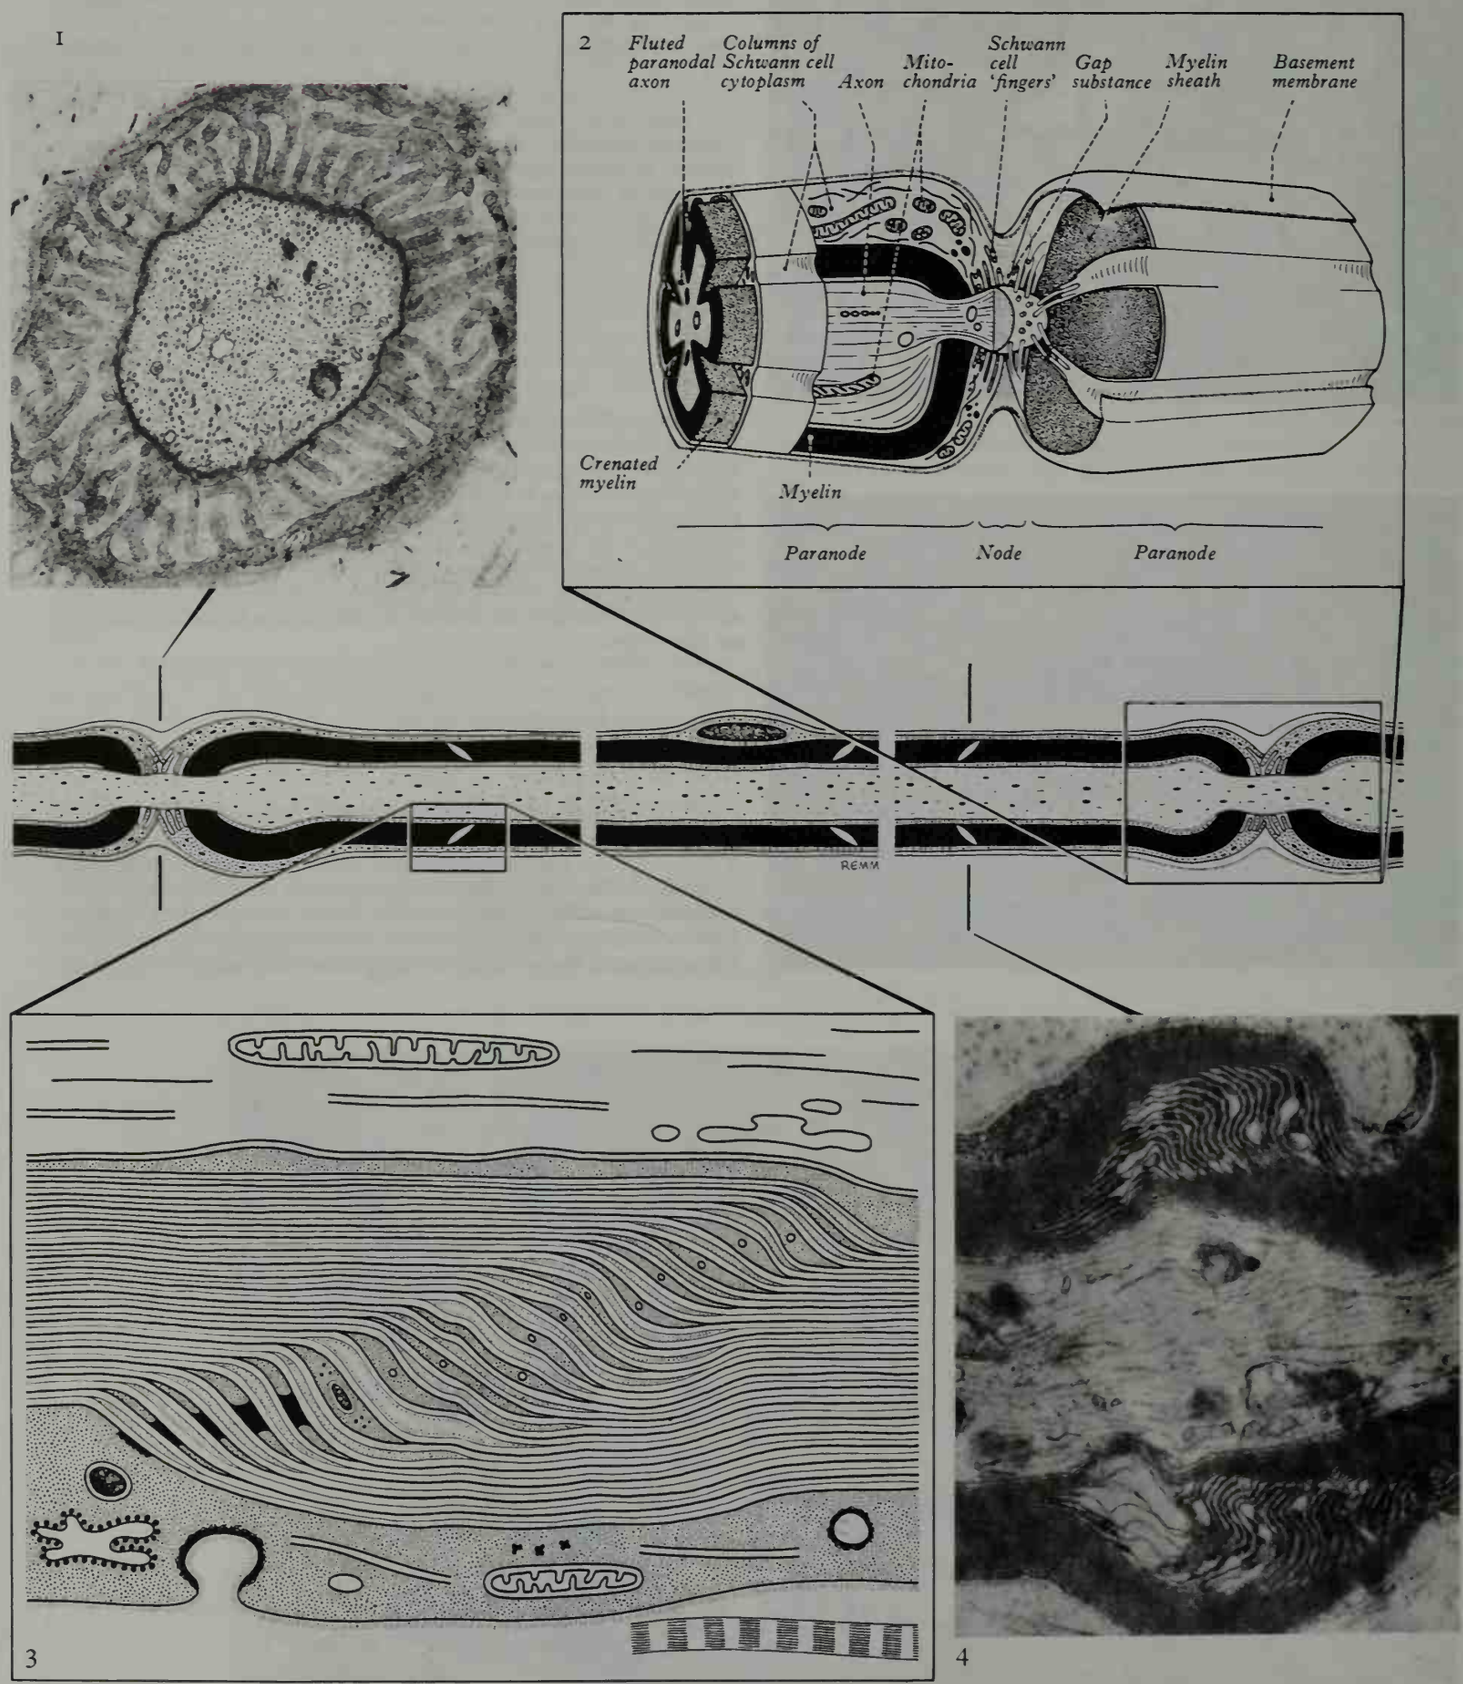
CHARACTERISTICS OF FIBRE					
Type of sheath	Myelinated				Non-myelinated
Fibre diameter	22 μm			1·5 μm	2·0–0·1 μm
Conduction speed (Metres/second)	120	60	50	30 4	0·5
CLASSIFICATION		A		B	C
1. Erlanger and Gasser *All fibres*					
Subclasses: Efferent	Aα Skeletomotor	Aβ Fusimotor collaterals of A fibres	Aγ Fusimotor	B Preganglionic autonomic	C Postganglionic autonomic
Afferent	Aα and smaller. Muscle and tendon; cutaneous			Aδ Cutaneous, muscle visceral, etc.	C Cutaneous, muscle visceral, etc.
2. Lloyd Afferent—skeletal muscle and articular	I *a* primary spindle ending *b* tendon ending	II Secondary spindle ending		III Free ending (nociceptor, etc.) paciniform ending?	IV Free ending (nociceptor, etc.)

It should be noted that the scale for conduction velocities is not arithmetic.

A



7.25A Transverse section of part of a mixed peripheral nerve from a mouse, showing a wide range of diameters of myelinated nerve fibres. Myelin: dark blue; axoplasm: pale blue, embedded in which are slightly darker blue dots, the axonal mitochondria. Note particularly the wide range of *axon* diameters; the smaller axons possess thinner myelin sheaths. The fibre with a particularly thick, double-contoured myelin sheath (bottom left) is sectioned through an incisure of Schmidt-Lanterman. The large fibres with more complex profiles (centre and bottom) are sectioned near the commencement of paranodal bulbs. On the left, between the myelinated fibres, groups of non-myelinated axons, enclosed by Schwann cells (medium blue) are just visible. A 1 μm epoxy resin section, stained with osmium tetroxide solution, and toluidine blue, photographed using oil immersion optics.



B

B A longitudinal section of material prepared in a similar manner to that in 7.25A. Note particularly the fibre just below the centre of the field which is sectioned through a node of Ranvier. As the internodal myelin sheath approaches the node, its diameter increases to a maximum (the paranodal bulb) and the myelin sheath then curves sharply inwards, to terminate at the limits of the 'nodal gap'. The myelin profiles, apparently lying free within the paranodal bulbs, are demonstrated to be paranodal shelves of myelin, when serial sections are examined (compare with 7.25D2). Note also the constriction of the nodal axon; long, narrow axonal mitochondria are also visible.

7.25C A transverse section of an immature peripheral nerve of a rat, taken one week after birth, showing the profiles of numerous axons. Some of the latter are non-myelinated and, either singly or in groups, are invaginated into the surfaces of cytoplasmic processes of adjacent Schwann cells. Other axons are in the process of myelination. Note the Schwann cell nucleus (right) to one side of a myelin sheath, and the ultrastructure of the Schwann cell cytoplasm at this stage of development.

C

2 7.25D A general plan of a myelinated nerve fibre in longitudinal section including one complete internodal segment and two adjacent paranodal bulbs, used as a key for the more detailed microarchitecture of specific subregions. 1: a transverse section through the centre of a node of Ranvier, with numerous finger-like processes of adjacent Schwann cells converging towards the nodal axolemma. Many microtubules and microfilaments are visible within the axoplasm. 2: a diagram showing the arrangement of the axon, myelin sheath and Schwann cell cytoplasm at the node of Ranvier in the paranodal bulbs. (Supplied by Prof. P. L. Williams and Dr. D. N. Landon.) 3: detailed substructure of one-half of an incisure of Schmidt-Lanterman; consult text for further information. (Supplied by Dr. Susan M. Hall and Prof. P. L. Williams.) 4: longitudinal section of part of a myelinated nerve fibre (mouse), including an incisure of Schmidt-Lanterman; this appears as oblique zones in the myelin sheath on both sides of the fibre. Consult text for structural details. (Nos. 1 and 4 kindly supplied by Dr. Susan M. Standring (*née* Hall) of Department of Anatomy, Guy's Hospital Medical School, London University.)

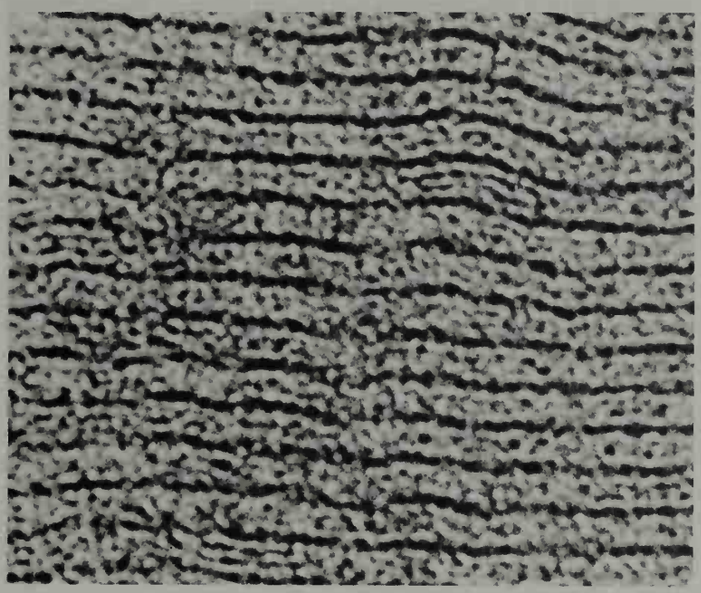
values quoted are only related to peaks in histograms of conduction velocity or fibre diameter frequency measured only in a few sites in certain nerves of a few species of mammal. However, if it is borne in mind that the figures quoted are relative, and that considerable overlap occurs between the functional classes of fibres, these schemes enable us to detect a general pattern of organization in the peripheral nerves of mammals including man, which is of considerable interest.

CONDUCTION IN PERIPHERAL NERVES

When a nerve trunk is stimulated, the *sum* of the action potentials in its many different nerve fibres, the *compound action potential*, can be recorded with extracellular electrodes. Since these potential variations travel at different speeds along different fibres, and since large fibres create larger electrochemical fluxes than small ones, a compound action potential recorded at a distance from the point of stimulation has a complex form, with at least four successive waves of different amplitude and velocity. These are known as the α, β, γ and δ waves. Just as each nerve trunk has its own characteristic spectrum of nerve fibres types, so the precise wave pattern is also distinctive. In the past, the fibre types have been classified by their conduction velocities, but it is now recognized that fibres of different physiological roles may have similar conduction velocities so that a more complex terminology taking into account size, conduction velocity and functional connexions has emerged (*vide supra*).

It is becoming clear that there is a series of factors which govern the conduction velocity of nerve fibres. In non-myelinated fibres, the action potential sweeps continuously over the axolemma as ionic eddy currents (electrotonus) which progressively excite neighbouring areas of membrane. The rate of spread is proportional to the cross-sectional area of the axon (Hodgkin 1964). In myelinated fibres, however, the presence of an insulating layer of myelin prevents the membrane from being excited at any point except the nodes of Ranvier, but once an action potential is initiated at one node, the resultant ionic eddy currents spread to excite the next node and others in sequence. Since the longitudinal flow of ions in tissue fluid and axoplasm is much more rapid than a continuous electrotonic spread along the axonal membrane, much higher conduction velocities are possible by this mechanism, which is known as *saltatory conduction* or *saltation* (Stämpfli 1954).

During excitation at a node of Ranvier, there is initially an increased permeability of the short, exposed, segment of nodal axolemma to sodium ions, which therefore flow down their concentration gradients to enter the nodal axon. Consequently, longitudinal ionic currents are generated which flow along the *internodal axon* to leave at the next node, the circuit being completed by longitudinal ionic currents in the reverse direction in the endoneurial tissue fluid. When the outflowing current density at the *second node* rises to a critical *threshold level*, its depolarizing effect is sufficient to initiate similar permeability changes in the nodal axolemma, and the whole process is repeated, with excitation of the third and subsequent nodes. However, myelin is an imperfect insulator and, as a result, the longitudinal currents are not completely confined to the axoplasm and external tissue fluid. Some radial leak of current occurs between the axoplasm and tissue fluid, with a resulting loss of efficiency. The details of these relationships will not be pursued here, but it may be noted that for a given total fibre diameter, maximum efficiency is achieved when the diameter of the axon and the thickness of its myelin sheath are such that the *ratio* of axon diameter to total fibre diameter is 0·6. Only the largest mammalian myelinated nerve fibres reach this ratio during growth.



Despite the general usefulness of the classification of nerve fibres described above, based in part upon total nerve fibre diameter variations, it should be emphasized that other dimensions are equally essential in determining the conduction characteristics of a myelinated nerve fibre. As just mentioned, these include the *diameter* of the axon *and the relative thickness* of its *myelin sheath*; in addition, the *internodal distance* between successive nodes of Ranvier, and the *area, characteristics* and *micro-environment* of the *nodal axolemma* are important. These structural parameters vary between species, between different functional categories of fibre, and at different points along the length of individual fibres and their branches (Williams and Wendell-Smith 1971).

SCHWANN CELLS

Schwann cells are the satellite cells of the peripheral nervous system. All peripheral axons lie for most of their course in invaginations of Schwann cell plasma membrane, separated from the endoneurial compartment by a Schwann cell basal lamina. Schwann cells are also sometimes known as neurolemmocytes, a not altogether fortunate term.)

In view of the large cytoplasmic volume and surface area of many neurons (which possess but a single diploid nucleus) it has long been inferred that this structural association is indicative of a functional interdependence. In recent years considerable experimental evidence has accrued to support this idea. Thus, Schwann cells have been implicated in the local support of the axon, supplying metabolites and trophic factors (Varon & Bunge 1978); influencing the ionic milieu of the periaxonal space and possibly the distribution of neuro-transmitters (Villegas 1975), and even in determining the siting of sodium channels along the axolemma (Ritchie & Rogart 1977). It is also clear that Schwann cells are influenced by the neurons they surround. The physiologically important parameters of myelin thickness and internodal length (i.e., expressions of Schwann cells' territories) are related to axonal size, possibly reflecting the spacing of antigenic determinants on or in the axolemma. Experiments using tissue culture of homogenous populations of neurites and Schwann cells, and allo- and xeno-grafting of nerve fascicles have demonstrated (*a*) that axons are mitogenic for Schwann cells, and (*b*) that Schwann cell differentiation (into myelinated or non-myelinated states) is at least in part dependent upon neuronally derived signals (Wood & Bunge 1975; Aguayo, Perkins, Duncan & Bray 1978). Schwann cells can even form myelin around central axons under certain experimental conditions.

The life history of the Schwann cell is divisible into two distinct phases: a perinatal *migratory* and *proliferative* stage, which is succeeded by the definitive *axon-associated* state when, if appropriately stimulated, myelin formation and maintenance may occur.

7.25E A high-power electron micrograph of part of a myelin sheath in section, showing dense period lines (the apposition of the cytoplasmic aspects of the cell membranes), alternating with less dense intraperiod lines (the apposition of the external aspects of the Schwann cell membranes). The preparative techniques used have caused the intraperiod line to split into two distinct lines in some places.

The immature Schwann cell is large and rounded with an oval nucleus and dense cytoplasm. As migration from the neural crest proceeds, the cells are at first fusiform and subsequently become irregular in outline, putting out processes which insinuate between bundles of outgrowing neurites, effecting their subdivision. In the mature myelinated fibre, Schwann cell cytoplasm is evident as thin, often apparently discontinuous, strips lying external to the myelin sheath and occasionally between the inner aspect of the sheath and the periaxonal space. Only at the paranodes, in the nodal gap fingers, throughout the spiral of the Schmidt-Lanterman incisure and in the perinuclear region, does any substantial volume of Schwann cell cytoplasm persist.

The relationship between axon and Schwann cell is emphasized in pathological material. It is well known that any disturbance of either axon or Schwann cell results in breakdown of the normal morphology of the nerve. Crushing or cutting a peripheral nerve produces Wallerian degeneration. All affected axons distal to the injury degenerate and there is a period of intense Schwann cell division during which myelin and axonal débris is phagocytosed by the Schwann cell population. Successful axonal regrowth into the persistent basal laminal tubes of the remaining Schwann cells in the distal stump is accompanied by a re-establishment of Schwann cell/axon associations and remyelination where appropriate. An insult (metabolic or chemical) which is primarily directed against the Schwann cell results in either demyelination or in hypomyelination but not necessarily in axonal degeneration.

Recent experimental trends have been directed towards elucidating the mitogenic and myelinogenic signals, preparing antigenically homogenous populations of Schwann cells for immunological studies, and examining abnormalities of Schwann cell behaviour in various human neuropathies by grafting abnormal nerves into normal (non-human) recipient nerves.

All of the larger axons of the nervous system of mammals are enwrapped in *myelin sheaths* and are termed *myelinated* or *medullated* fibres. The fatty composition of the myelin is responsible for the glistening whiteness of the peripheral nerve trunks and of the white matter centrally. Axons less than about 0·5–1·0 μm in diameter generally lack these sheaths and are therefore termed *non-myelinated*, *non-medullated* or *grey* fibres. These two types of fibre have great physiological significance and will be described in some detail.

NON-MYELINATED FIBRES

In mammals, approximately 75 per cent of axons are non-myelinated in cutaneous nerves and dorsal spinal nerve roots, 50 per cent in muscle nerves and 30 per cent in ventral spinal nerve roots. In the autonomic nervous system, post-ganglionic axons are almost exclusively non-myelinated, and pre-ganglionic fibres contain significant numbers of non-myelinated axons. A non-myelinated 'fibre' consists of a group of small axons (0·15–2 μm in diameter) associated with a longitudinal chain of Schwann cells. In mature nerve, the way in which the Schwann cells enclose the axons within each group shows inter-species variation, and even varies in different nerves in the same species. In general, individual axons are segregated from their neighbours by tongues of Schwann cytoplasm, but are sometimes further isolated by separate processes of cytoplasm that only come together in the perinuclear region of the Schwann cell (Gamble and Eames 1964). A more primitive organization, resembling that of fetal nerves, persists in some adult nerve, notably the olfactory nerve, where bundles of many small axons are engulfed within common invaginations of Schwann cell cytoplasm.

Three-dimensional reconstruction based on analyses of semi-serial ultra-thin sections of somatic and autonomic nerves has revealed that the spatial relationships between axons and satellite cells alters continuously and in a complex fashion within each cell, and along the chain (Aguayo *et al.* 1973). Transfer of axons between Schwann cells usually occurs at the extremities of the engulfing Schwann cells where their elongated cytoplasmic processes interdigitate (Gamble *et al.* 1978).

Thus, non-myelinated fibres comprise the smaller axons of the central nervous system, in addition to peripheral post-ganglionic axons of the autonomic nervous system, and the several types of fine sensory fibres such as some of those responsible for signalling pain (i.e. from nociceptors, but see also below and pp. 852, 856), the olfactory nerve axons, and others. As indicated above, these axons are engulfed either singly or in small bundles into longitudinal invaginations of a series of Schwann cells which therefore separate them from the endoneurial space (7.25C). The original line of invagination during development of non-myelinated axons which are deeply embedded in Schwann cells is marked by a *mesaxon* consisting of a double layer of the Schwann cell plasma membrane, the external surfaces of which are parallel but separated by a gap of 15–20 nm. Deeply, the two layers separate to enclose the axon from which they are again separated by a *periaxonal space* of similar dimensions; superficially the mesaxonal layers separate to become continuous with the general outer plasma membrane of the Schwann cell. The endoneurial tissue fluid has access to that in the periaxonal space by way of the gap between the two layers of the mesaxon. Although narrow, these intercellular spaces are of sufficient dimensions to allow the mobility of ions necessary for the *continuous* electronic (ionic) current fluxes which characterize non-myelinated fibre conduction. Thus, in the absence of a myelin sheath and nodes of Ranvier, saltatory conduction does not occur, and the progressive uninterrupted passage of impulses in non-myelinated fibres is a relatively slow process, conduction velocities being in the range of about 4·0–0·5 m/s.

On the classification of Erlanger and Gasser, non-myelinated fibres are classified as C fibres; on that proposed by Lloyd non-myelinated afferents are designated Group IV (*see* p. 840).

Where synaptic or motor transmission occurs, the Schwann cell is reflected back from the axonal surface to expose the active regions. The terminal branches of myelinated fibres where they taper, are also provided with Schwann cell sheaths of a similar nature.

MYELINATED FIBRES

Myelinated fibres (7.24, 25) form the bulk of the elements of the somatic nervous system. To understand the structure of the myelin sheath it is convenient to describe its developmental sequences. The formation of myelin begins some time before birth in many tracts and nerve trunks although it is not completed until a considerable and variable time postnatally. The pattern of myelination varies in its timing in different mammalian groups and in different parts of the same nervous system.

In the peripheral nervous system axons grow out from the central and ganglionic cell bodies along with Schwann cells which initially multiply as the nerve grows in length, but later they cease dividing and increase only in size. At first, all axons are non-myelinated, but later a flap-like extension of the Schwann cell cytoplasm begins to spiral around the neurite, with the bulk of the cytoplasm and nucleus remaining outside the spirals (7.24B, 25C). As development proceeds, more and more turns are made, and the spirals become transformed into compacted layers of cell membrane (Robertson 1955). In electron micrographs, the myelin sheath, when mature, is seen as a laminated structure with regular dense *period lines* (representing the plane of apposition between the internal surfaces of the plasma membrane) alternating with less conspicuous *intraperiod lines*, representing appositions between the external surfaces of the plasma membrane spiral (7.24B). Suitable osmotic treatment which results in swelling of the sheath causes the intraperiod line to split, showing that the external surfaces are not fused to form a specialized junctional zone, but are apparently able to move on one another (Napolitano and Scallen 1969). On the inside and outside of the myelin sheath is a delicate zone of Schwann cell cytoplasm which, in many parts of the internode in mature fibres, is only about 20–30 nm thick. The internal layer is covered deeply by the inner plasma membrane of the Schwann cell which adjoins the 15–20 nm wide *periaxonal space*, and which is continuous through an *internal mesaxon* with the deepest lamella of myelin. Similarly an *external mesaxon* connects the outermost myelin lamella with the superficial part of the plasma membrane of the Schwann cell. Larger accumulations of Schwann cell cytoplasm are found in the external layer related to the grooves in the

paranodal myelin sheath, in the perinuclear region, where the nucleus dimples the external aspect of the myelin sheath near the mid-point of the cell, and also on the internal and external aspects of the Schmidt-Lanterman incisures (*vide infra*, p. 846). These cytoplasmic regions often contain mitochondria, lysosomes and a variety of vesicles and granules. The inner and outer zones of cytoplasm are also connected with each other by helical channels containing granular cytoplasm and microtubules at the nodes of Ranvier and Schmidt-Lanterman incisures (*vide infra*). The outer plasma membrane of the Schwann cell and its adjacent basement membrane correspond to the neurolemma of light microscopists.

When the lipids are removed from the myelin sheath chemically, as in the processing of histological material for wax embedding, without prior fixation and stabilization of the lipid components, a network of proteinaceous filaments, termed *neurokeratin*, is seen by light microscopy, but this has not yet been confirmed by other means.

CHEMICAL COMPOSITION OF MYELIN

Myelin is formed by the compaction of Schwann or glial cell plasma membranes. It is therefore not surprising to find that myelin resembles the plasma membranes of any cell in that it contains lipids, proteins and water (the bound water in myelin accounts for at least 20 per cent of the wet weight). However, the relative proportions of the various components and their disposition within the sheath are unique to myelin.

Myelin can be isolated from central or peripheral nervous systems by techniques involving the centrifugation of tissue suspensions against sucrose solutions, followed by osmotic shock of the bulk material and subsequent sedimentation or isolation on a sucrose gradient. Recently, immunological and autoradiographical methods have been used to 'dissect' further the constituents of the sheath. The proportions of cholesterol, total phospholipid and glycolipid in myelin are different from those found in other membranes, and differ between central and peripheral myelin. On a molar basis, cholesterol represents the major lipid of the myelin sheath (approximately 40 moles per cent of the total lipid). Although it is not synthesized within the sheath, it has been demonstrated that interference with cholesterol synthesis affects myelin synthesis as a whole. Of the glycolipids, the most important are galactocerebroside, sulphatide and ganglioside. Peripheral myelin has a lower concentration of galactocerebroside and a higher concentration of choline glycerophosphatide and sphingomyelin than central myelin. The choline glycerophosphatides have a higher proportion of unsaturated fatty acids than their central counterparts, although long chain fatty acids (C_{25} and C_{26}) constitute less than 2 per cent of the total, whereas in the central nervous system they account for up to 20 per cent of the total fatty acids. It is interesting that most of the organ-specific complement-fixing or precipitating activity of certain demyelinating antisera appears to be anti-galactocerebroside. Galactocerebroside has been found to be a cell-surface marker for cultured rat oligodendroglia, the satellite cells responsible for myelinogenesis in the central nervous system.

About 30 per cent by weight of myelin in the adult human central nervous system is protein. The myelin proteins have been examined by means of polyacrylamide gel electrophoresis of isolated myelin which has been made soluble by either phenol or sodium dodecylsulphate. Whatever solvent system is used, at least three major proteins have been described in central and peripheral myelin; as with the lipid moiety, there are considerable differences between myelin proteins from these sites. Peripheral myelin contains a low molecular weight glycoprotein P_0, and two basic proteins P_1 (which constitutes *c.* 5 per cent of the total protein) and P_2 (which constitutes *c.* 20 per cent of the total protein). P_1 is considered to be analogous to the encephalitogenic basic protein of central myelin. Analysis of the immune responses mounted against various regions of the basic proteins has provided information about the position and relationships of these proteins within the myelin sheath in various species.

It seems likely that very few enzymes are associated with myelin. Only one, 2:3′ cyclic AMP 3′-phosphohydrolase, has been examined in any detail, and is used experimentally as a myelin marker. The significance of this enzyme remains obscure.

FORMATION AND GROWTH OF MYELIN

Although the geometry of myelin is now understood in some detail, exactly how it is laid down during myelination is still debatable. Early models, supported by tissue culture observations, involved the formation of a loop of Schwann cell cytoplasm around the enclosed axon, and the subsequent migration of the perinuclear region of the cell around it in a spiral manner (Geren 1954). In the central nervous system at least, such a mechanism appears to be ruled out since a single oligodendrocyte can simultaneously form myelin sheaths around several separate axons which would be impossible by the above method of growth (Bunge 1968). Other possibilities are the interstitial deposition of myelin within the lamellae of the sheath, or ingrowth of the spiral by slipping of the turns on one another, new myelin being formed externally (Webster 1971). Alternatively, it was suggested that the enclosed axon may rotate to wind myelin upon itself; recent reports that myelin in different internodes of the same fibre has different directions of spiralization would appear to rule this possibility out, however. Whilst perhaps excessive ingenuity has been expended in devising models which may explain 'spiralization' of the myelin sheath, much less attention has been paid to the other dimensional changes which are occurring. Thus, whilst the myelin sheath increases in *thickness* from the initial few lamellae to one containing perhaps 300, in a large mature peripheral fibre, the *axon* also increases in *diameter* from about 1 to 15 μm, and each internodal segment increases in length from about 150 μm to perhaps 1,500 μm (Williams and Wendell-Smith 1971). After the onset of myelination, no further multiplication of Schwann cells occurs and each elongates in proportion to the overall growth in length of the part of the body in which the nerve lies (Vizoso and Young 1948; Williams and Kashef 1966). Clearly, much remains to be learnt about the initiation, mechanisms, and cessation of myelination and the continued maintenance of the mature sheath.

In late fetal and early postnatal development, myelination does not occur simultaneously in all parts of the nervous system, different nerves and tracts having their own particular myelination characteristics which can be related to the functional maturity of various functional pathways (Ochoa and Mair 1969 *a* and *b*). Amongst other factors which are largely unknown, the onset of myelination is associated with the growth in diameter of the non-myelinated axons, and in those animals which have been investigated, the critical point appears to be reached when the axon is about 1·0 μm in diameter, although some larger non-myelinated fibres are sometimes found (Matthews 1968) and, with the advent of electron microscopy, many fibres <1 μm in diameter have been found to possess myelin sheaths. Once begun, myelination continues at a steady rate with the growth of the axon until the latter stops, so that there is a predictable mathematical relationship between axon diameter and sheath thickness. The numerical value of this relationship, however, varies with the type of fibre (i.e. in terms of the tissue it innervates), and its distance from the cell body of the parent neuron (Williams and Wendell-Smith 1971).

THE NODE OF RANVIER

At the junction between adjacent Schwann cells or oligodendrocytes of myelinated nerve fibres is a gap where the axolemma is exposed, termed the node of Ranvier (*see* Hess and Young 1952, for a review of the earlier literature, and Landon 1976 for a comprehensive recent survey). These gaps are placed at regular intervals, the myelinated segments between being known as *internodes*. The distance between nodes varies directly with the diameter of the fibre from about 150 to 1,500 μm (Kashef 1966). When fibres branch, they do so at nodes.

In peripheral nerves, the myelin sheaths on both sides of each node are usually expanded into *paranodal bulbs* (7.25B, D) which

often show an asymmetry related to the growth patterns of the surrounding topographical region. The surfaces of the bulbs and of the underlying axolemma are fluted as they approach the node, and numerous Schwann cell mitochondria are present in the external cytoplasm-filled grooves so formed (Landon and Williams 1963; Berthold 1968; Landon 1976). The axon itself also narrows considerably at the node. Where each myelin lamella ends it makes contact with the paranodal axolemma as an expanded loop in which are situated spirally orientated microtubules and dense cytoplasm. The external paranodal cytoplasm of the Schwann cell sends a number of finger-like processes which curve towards, and their tips abut on, the otherwise naked axolemma of the node (7.25D). The fingers are numerous and form a regular hexagonal array in large fibres, but are few and irregular in small ones. The depression formed at the node by the narrowing of the axon at this point is filled between the nodal fingers with an acidic mucosubstance (*gap substance*) which may form a reservoir of ions, or a selective barrier to their flow in the conduction of nerve impulses (*vide supra*, p. 843, and Landon and Langley 1971). The narrowing of the nodal axon probably increases the transmembrane current density and hence the efficiency of nodal excitation.

Central nodes have been less extensively investigated, but appear to be of a more simple construction, with few nodal fingers, and small or absent paranodal bulbs.

INCISURES OF SCHMIDT-LANTERMAN

Originally described as cytological features, the clefts or incisures of Schmidt-Lanterman were subsequently long regarded as artefacts of preparation. Ultrastructural and *in vivo* observations have restored them as characteristic features of central and peripheral myelinated fibres (Hall and Williams 1970; Landon 1976). The incisures are fairly regular oblique discontinuities in the close packing of the myelin lamellae (7.25D), forming funnel-shaped zones of cytoplasm spiralling between the internal and external layers of Schwann cell cytoplasm. Thus, at the incisure, the major dense line separates to enclose a helical band of granular Schwann cell cytoplasm, bearing one or more microtubules which follow this spiral pathway, microfilaments, and occasionally other organelles. The dense cytoplasm is modified in places, where it is similar to that found in the zonula adherens of epithelial and other cells, forming an oblique row or *stack* of '*desmosomoid*' attachments at one or more points near the external surface of the incisure. The intraperiod line also splits at the incisure to create an extracellular space interconnecting the periaxonal and endoneurial spaces.

The incisures possibly provide conduction channels for metabolites into the depths of the myelin sheath and to the subjacent axon; they have been claimed to be importantly involved in the initial stages of Wallerian degeneration (Williams and Hall 1971) and focal demyelination.

The *classical view* of Wallerian degeneration was that the first week after crush or section of a peripheral nerve was largely a period of *morphological disruption* of the part of the nerve distal to the injury, but it was also a period of *biochemical stability*. The morphological disturbances included the formation of myelin *ovoids* containing 'digestion chambers' with disruption of the axon. Only in the second week was there considered to be any biochemical change, and this consisted principally of the degradation of phospholipid in the sheath with the liberation of cholesterol esters.

More recently, *in vivo* examination of nerves undergoing Wallerian degeneration (Williams and Hall 1971), has shown that the time scale of events is considerably faster. The initial morphological changes include retraction of the paranodal myelin sheath, wide dilatation of the incisures of Schmidt-Lanterman, with the subsequent collapse and rounding off of the myelin to form ovoids at these points. These changes start within minutes in zones near the lesion, and occur progressively over the next 36–48 hours in more distal parts of the nerve. Further, it has been shown that there is an increase in the concentration of hydrolytic enzymes within 12 hours of injury; this is associated with a loss of trypsin-digestible *basic protein* from the sheath which can be demonstrated as a loss of *trypanophilia* in histological sections.

Electron microscopically the changes associated with Wallerian degeneration have been described as an accumulation of membrane-bound bodies in the axoplasm proximal and distal to the site of injury. Distally, there follows a degradation of the axoplasmic organelles, and at the previous sites of dilated incisures, there is a collapse of the previously compact myelin lamellae, with alterations in the repeat distances in their radial structure. Within 4 days, lipid droplets accumulate around the degrading myelin within the Schwann cell cytoplasm, and these are then extruded into the endoneurial space, where they are subsequently phagocytosed by invading haematogenous macrophages. The early increase in acid phosphatase activity has been correlated with the appearance of numerous lysosomes within the Schwann cell cytoplasm at this time.

As degradation of the myelin proceeds, the Schwann cells begin to proliferate rapidly; in some nerves which contain many large diameter myelinated fibres, the total number of nuclei per transverse section of the nerve rises to about 16 times that of a normal nerve, by the end of the third week of degeneration. These proliferating Schwann cells become aligned in parallel longitudinal chains within the persistent basement membrane, where they are of great importance in any subsequent regenerative phenomena which may ensue (p. 861).

CENTRAL-PERIPHERAL NERVOUS SYSTEM TRANSITIONAL ZONE

Crossing the transitional zone between the central (CNS) and peripheral (PNS) nervous system the sections of axons that comprise a nerve root are enclosed within a short glial segment lying close to the surface of the spinal cord or brainstem. In man the zone lies more peripherally in sensory nerves than in motor nerves: in both cases, the apex of the transitional region has been described as the '*glial dome*', with its convexity directed toward the periphery. Electron microscopy has shown that the centre of the dome consists of fibres showing typical central organization, surrounded by an outer mantle of astrocytes (corresponding to the external glial limiting membrane). From this mantle numerous processes, the '*glial fringe*', project into the endoneurial compartment of the peripheral nerve and interdigitate with the Schwann cells. The astrocytes form a loose meshwork through which the axons pass. There is currently some debate as to whether the basement membrane which surrounds the astrocytes is capable of preventing central Schwann cell migration. In general, peripheral myelinated fibres cross the transitional zone at a node of Ranvier, termed a *PNS-CNS compound node* by Carlstedt (1977). At such a node, on the peripheral side, the axon has a corona of Schwann cell microvilli and mitochondria-laden paranodal Schwann cell cytoplasm, while on the central side it is related to a few astrocyte processes, which typically make specialized contacts with the axolemma (Berthold 1978). In the transitional region of cat first sacral spinal nerve roots, an average of 4–5 nodes were associated with the processes of a single astrocyte, and it has been suggested that these node-astrocyte relationships are specific to the borderline nodes. In some myelinated fibres, however, the central–peripheral transition occurs along an internode, the central myelin being telescoped within an external peripheral myelin sheath.

Considerable rearrangement of axons occurs in the rootlets; moreover, many of the largest non-myelinated peripheral axons become invested with a thin myelin sheath as they pass through the transitional region.

Peripheral Endings of Effector Neurons

Of the various types of effector endings, the most intensively studied are those which innervate muscles, and particularly those of skeletal muscle, which are quite distinct from the efferent nerve endings in non-striated muscle. All such endings, termed *neuromuscular* or *myoneural junctions*, are, however, similar in being specialized regions of the neuronal cytoplasm from which neurotransmitters are released on to the surface of an adjacent muscle unit, causing a change in its electrical state. Because of the

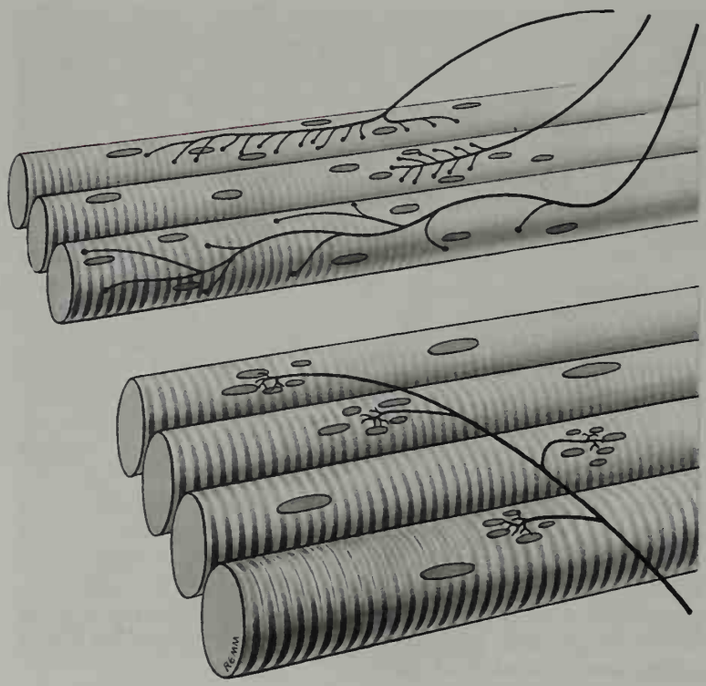
similarity between these junctions and synapses, and the relative ease with which neurophysiological studies can be carried out at the former, much general knowledge of neurotransmission stems from ultrastructural, physiological, biochemical and pharmacological analysis of neuromuscular junctions rather than synapses.

NEUROMUSCULAR JUNCTIONS IN SKELETAL MUSCLE

The general structure of these has been outlined elsewhere (p. 512) and will be described only briefly here. Essentially, the terminals consist of end branches of somatic motor fibres, each of which innervates from a few to many hundreds of muscle fibres, depending upon the precision of muscle control. The structural specialization of the motor terminal varies with the type of muscle innervated. Two major types of ending have been recognized, the '*en plaque*' terminals typical of extrafusal muscle fibres together with the *plate endings* of intrafusal fibres; the second type includes the '*en grappe*' terminals found on certain extraocular muscle fibres and also present in the '*trail*' endings on intrafusal fibres (Harker 1972; Barker 1974). In the former type each terminal branch of the axon ends midway along a muscle fibre in a discoidal expansion, the *motor end-plate* (7.26A–C). In the latter, the axon gives numerous subsidiary branches which form a cluster of small expansions which may extend for some distance along the muscle fibre (7.26A). The *en plaque* endings usually initiate action potentials in the muscle fibre which are rapidly conducted to all parts of the fibre, whereas in the *en grappe* ending, in the absence of propagated muscle excitation, the muscle fibre is excited at several points by the branched axon, ensuring activation of the entire fibre. Both types of ending are characterized by a specialized region of the muscle fibre surface, the *sole-plate*, in which a number of muscle fibre nuclei are grouped in a mass of granular sarcoplasm, and ultrastructurally, by the presence in the muscle of numerous mitochondria, endoplasmic reticulum, and by the folding of the sarcolemma into a series of parallel grooves or gutters (7.26B, C). The terminal expansion of the efferent fibre is separated by a gap of about 30–50 nm from this complex *subneural apparatus*, and contains mitochondria and large numbers of clear spherical vesicles similar to those of presynaptic boutons, which are clustered against the membrane throughout the zone of apposition. Ensheathing the motor terminal are Schwann cells sometimes termed *teloglia*, with fingers sometimes projecting into the synaptic cleft. It is interesting that *en plaque* endings of 'fast' and 'slow' twitch muscle fibres differ in their detailed structure, the sarcolemmal gutters being deeper and the presynaptic vesicles more numerous in the former (Padykula and Gauthier 1970). Recent freeze-fracture studies have shown the presence of numerous intramembranous particles corresponding to acetylcholine receptors in the crests of the sarcolemmal folds where they lie nearest to the presynaptic membrane (Heuser *et al.* 1974). In the motor end-plate opposite these crests the membrane is slightly invaginated, and vesicles are clustered along the borders of the groove so formed, which is considered to be the main site of their release (i.e. the '*active zone*' of the synapse). Microtubule arrays bearing synaptic vesicles, similar to those in central synapses, have also been described (Gray 1978).

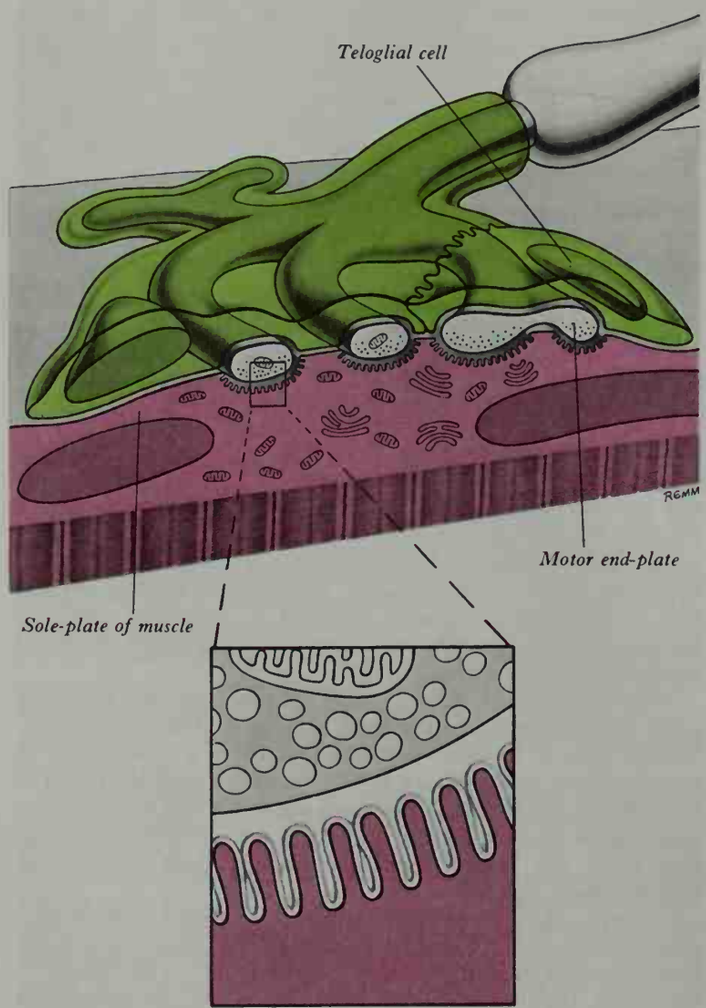
Physiological and pharmacological studies (Katz and Miledi 1965) have shown that the neuromuscular junctions with skeletal muscle fibres are *cholinergic*, that is, they act by the release of *acetylcholine* from the nerve terminal on to the specialized surface of the underlying sarcolemma, and this changes its ionic permeability. The resulting depolarization of the sarcolemma, if sufficiently intense, initiates an action potential which is propagated over the surface of the muscle fibre and results in its contraction (p. 511). As with synapses, the quantity of neurotransmitter released depends upon the number of nerve impulses arriving at the motor terminal, and since the transmitter is inactivated at a constant rate by the enzyme *acetylcholinesterase*, the amount present at a particular time is dependent upon its *rate* of release, which in turn reflects the *frequency* of arrival of action potentials along the nerve fibre. In this way the contraction of a muscle is controlled by the frequency of firing of its efferent nerves. Even in quiescent muscle fibres, small sporadic depolarizations have been detected (*miniature end-plate potentials*), which are too small to cause contraction. When recorded electrophysiologically, their amplitudes cluster at a series of preferential levels, indicating that multiples of small *quanta* of transmitter are occasionally released in the resting stage; calculations suggest that the amount of transmitter necessary to cause these unitary changes probably occupies the volume of a single synaptic vesicle (Katz and Miledi 1965).

Acetylcholinesterase can be demonstrated cytochemically in the myoneural cleft, and experiments with the specialized motor endings in the electric organ of the rayfish *Torpedo* show the enzyme to be located in the sarcolemma close to its site of action. Activity of the neurotransmitter can be blocked by various substances including *curare* and its derivatives, a sea-snake venom substance *α*-bungarotoxin and black widow spider venom, all of which bind irreversibly with receptor molecules so causing paralysis at the neuromuscular junction (Miledi *et al.* 1971). If the activity of the enzyme acetylcholinesterase is inhibited with *eserine (physostigmine)* or other poisons, transmitter action is cumulative and the muscle responds with a tetanic spasm. The neuromuscular junction is also partially blocked by high concentrations of lactic acid, and this is responsible for some types of muscle fatigue after prolonged exercise during which lactic acid accumulates (Miledi *et al.* 1971).



AUTONOMIC MOTOR ENDINGS

Unlike those in skeletal muscle, autonomic nerve-endings are not closely applied to the non-striated myocytes but end at variable distances from their surfaces (Richardson 1962). Non-myelinated autonomic axons branch to give many tapering, varicose collaterals (7.27A). At zones where transmission occurs, clusters of ultramicroscopic vesicles are present within an expanded region of axoplasm, and the Schwann cell, which closely enwraps the axon elsewhere, is retracted at this point so that the axon lies in a shallow groove, thus forming a free diffusion path between the axon and the muscle cells. In *sympathetic nerves* the vesicles are usually of the *dense-cored* type (p. 828), and these can be correlated with the characteristic fluorescence of catecholamines using light microscopy, when preparations which have been fixed in formalin vapour are viewed with ultraviolet illumination (Falck and Owman 1965). Besides noradrenalin, these vesicles also contain certain enzymes involved in their synthesis. Larger vesicles, 100 μm across are often also present.



Generally, *noradrenalin* is the transmitter at sympathetic postganglionic endings, whilst some *adrenalin* is also present chiefly in the *chromaffin cells* of the adrenal medulla. It is possible to distinguish ultramicroscopically between the synaptic vesicles which contain the two types of catecholamine by using appropriate fixatives. Catecholamines can be released experimentally with various drugs, such as *reserpine*, and this constitutes a valuable research tool, in addition to its clinical usefulness. After release a proportion of the transmitter is taken back into the ending by endocytosis in vesicles. Sympathetic endings are also rich in monoamine oxidases involved in degrading catecholamines, and the control of these enzymes is important in clinical regulation of sympathetic function.

At *parasympathetic* endings, clear spherical vesicles, similar to those in the motor end plates of skeletal muscle, are present. Several lines of evidence indicate that these are *cholinergic* in nature; similar terminals are also found in the neighbourhood of sympathetic endings, and it has been suggested that in addition to their action on non-nervous tissues, some cholinergic endings may cause the release of catecholamines from sympathetic endings (Burn 1968).

Recently a third category of autonomic neurons with properties quite distinct from those of noradrenergic or cholinergic cells has been described by Burnstock and his colleagues (*see* the review by Burnstock 1975). Since there is evidence that the conjugated purine adenosine triphosphate or ATP (a nucleoside), or a related compound, is the neurotransmitter at their axon terminals, these cells have been classed as *purinergic* in their properties. Typically, their axons contain large, dense vesicles some 80–200 nm across

Landon, Neurobiological Unit, National Hospital for Nervous Diseases, London.)

('*large opaque vesicles*') when seen in electron microscopic sections, congregated particularly in varicosities which occur at intervals along the nerve fibres. Such nerves have been demonstrated in many sites in the mammalian body, including the external muscle layers and sphincters of the alimentary tract, lungs, blood vessel walls, in the urogenital tract and central nervous system. In the wall of the gut, the cell bodies are in the myenteric plexus, and their axons branch and spread caudally for a few millimetres, chiefly to innervate the circular non-striated muscle (7.27B). The purinergic cells are themselves under cholinergic control from preganglionic sympathetic efferent nerve fibres.

The main action of purinergic endings is to hyperpolarize the muscle cells they innervate, causing their relaxation, for example, in front of peristaltic waves in the alimentary tract, opening sphincters and, in the case of the stomach, probably causing reflex distension on the receipt of food. Release of transmitter appears to be rather similar to that in other autonomic endings, that is, from axon varicosities at up to 100 nm away from the target cell, although details are not yet available.

The precise pattern of axonal branching and termination of autonomic efferents is closely related to the nature of the controls which they exert (Burnstock 1970); in non-striated muscle, with a slow widespread action, the branching may be extensive, a single neuron innervating a large number of muscle cells, and the distance between synaptic varicosity and muscle fibre surface being relatively large (50 nm or more). In quick-acting muscle which has a greater precision of control, such as that in the iris or ductus deferens the innervation is more localized, with much less branching of the axons, and the apposition is usually close (15–20

7.27A A diagram of an autonomic neuromuscular junction between a group of non-myelinated axons (above) and smooth muscle cells (below). The Schwann cell (blue) is reflected at intervals to expose enlargements of the axons (yellow) which contain synaptic vesicles.

known example of this type of receptor in mammals is the sensory cell of the olfactory epithelium, although in many invertebrate groups it is the chief type of sensory receptor and must be regarded as phylogenetically primitive. A second arrangement is for the sensory cell to be a modified epithelial cell, an **epithelial receptor**, derived from the non-nervous tissue at the sensory surface and innervated by the peripheral process of a primary sensory neuron, the cell body of which is situated close to the central nervous system. Activity in this type of receptor involves the passage of excitation from the sensory cell across a synaptic gap; examples are gustatory and cochlear auditory receptors. It is known that in gustatory sensory receptors there is a high turnover of individual cells which are constantly being renewed from the pool of surrounding epithelial cells, a phenomenon which may

7.27B Electron micrograph of a group of autonomic axons in the myenteric plexus, showing profiles with large dense-cored vesicles typical of the putative purinergic system (see text); smaller, catecholamine-type vesicles are also visible (lower left). Magnification × 40,000.

nm), the ending sometimes being invaginated in the sarcolemma (Burnstock 1975). In addition to non-striated muscle, many other tissues are innervated by autonomic efferents, including glands, myoepithelial cells, and adipose tissue. Many physiological actions depend upon autonomic control of the cardiovascular system whereby the activities of the tissues are in part regulated by varying the perfusion of blood through them.

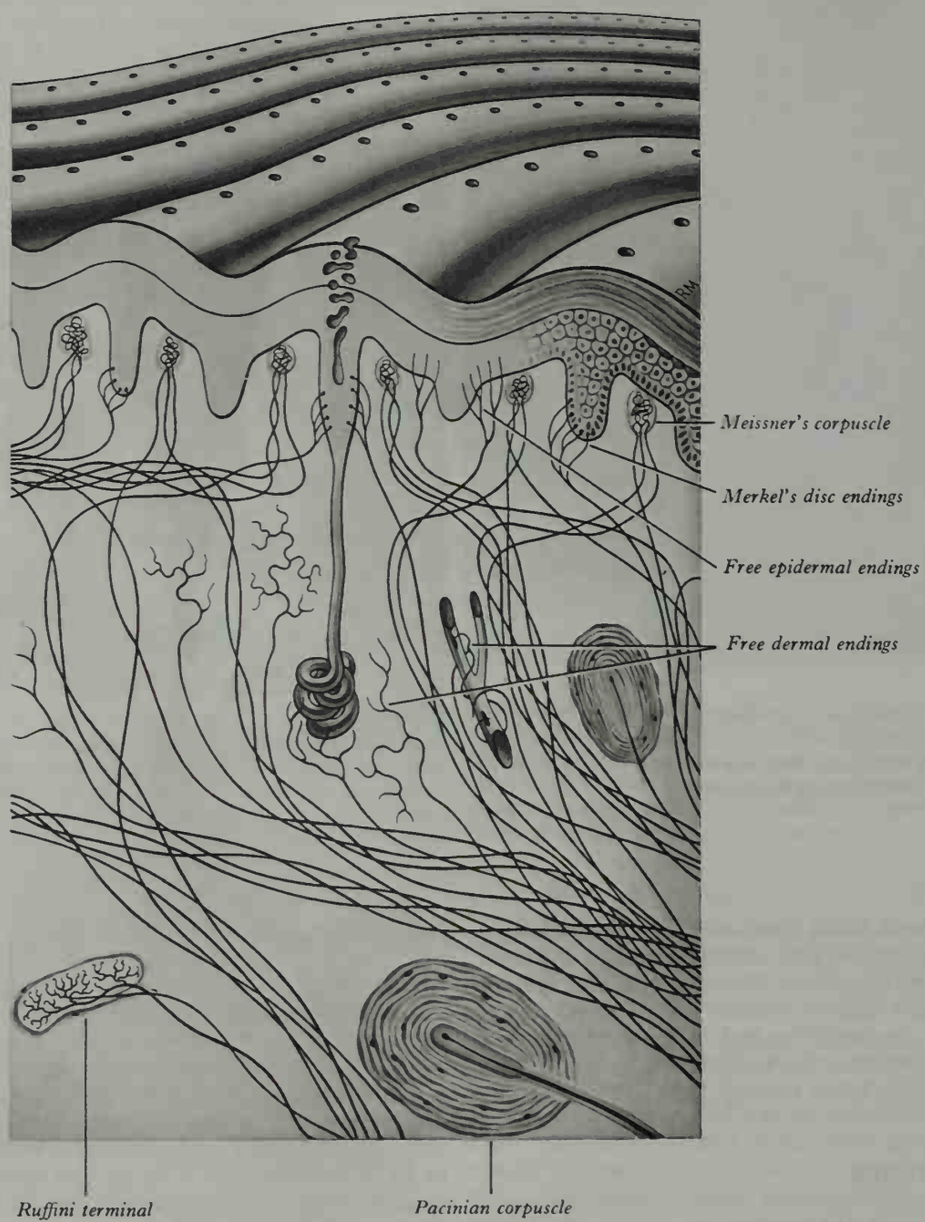
Sensory Receptors

As has already been stated, the manner in which an organism reacts to changes in its environment depends upon the presence of suitable sensory receptors which can monitor various parameters important to its survival. Although in unicellular organisms the whole cell may be able to detect mechanical deformation, changes of temperature, osmotic pressure, concentrations of various chemicals, light, and so on, in more elaborate animals individual cells have become differentiated to sense such changes with great acuity, different cells being responsive to their own particular range of physico-chemical variables. Such cells are termed sensory receptors; they take various forms in the animal kingdom, but in mammals there is, with minor exceptions, a common pattern which will be outlined below.

Structurally, sense organs take one of three basic forms, depending upon the relationship of the nervous system to the sensory surface. In **neuroepithelial receptors** the sensory cell is itself a neuron of which the perikaryon is peripherally situated near the sensory surface and the axon extends back into the central nervous system to connect with second order neurons. The only also occur in other sensory systems of this general type. Visual receptors are in many ways similar in their organization, since they are formed from the lining of the ventricle of the fetal brain; but no cell replacement occurs. Thirdly, a **neuronal receptor** is itself a primary sensory neuron with a perikaryon situated in a craniospinal ganglion and a long peripheral process, the ending of which constitutes the actual sensory terminal. All cutaneous sensors and many proprioceptors are thought to be of this type, although the sensory terminals may in some cases be encapsulated or lie in association with specialized mesodermal or ectodermal elements which form an integral part of the sensory apparatus; however, it appears that these non-neuronal elements are not themselves excitable but rather create the right environment for the excitation of the neuronal dendrite.

RECEPTOR RESPONSES

The various events occurring between the presentation of a stimulus and the signalling of this to the central nervous system have been extensively studied (e.g. Granit 1962), but are not yet entirely understood. It is convenient to divide these processes into a number of stages: initially there is the presentation of an effective stimulus, then its transduction at the receptor surface into a graded change of electrical potential (*generator potential*), and the initiation of an all-or-none action potential which passes to the central nervous system. All of these processes may occur within the confines of the receptor where this is a neuron, or some of them may take place partly in the receptor and partly in the dendrite of the neuron innervating it in the case of epithelial receptors.



The nature of the transduction process varies, of course, with the modality of the stimulus, and involves a change in the permeability to certain ions in the receptor membrane, usually to cause a depolarization (or in retinal cells, a hyperpolarization).

How a stimulus causes such a change is not yet known in any sensory cell. In mechanoreceptors it may involve a physical deformation in membrane structure; in chemoreceptors the action may correspond to that postulated for the action of acetylcholine at the neuromuscular junction (p. 514), involving specific receptor proteins which undergo alterations when stimulated, leading to the opening of ion channels with consequent depolarization of the sensory ending. Visual receptors appear to be rather similar to chemoreceptors; chemical changes occur within the cell as a result of illumination and so presumably act on the *internal* aspect of its membrane. Osmoreceptors may be similar to mechanoreceptors except that they react to mechanical deformation of their cell surface resulting from osmotic inflow or outflow of water with respect to the cytoplasm.

It is interesting that in certain fishes a quite distinct type of transduction occurs in electroreceptors which are capable of sensing changes in the electric fields set up in the external medium by their own bioelectric processes, or by those of other fishes (Lissmann and Machin 1958). So far a similar sensory mechanism has not been reported in tetrapods.

The quantitative responses of sensory endings to stimuli vary greatly and give additional flexibility to the design of sensory systems. Although an increase in the level of excitation with increase of stimulus strength is a common pattern (the *'on' response*), some receptors respond instead to a decrease in stimulus strength (the *'off' response*). Even when not stimulated, receptors show varying degrees of spontaneous activity, sometimes of a high level, against the background of which an increase or decrease in activity occurs with changing levels of stimulus strength.

When a steady stimulus is presented, there is, in all receptors yet studied, an initial burst of activity (the *dynamic phase*) followed by a gradual slowing or *adaptation* to the steady level of the stimulus (the *static phase*). Although all receptors appear to show these two phases, either one or the other may predominate, so that it is possible to distinguish between *rapidly-adapting* endings giving accurate estimates of changes in stimulus strength, and *slowly-adapting* endings which signal relatively constant stimuli such as those associated with position sense. Dynamic and

7.28A Schematic illustration of some of the principal sensory endings of thick (hairless) skin and associated structures, including various types of encapsulated and 'free' endings, of the epidermis, dermis and subcutaneous connective tissue.

static phases occur in both the amplitude of the generator potential and the frequency of action potentials set up in the sensory fibre. The stimulus strength necessary to elicit a response in a receptor (i.e. its *threshold level*) varies considerably. Such high and low threshold responses gives added information on stimulus strength.

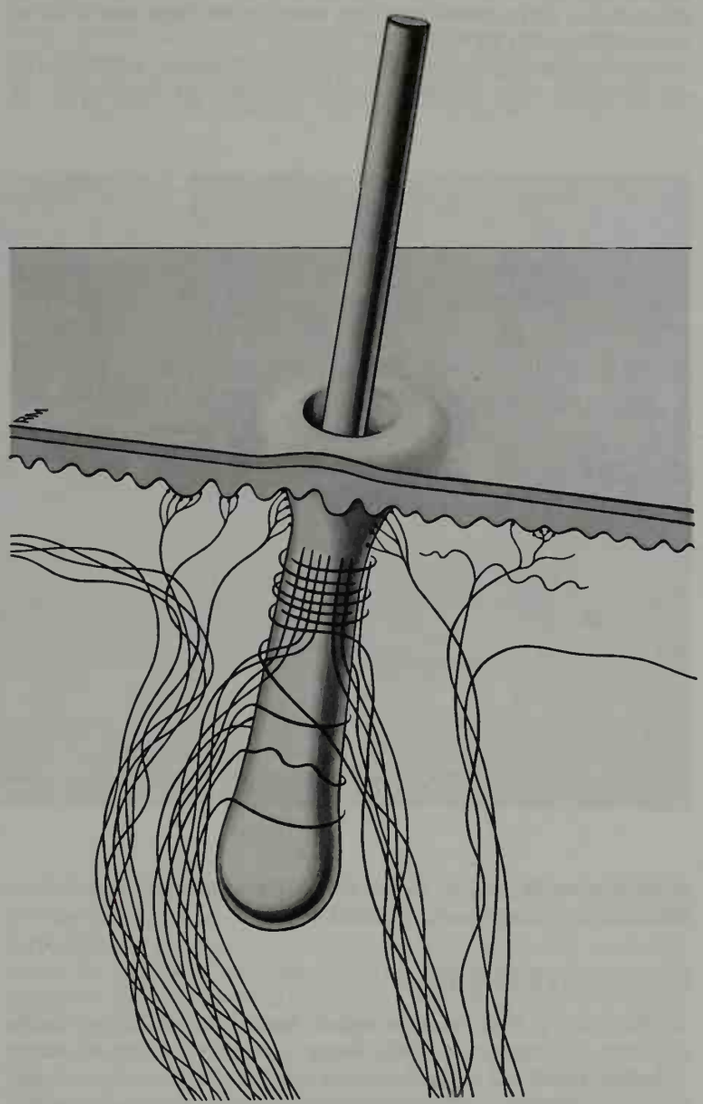
GENERAL CLASSIFICATION OF RECEPTORS

Receptors can be classified in various ways, for example, by the particular energy forms or '*modalities*' to which they are especially sensitive. We can therefore group them into *mechanoreceptors* which are particularly responsive to mechanical disturbances (touch, pressure, sound waves, etc.), *chemoreceptors* sensitive to chemical changes, *photoreceptors* responsive to electromagnetic waves in the visual frequency range, *thermoreceptors* which sense changes in temperature, *osmoreceptors* which react to changes in osmotic pressures (in contrast to chemoreceptors which are activated by specific chemical groups in their environment). Some receptors are selectively sensitive to more than one mode of stimulation (*polymodal receptors*), these usually being endings with high thresholds, responding to noxious or damaging stimuli, and associated with irritation or pain (*i.e.* they are *nociceptors*).

Another widely used (but rather arbitrary) classification divides receptors on the basis of their distribution and role in sensory activities of the body, into three main groups, namely *exteroceptors*, *proprioceptors* and *interoceptors*. Exteroceptors and proprioceptors are the receptor end-organs of the somatic afferent components of the nervous system and the interoceptors constitute the receptor end-organs of the visceral afferent components.

Exteroceptors respond to stimuli from the external environment and are placed at or close to the surface of the body (Sinclair 1967); they can be divided into the *general* or *cutaneous sense organs* and the *special sensory organs*. The general sensory organs include the non-encapsulated and encapsulated terminals in the skin and around hairs; the special sensory organs are olfactory, visual, acoustic, and taste receptors, which will be described elsewhere (p. 1138).

Proprioceptors respond to stimuli arising in the deeper tissues particularly in the locomotor system. They are concerned with movement, position and pressure, and include the neurotendinous organs of Golgi, the neuromuscular spindles, deeply placed Pacinian corpuscles and perhaps other endings such as those of joints, and the vestibular receptors in the membranous labyrinth. The proprioceptors are stimulated by the activity of the muscles, movements of joints and changes in the position of the body as a whole or its various parts, and are essential to the coordination of muscles, the grading of muscular contraction and the maintenance of its equilibrium.



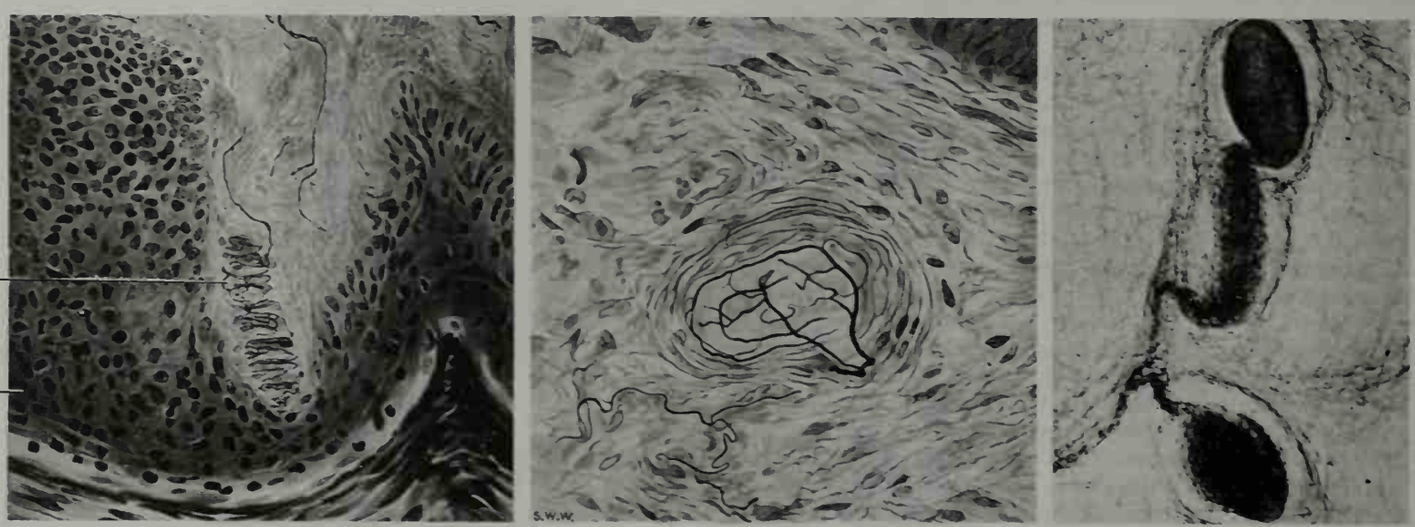
Interoceptors include the receptor end-organs in the walls of the viscera, glands, and blood vessels, (*see* e.g. p. 1136), where a variety of fibre terminations and end-organs including naked nerve endings, loops and encapsulated terminals, has been described. Nerve terminals are found in all layers of the visceral walls including the lining epithelium, and they are numerous in the adventitia of blood vessels, although the nature of many of these endings is open to doubt. Lamellated corpuscles have been described in the heart, adventitia of blood vessels, pancreas and mesenteries; free terminal arborizations are also present in many situations including the endocardium, loose connective tissue, the endomysium of all types of muscle, and connective tissue generally.

The nerve terminals in the viscera are not, in general, responsive to the same stimuli which act on the exteroceptors placed at the surface of the body and with certain exceptions do not respond to localized mechanical and thermal stimuli. However, tension produced by overstretching or excessive muscular contraction, often gives rise to visceral pain, particularly in pathological conditions, which is frequently poorly localized and of the deep-seated variety.

Amongst the interoceptors are included various vascular chemoreceptors and baroceptors (pressure receptors) the activity of which is important in the regulation of blood flow and pressure in the whole cardiovascular system, the control of respiration and other important aspects of homeostasis.

Irritant receptors responding polymodally to various noxious chemical or mechanical stimuli are also widely distributed in the epithelial linings of the alimentary and respiratory tracts where they may initiate protective reflexes.

It should be pointed out that this scheme of classification is in many cases arbitrary, since many types of end-organ are present in all three classes, and also their activities may be closely linked in the central nervous system. For convenience, therefore, the sensory terminals will be classified in the following description on the basis of their structural characteristics.



7.28B The innervation of a hair follicle; fine and coarse axons terminate around the intermediate and superficial regions, some branching in a circular direction, and others pursuing a longitudinal course. Nerve terminals associated with Merkel's cells are also shown surrounding the neck of the follicle.

STRUCTURAL CLASSIFICATION OF SENSORY ENDINGS

In addition to the foregoing division of receptors into broad functional categories, the general receptors have been grouped on morphological grounds (7.28 to 7.32). How much functional significance can be attached to some differences in detail in such a structural classification is debatable. Complicating factors

include changes in receptor ending morphology associated with ageing, regeneration, local topography and also species differences. The terminology is further confused, as there is no general agreement on the structural definition of many types of sensory ending. Accordingly, the scheme which will be outlined below is not exhaustive. Some receptor endings are limited to a particular tissue or combination of tissues; others are present in many situations in the body. Generally, however, we may distinguish between *free nerve endings* which form plexuses or are otherwise spread freely without any particular association with other cell types, *encapsulated endings* where specialized non-nervous cells completely invest the neural process with several or many layers, and *epidermis-associated endings*, where the sensory fibre is attached to, but not enclosed in, specific non-nervous cells or tissues (Bannister 1976).

Such specialized non-sensory cells are, of course, additional to the Schwann cells which normally ensheath all three types of sensory terminal except in the few instances mentioned below, although they may have a common origin.

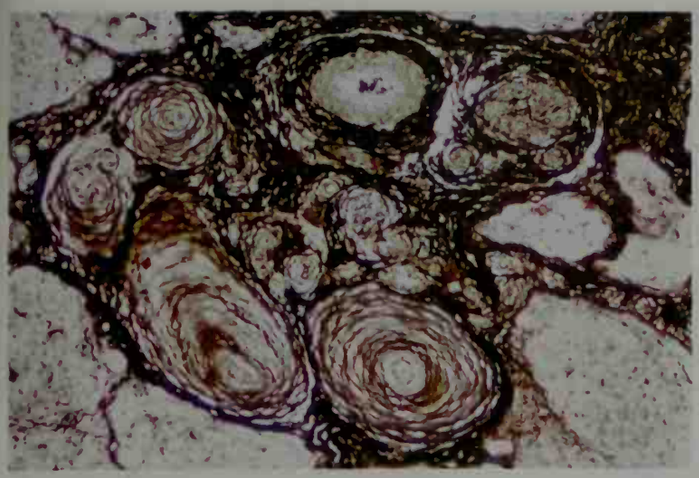
FREE NERVE ENDINGS

Sensory nerve fibre endings which branch repeatedly to form plexuses, or terminate with fewer branches, occur in many different sites of the body. Such free nerve endings are found in all types of connective tissue including the dermis, fascia, ligaments, tendons, sheaths of blood vessels, meninges, joint capsules, periosteum, perichondrium, Haversian systems of bone, and the endomysial spaces of all types of muscle. They also innervate the epithelium of the integument, cornea, buccal cavity, and the alimentary tract with its associated glands, although in the latter examples they are devoid of Schwann cell sheaths; they are enveloped instead by the cells of the epithelium and are not truly 'free' endings (Cauna 1966).



The afferent fibres from free terminals are both myelinated and non-myelinated, but are always of small diameter and low conduction speeds, being of the group III (Aδ) or IV (C) afferent types. Where the fibre is myelinated, terminal arborizations are non-myelinated and it is possible that they are devoid of Schwann cell sheaths altogether at their tips.

Electrical recordings from their afferent fibres show that such fine terminals subserve a number of different modalities. In the dermis, some of these narrow terminals belong to fibres responsive to moderate cold or heat (*thermoreceptors*), to light mechanical touch (low threshold, rapidly adapting *mechanoreceptors*), to damaging temperature changes or mechanical trauma (*unimodal nociceptors*) or to damaging stimuli of all kinds (*polymodal nociceptors*). Similar fibres in deeper tissues may also signal extreme conditions, experienced, as with all nociceptors, as pain. The free endings in some regions, e.g. those of the cornea, dentine and periosteum may be exclusively of the nociceptor type.

ENDINGS ASSOCIATED WITH EPIDERMAL STRUCTURES

Terminals on hairs arise from myelinated fibres derived from the deep dermal cutaneous plexus of nerves; their number, size and form are related to the size and type of hair follicle innervated (Cauna 1966). In *palisade endings* the fibres approach the hair follicle from different directions to reach it just below the duct of the sebaceous gland where they divide into branches which run parallel to the hair in the outer coat of the follicle (7.28B). Some of these fibres pass into the middle of the outer coat where they give rise to axon branches encircling the hair and terminating as free nerve endings amongst the collagen bundles. Others pass into the hyaline layer between the outer and inner coats and, after losing their myelin sheaths, break up into fine filaments which course in a series of parallel branches along the axis of the follicle, each fibre being ensheathed by two Schwann cell cuffs. The precise pattern of innervation depends upon the type of hair; in many mammals three forms of hair are found, the fine *down hairs*, coarser *guard hairs*, and *whiskers* or *vibrissae* which have erectile vascular tissue around their follicles and which are the most complex, with at least three types of nerve ending (*see* 7.28B). Human hair is probably of the first two of these types. The palisade hair endings respond mainly to rapid movements of the hair shaft when the hair is deformed mechanically, and belong to the rapidly-adapting mechanoreceptor group. (*See* also 7.29H.)

Merkel cell endings or *tactile menisci* are found immediately below the epidermis or around the apical ends of certain hair follicles (7.29F). The nerve fibre of these structures expands into a disc or flattened sole applied closely to the base of a specialized non-nervous cell (the *Merkel cell*) which is inserted into the base of the epithelium, and bears numerous protrusions in the form of spikes which interdigitate with surrounding cells. Such cells contain numerous large (50–100 nm) dense-cored vesicles which are congregated towards the junction with the nerve fibre. Often many such nerve-Merkel cell units are assembled at the base of a dome-like epidermal disc (the *touch dome*) supplied by a single branched nerve fibre, and are also frequently associated with specialized hairs (*tylotrichs*). Electrophysiology shows these endings to be slowly-adapting (Type I) mechanoreceptors

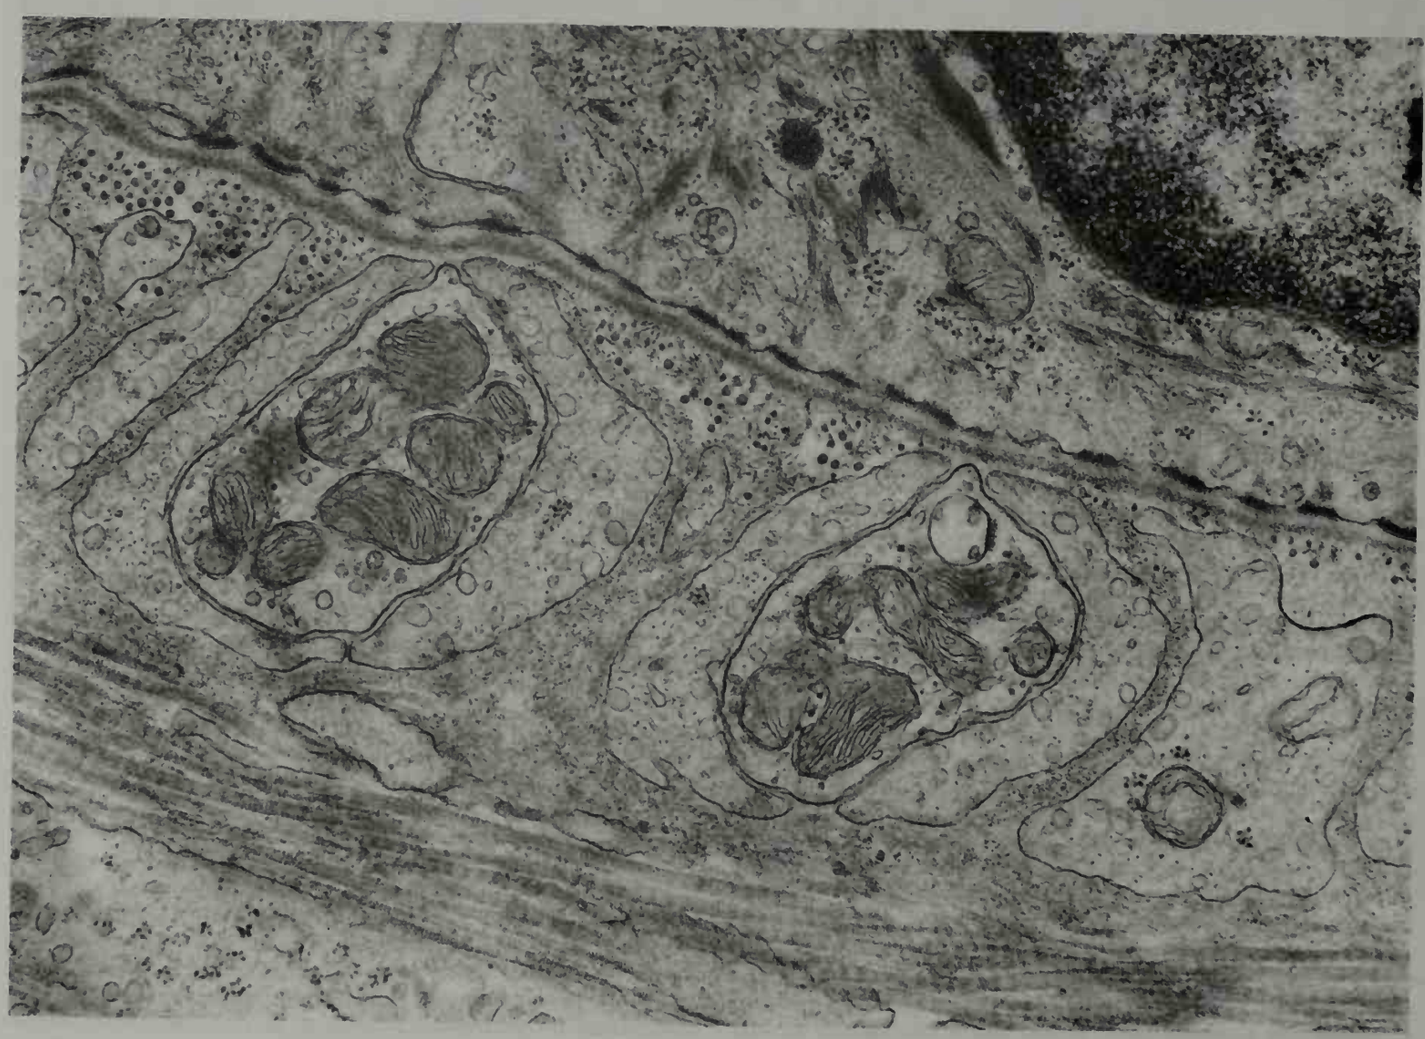
F

responsive to vertical pressure and served by large myelinated (Aα) afferents. The structure of the ending suggests some form of synaptic transmission, but all attempts to demonstrate this have so far been unsuccessful (*see* Iggo and Muir 1969; English 1978).



ENCAPSULATED NERVE ENDINGS

These are special end organs (or *corpuscular endings*) which exhibit great variety in size and shape, but have one feature in common, that is, the termination of the nerve is enveloped by a capsule. Included in this group are the lamellated corpuscles together with the neurotendinous endings, neuromuscular spindles, and Ruffini endings, all of which are well-defined morphological entities. Many other types of nerve endings have been described such as bulbous and hederiform corpuscles, articular corpuscles, genital corpuscles, and Golgi-Mazzoni endings, but there is considerable confusion as to their nature and function, contributed to by several factors, for example, technical difficulties, species and regional variations and age changes. (*See* 7.28, 29.)

The tactile corpuscles (of Meissner) are sited in the papillae of the skin of all parts of the hand and foot, in the front of the forearm and lips, palpebral conjunctiva and the mucous membrane of the tip of the tongue. They occur mainly in glabrous skin. Mature corpuscles are cylindrical in shape, orientated with their long axes perpendicular to the deep surface of the epidermis and about 80 μm long and 30μm broad. The corpuscle consists of a capsule and a central core (7.28A, 29A). The capsule is only loosely attached to the core of the corpuscle and is absent at the extremities. Light microscopists have maintained that the capsule consists of fine elastic fibres orientated along the long axis of the corpuscle and interspersed with fibrocytes and possibly other cell types. It has been claimed that the elastic fibres anchor the corpuscle to the epidermis (Quilliam 1966). Electron microscopy shows the capsule to be continuous with the perineurium of the nerves supplying the corpuscle and to consist of a variable number of lamellae of greatly flattened cells with their associated basement membranes. Between successive lamellae there is a substantial amount of collagen but no elastic fibres have been identified. Extensions of the capsule, often only one lamella in thickness, may form complete or incomplete septa dividing the corpuscle into lobules, particularly at the epidermal extremity. The core of the corpuscle consists of cells and nerve fibres. At the epidermal end the cells are described as discoid, lightly staining, transversely disposed and about 2–4 μm thick and 30–40 μm in diameter; these cells are claimed to be epidermal in origin. At the opposite end of the core the cells are irregular in shape with small oval or round nuclei devoid of nucleoli and with deeply staining chromatin. These are believed to be Schwann cells. In addition to Schwann cells, electron microscopy reveals occasional fibroblasts and collagen fibres, disposed in bundles or singly and mainly orientated parallel to the nerve fibres; the flattened apical cells have been studied in electron micrographs (7.29G). Each tactile corpuscle is supplied by a few heavily myelinated nerve fibres derived from the deep corial plexus and possibly also by additional non-myelinated fibres which are branches of myelinated fibres in the deep corial plexus. Within the corpuscle the nerve fibres ramify profusely and decrease in size; large numbers

G

H

of both myelinated and non-myelinated branches are visible in ultra-thin sections, the former being most numerous at the deep extremity of the corpuscle and the latter constituting the majority at the epidermal extremity (7.29G) and in the smaller lobules. In all cases the nerve fibres are associated with Schwann cells or their processes and no naked axons are present. Some of the non-myelinated fibres in the core of the corpuscle are less than 0·1 μm in diameter. The cytoplasm of the non-myelinated fibres may contain small vesicles but no special significance can be attached to them.

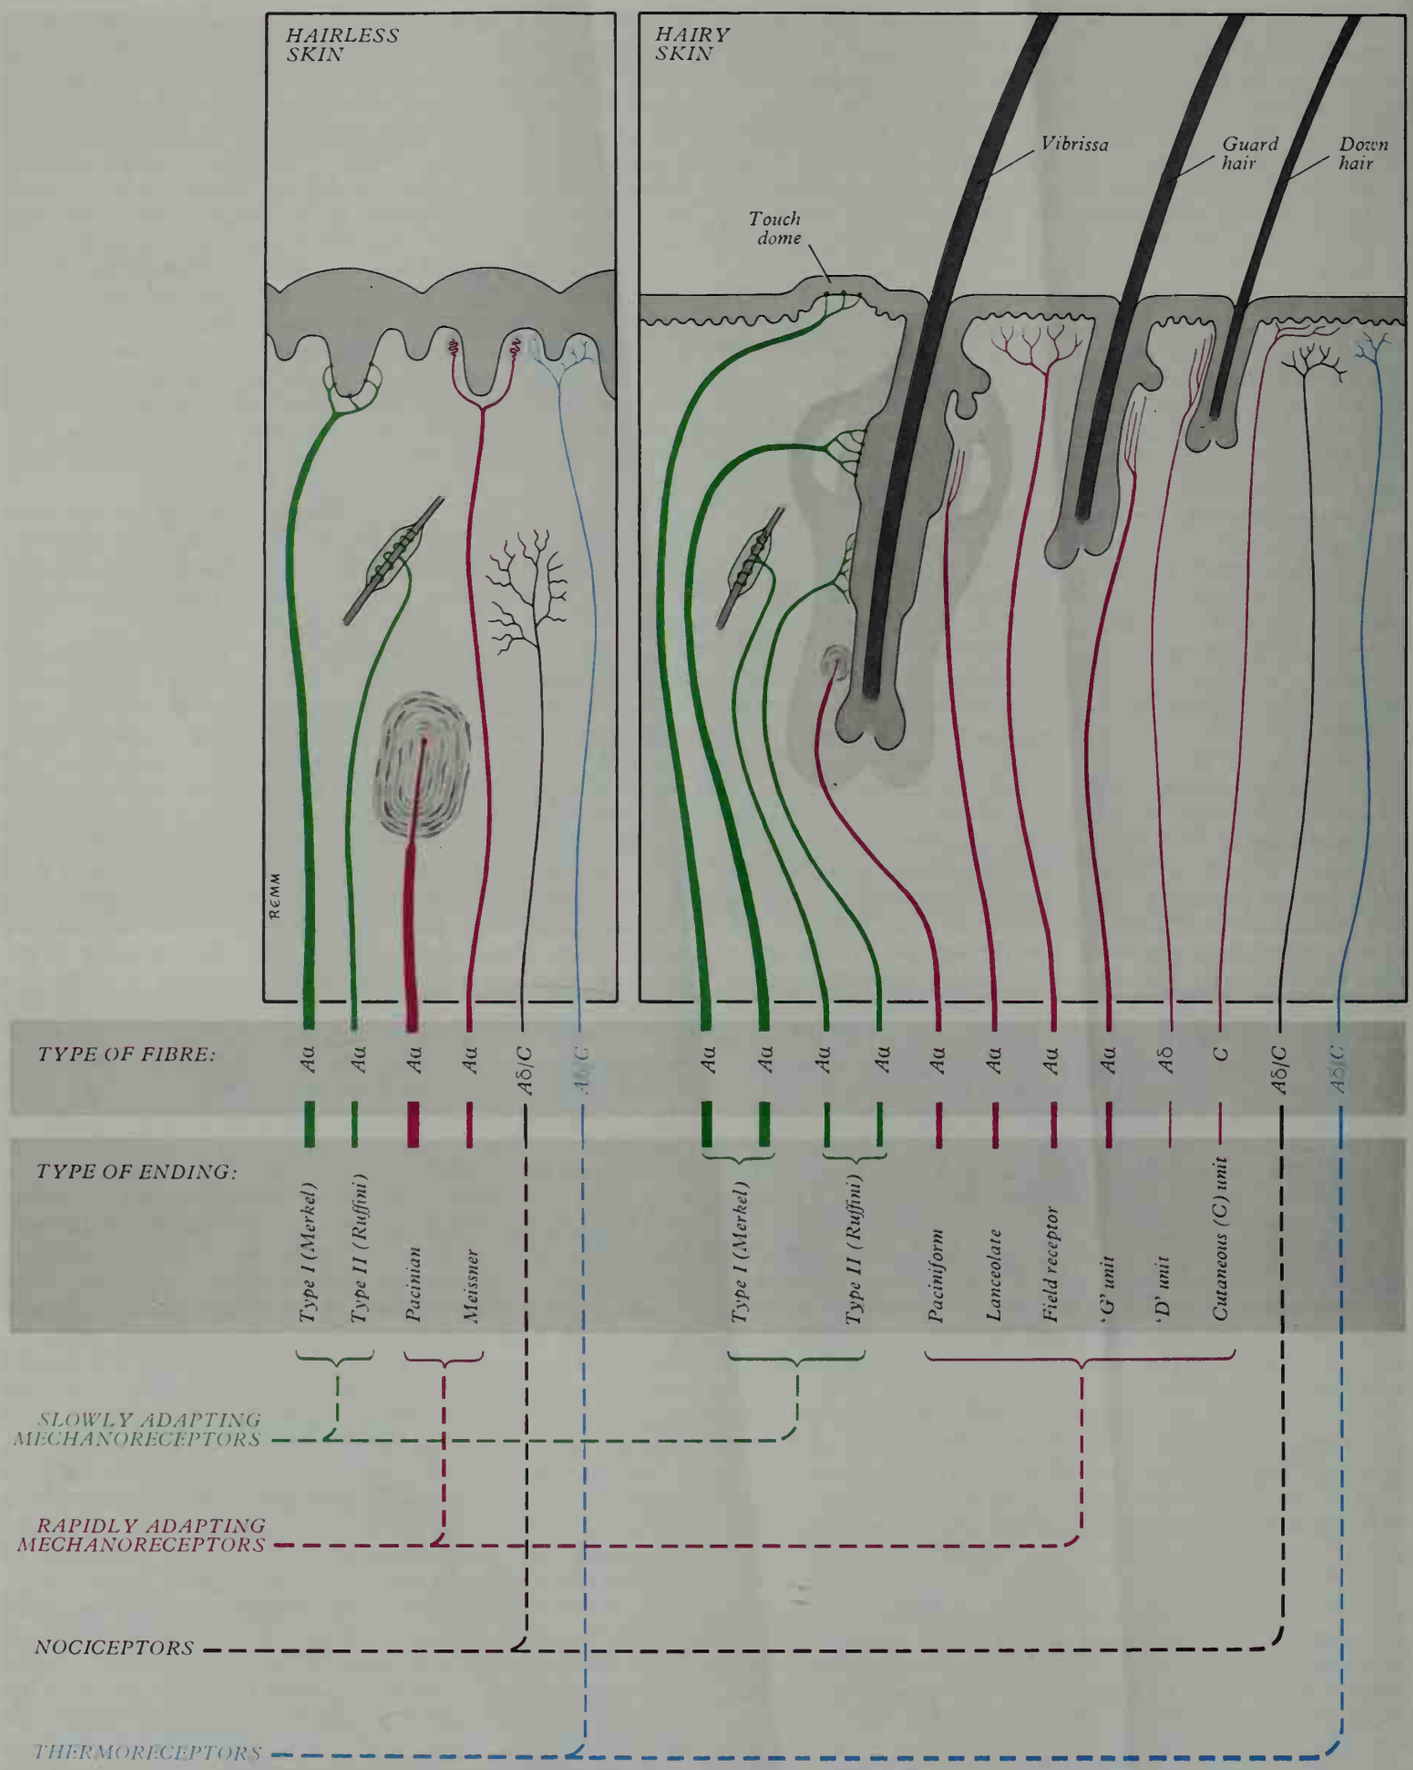
Tactile corpuscles develop just before or just after birth. There is a reduction of about 80 per cent in their numbers between birth and old age when the number of nerves supplying each corpuscle is also reduced and the nerve endings are confined to the deep end of the core. These endings function as low threshold, rapidly adapting mechanoreceptors, providing information about fluxes in mechanical forces acting on the volar surfaces of fingers, toes and other areas of glabrous skin (Valbo *et al.* 1979).

The lamellated (Pacinian) corpuscles of Vater-Pacini (7.28A, 7.29C, D, E, 7.30) are found subcutaneously in the palmar aspect of the hand and plantar aspect of the foot and their digits, in the genital organs of both sexes, the arm, neck, nipple, periostea, interosseous membranes of the forearm and leg, near joints and in the mesentery and pancreas of the cat. The corpuscles are oval in the fetus and oval, spherical or even irregularly coiled in the adult. They are relatively huge, being up to 2 mm in length and 100–500 μm across, the larger ones being visible to the naked eye. Each corpuscle consists of a capsule, an intermediate growth zone and a central core containing the nerve terminal. The capsule comprises about 30 concentrically arranged lamellae of flattened cells each about 0·2 μm thick. The neighbouring cells overlap at their edges and successive lamellae are separated by intervals containing some amorphous material and collagen fibres. The latter tend to be disposed circularly and to be closely applied to the surfaces of the lamellae, in particular to their outer surfaces. The amount of collagen increases with age. The intermediate zone is a cellular layer between the capsule and core. Occasional mitoses are seen in this zone and with growth of the corpuscle the cells are incorporated either into the capsule or the core, and the intermediate zone is not a conspicuous feature of the mature corpuscle. The core of the corpuscle consists of about 60 bilaterally arranged, closely packed lamellae, placed on both sides of the central nerve terminal and separated by two longitudinally running clefts. Nucleated cell bodies are situated in the outermost part of the core, at its junction with the intermediate zone. From these cells there arise cylindrical cytoplasmic arms which fold into the longitudinal clefts. Here they give rise to flattened sheet-like processes which pass to one or both sides to form the core lamellae and interdigitate with processes from other cytoplasmic arms. Adjacent lamellae do not arise from the same arm.

Each corpuscle is supplied by one or, rarely, two thick myelinated nerve fibres (A*α*) derived directly from peripheral nerves without the intervention of the corial plexus. The fibre first loses its myelin sheath and at its junction with the core the Schwann cell sheath terminates. The naked axon traverses the length of the central axis core, usually without division or branching and terminates in an expanded end bulb. It is in contact with the innermost core lamellae and is oval in transverse section, with the longer axis in the plane of the longitudinal clefts between the core lamellae. It contains numerous large mitochondria, the more superficial of which are usually arranged radially in palisade fashion beneath the axolemma. Minute vesicles of about 5 nm diameter are also present; these tend to be aggregated opposite the longitudinal clefts. The cells comprising both the capsule and core lamellae are believed to be modified fibroblasts and appear to be distinct from Schwann cells (Pearse and Quilliam 1957). Butyryl cholinesterase has been demonstrated in the core of the lamellated corpuscle. Lamellated corpuscles are said to be closely associated with glomeral arteriovenous anastomoses and to derive their blood supply from the capillaries accompanying the nerve fibre to the capsule at the site of entry. A condensation of the surrounding fibrous tissue forms an external capsule to the whole corpuscle.

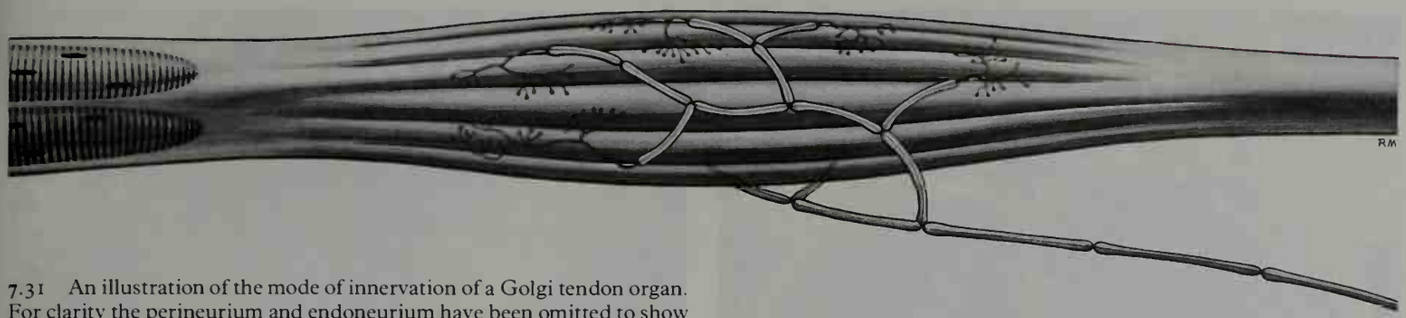
Lamellated corpuscles commence to develop in the third month of fetal life; the nerve terminal becomes surrounded by capsular lamellae which continue to be laid down into adult life, thus increasing the size of the corpuscle (Cauna and Mannan 1959).

Lamellated corpuscles are believed to possess considerable turgidity due to fluid pressure between the capsular lamellae. Extensive electrophysiological studies have shown this type of ending to be a very rapidly adapting mechanoreceptor, responding only to sudden mechanical disturbances and particularly sensitive to vibration (Loewenstein 1971; Gray and Sato 1973). It is thought that the extreme rapidity with which the ending adapts to stimuli is partly due to the lamellated capsule, which acts like a frequency 'filter', damping the effects of slow distortions by virtue of the fluid movements between the lamellar cells which only allow rapid movements to be transmitted to the central axon. If the capsule is removed, the selectivity of the response, although still quite rapidly adapting, is much less extreme.



Other lamellated endings include a wide variety of encapsulated receptor terminals, described in various species and different sites in the body. Since there are very few electrophysiological studies of such endings, it is difficult to establish whether they represent many distinctive categories or varieties of a few. However, the structures of some of them have been described in detail, and have been shown to possess a circumferential, concentric, lamellar pattern similar to that in the Pacinian endings, though perhaps less regular, and certainly much smaller. Amongst such terminals are the paciniform endings present in the connective tissue sheaths of vibrissae in cats and some other mammals (Gottschaldt *et al.* 1973), in joint capsules, and other connective tissue sites (*see* Polaĉèk and Halata 1970); other endings with a similar organization are the *end bulbs of Krause*, *bulbous corpuscles*, *genital corpuscles*, and probably the '*innominate corpuscles*' and *Golgi-Mazzoni endings* (*see* Bannister 1976).

Ruffini terminals (Type II slowly-adapting cutaneous mechanoreceptors) are found in the dermis of hairy skin, and each consists of the highly branched, unmyelinated endings of an A*α* (or II) myelinated afferent, enclosing and invading a bundle of collagen fibres and enclosed in a cellular capsule (Chambers *et al.* 1972). Although less tightly organized, the structure has many characteristics in common with the neurotendinous ending of Golgi (*vide infra*), and appears to be somewhat similar electrophysiologically, being responsive to stresses set up in the dermal collagen. Similar structures appear to be present in joint capsules.



Neurotendinous endings of Golgi (Golgi tendon organs) are chiefly sited near the junctions of tendons and muscles (7.31). Each is about 500 μm long and 100 μm in diameter and consists of small bundles of tendon fibres enclosed in a delicate capsule. The tendon fibres (*intrafusal fasciculi*) are less compact than those elsewhere in the tendon, the collagen fibres are smaller and the associated tendon cells are larger and more numerous. The sheath or capsule consists of concentric sheets of cytoplasm, each about 100–300 nm thick, belonging to capsular cells. Within each layer the capsular cells are closely opposed and successive layers are

7.29G Ultrastructure, near the apex, of a tactile corpuscle of Meissner in vertical section, showing flattened lemmal cells arranged horizontally, with their nuclei to the right of the field. The sectional profiles of the terminal nerve fibres, appearing between the lemmal cells, contain numerous dense mitochondria. (Magnification about × 5000.)

7.29H Ultrastructure of terminal nerve fibres in close association with a hair follicle in the auricle of a rat. Note, above, part of the nucleus and cytoplasm of a keratinocyte; the plasma membrane adjoins a well-defined basal lamina, and presents a series of hemidesmosomes. The two nerve fibres contain numerous mitochondria and are enveloped by Schwann cell processes. Surrounding the latter are basal laminae, reticulin fibres (above) and collagen fibres (below). Magnification × 35,000. (G and H respectively from Ciba Foundation Symposium on *Touch, Heat and Pain*, 1966, and *J. comp. Neurol.*, **136**, 1969, by kind permission of Prof. N. Cauna and the publishers, J. & A. Churchill and the Wistar Press.)

7.30 A schematic survey of the major types of mammalian cutaneous sensory endings and their afferent fibres. The endings are depicted symbolically according to their structural features, and their mode of response to specific types of stimulus are indicated by colour coding, i.e. slowly-adapting mechanoreceptors, green; rapidly-adapting mechanoreceptors, red; nociceptors, black; thermoreceptors, blue. The class of afferent fibre is labelled according to the classification of Erlanger and Gasser referring to relative conduction velocities and fibre diameter (see text and accompanying table). The endings typical of hairless skin are shown on the left, and those of hairy skin on the right.

7.31 An illustration of the mode of innervation of a Golgi tendon organ. For clarity the perineurium and endoneurium have been omitted to show the distribution of nerve terminals which ramify amongst the collagen fibres of the tendon.

separated by intervals of varying width containing basal laminae. Numerous minute endocytic vesicles are present, suggesting that the capsular cells may be concerned with the maintenance of the internal environment of the ending. Outside the capsule is a thin layer of collagen fibres. One or more heavily myelinated group I*b* nerve fibres pierce the capsule and divide in a spray-like manner. The ramifications, which may lose their Schwann cell sheaths, terminate in leaf- or clasp-like enlargements, rich in small vesicles and mitochondria, which are wrapped around the tendon fasciculi with the basal lamina or Schwann cell cytoplasm intervening (Schoultze and Swett 1972, 1974).

The endings are highly active when tendons are stretched either actively or passively, and initiate myotactic reflexes which inhibit the development of excessive tensions during muscular contraction. Their responses are of the slowly adapting type, signalling maintained tension particularly well (*see* Matthews 1973). Structural and physiological evidence indicates that these sensory endings may be deformed by the surrounding collagen fibres which tend to lie more parallel and closer together as tension develops in the tendon.

Neuromuscular spindles are, somewhat arbitrarily, treated below under: Special configurations of sensory endings—p.858.

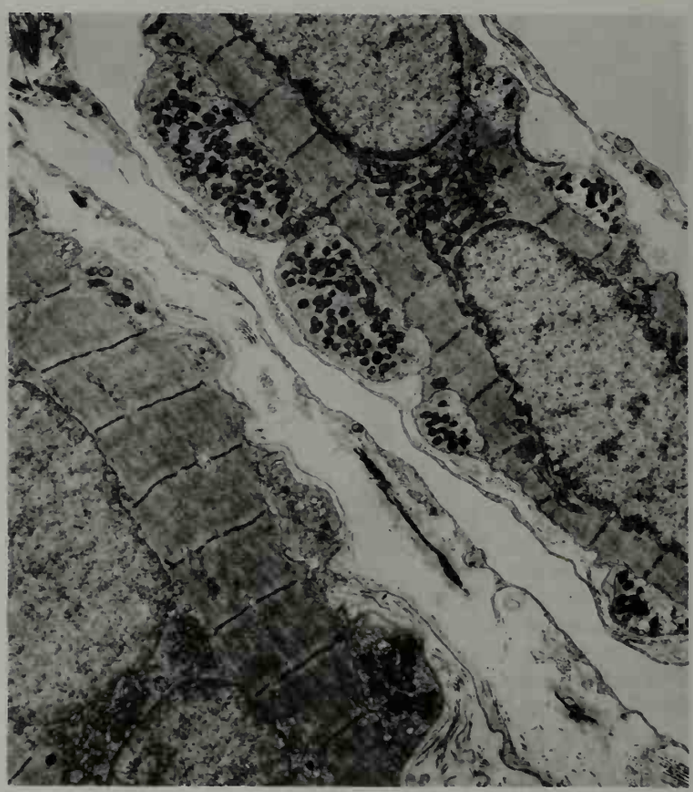
Special Configurations of Sensory Endings

The different varieties of sensory endings have now been discussed individually. Physiologically, however, it is necessary to consider *arrays* of several types of ending, which act in concert, to provide information about the forces and influences acting at a particular locality, to be analysed together in the central nervous system. Although our knowledge of such multiple patterns is as yet only partial, at least three situations have been explored in some detail. These are cutaneous and joint receptors, and neuromuscular spindles.

CUTANEOUS ARRAYS

The skin is a major sensory organ, containing the receptor endings of multitudes of sensory nerve fibres which report on the mechanical and thermal state of the body surface, including the presence of noxious or damaging stimuli. The way in which this array of sensory endings is able to discriminate between different types of stimulus has been a matter of constant debate; in the second half of the last century and the first half of the present one it was widely supposed that the different types of end-organ made visible by the current histological methods corresponded to specific sensory modalities, e.g. touch, pressure, and cold, although conclusive physiological evidence was lacking. However, in the 1950s it was pointed out that various areas of the body which are sensitive to different stimuli lacked complex end-organs (e.g. Weddell, Palmer and Pallie 1955). It was then suggested that each sensory ending might be responsive to a range of stimuli, and that small differences in the optimum sensitivities of a large number of fibres would be detectable as a pattern of activity by the central nervous system, each pattern being characteristic for each stimulus category (*see* Sinclair 1967).

Although this idea has considerable attractions, subsequent work with improved electrophysiological and electron microscopic techniques has reinstated the concept of a wide range of specific nerve endings each highly sensitive to a particular type of stimulus (*see* e.g. the reviews by Brown 1973; Burgess and Perl 1973; Iggo 1978), although these are not always separable by their structural features. Although the types of ending fall into three major categories, that is mechanoreceptors, thermoreceptors and nociceptors (responding to potentially or actually damaging stimuli), several subdivisions of these have also been discovered (*see* 7.30). Thus within the mechanoreceptors are rapidly adapting endings which respond only, or chiefly, to *changes* in mechanical stimulation, and slowly adapting endings which report on steady deformations of the skin. Examples of the first class are the palisade endings close to the follicles of hairs, Pacinian endings in the subcutaneous tissues, and Meissner or 'field' endings adjacent to the epithelium; the second class of receptors includes 'Type I' slowly adapting cutaneous mechanoreceptors, or Merkel endings which are generally associated with thickened patches of epidermis ('touch domes') giving information concerning steady pressures operating perpendicularly to the skin surface, and the 'Type II' slowly adapting cutaneous mechanoreceptors sensitive to steady stresses in the dermis. Another rather different type of mechanoreceptor is the ending of a class of fine non-myelinated fibres which have a low threshold but require prolonged stimulation.



Thermoreceptor fibres with branched 'free' endings can be separated into those which increase their firing frequency on warming and those which are more active on cooling ('warm' and 'cold' fibres, respectively, supplying restricted areas of the skin corresponding to the 'warm' and 'cold' spots first described by Blix in 1882).

Nociceptor fibres have rather similar free endings, responding to various types of damaging stimulus signalled centrally as pain, discomfort or irritation of the skin. Some fibres only respond to extreme cold, others to extreme heat or gross mechanical insult; yet others are stimulated by combinations of noxious agents. Often such fibres may also be activated by the release of inflammatory substances in the tissues through which they pass, giving the experience of prolonged pain or itching (Iggo 1974).

The precise form of the sensory endings varies depending upon their location at the body surface, and indeed with the species of mammal studied, so that in man and other primates the special skin of the hairless areas of the volar and plantar surfaces of the hands and feet has a different pattern of endings from the rest of the body. Likewise the density of endings and therefore of the fineness of discrimination varies. In general, however, we can distinguish similar arrays of sensory ending in each, ranging from the complex encapsulated or tissue-associated endings of large diameter myelinated nerve fibres capable of carrying rapid information about mechanical stimuli of various kinds, to the free endings of fine myelinated or non-myelinated fibres conveying, more slowly, signals of thermal or damaging effects or of light mechanical stimulation. The entire complex clearly provides a

B An electron micrograph of a longitudinal section through two intrafusal muscle fibres from a neuromuscular spindle of a rat. Note the primary (annulospiral) afferent nerve fibre endings cut in cross-section as they spiral around the equatorial region of a nuclear chain fibre (top right) and of a nuclear bag fibre (lower left). Note also the large numbers of mitochondria present in the sensory fibres. See text for further description. (A and B were kindly provided by Dr. D. N. Landon, National Hospital for Nervous Diseases, London.)

wealth of data about the state of the body surface, to be further analysed by the central nervous system.

JOINT RECEPTORS

The arrays of sensory endings placed within and around the articular capsules of synovial joints are of great importance in providing information about the position, movements and stresses acting on these structures (Wyke 1967). Both structural and physiological studies have shown that there are at least four classes of receptor terminals present, the proportion of each varying with the topographical position of the joint. Three of these classes comprise encapsulated endings and the fourth free terminal arborizations. Wyke has named these terminals types I to IV, and this classification will be followed here.

Type I endings are encapsulated spray terminals of the Ruffini type (*vide supra*) present in the superficial layers of the fibrous capsule in small clusters, supplied by myelinated afferent fibres of the group II category. Physiologically they are slow-adapting receptors, giving conscious awareness of joint position and joint movement, responding, it is thought, to patterns of stress in the articular capsule (Skoglund 1973). This type of ending is particularly common in articulations such as the hip joint, where static positional sense is of importance in the control of posture.

Type II endings are lamellated (Paciniform) receptors, similar to, but smaller than, Pacinian receptors found elsewhere in connective tissue. They are present in small groups throughout the joint capsule but particularly in the deeper layers and also, in the temperomandibular joint, in the posterior articular fat pads. They are rapidly adapting, low-threshold receptor endings, highly sensitive to movement and to pressure change, responding to joint movement and transient stresses in the capsule. They are supplied by group II or III myelinated afferent fibres; but they are not considered to be associated with conscious awareness of joint sensation.

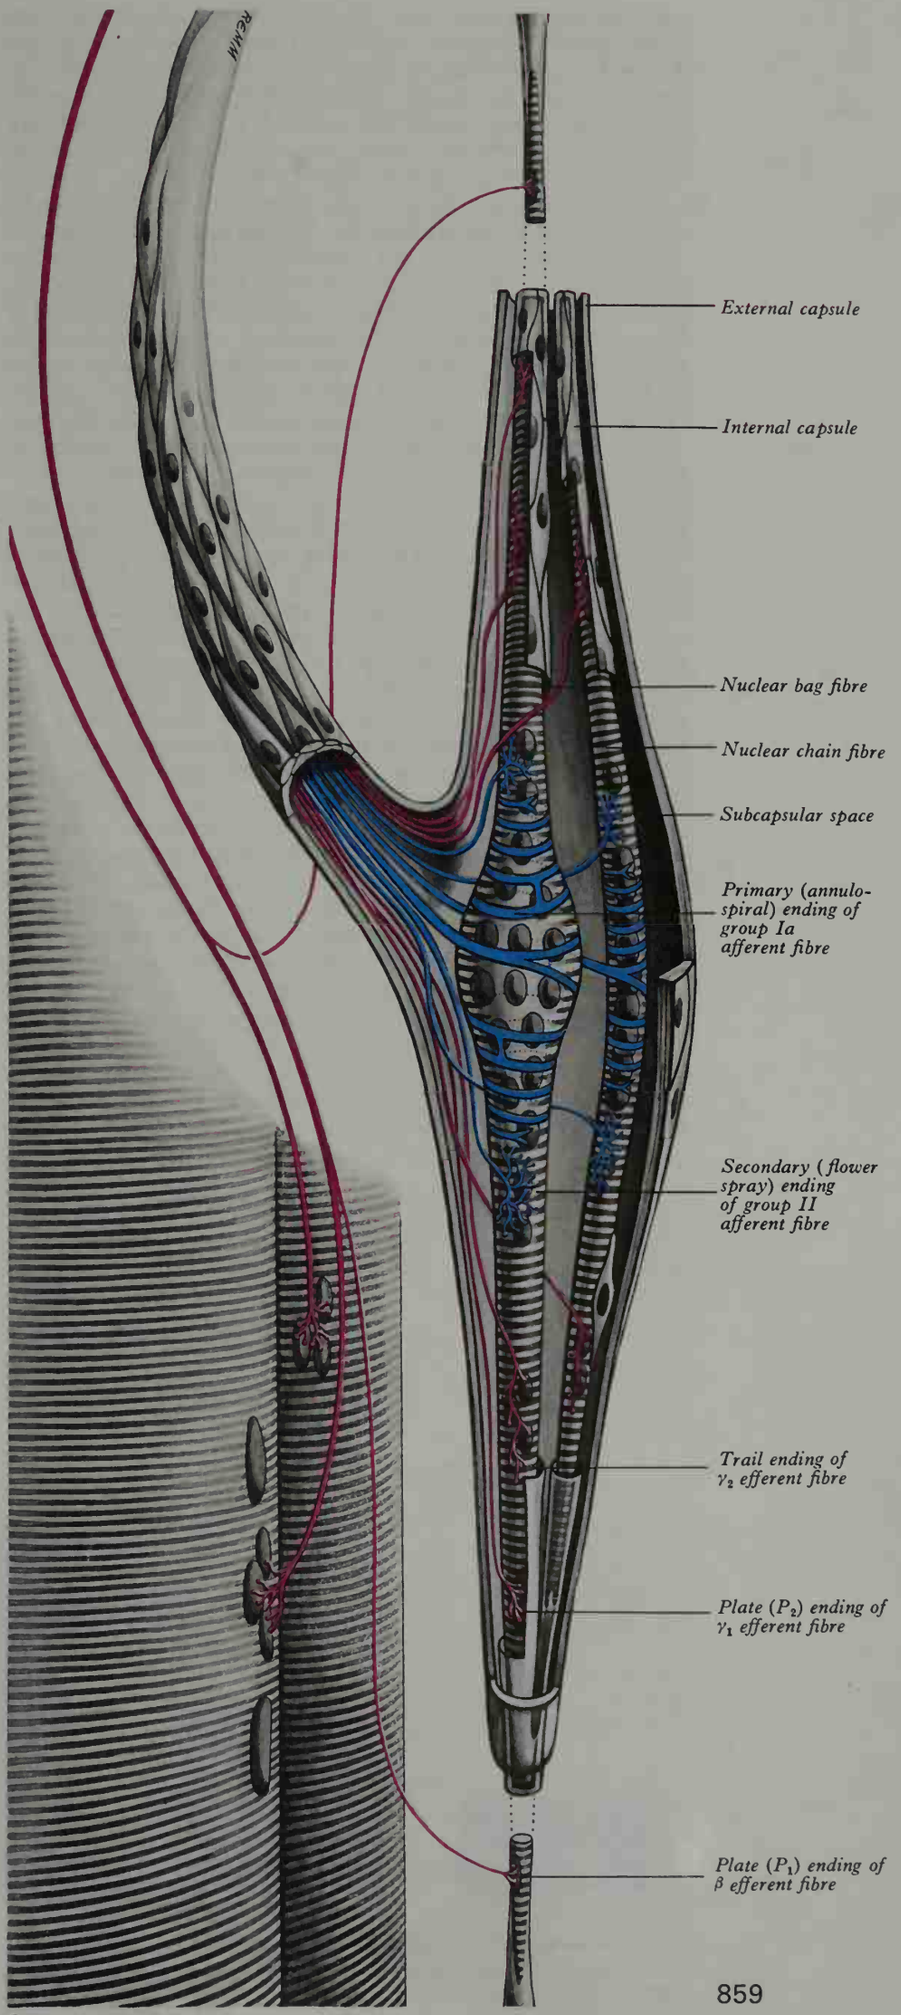
Type III endings are identical to Golgi tendon organs in structure and physiology (p. 855), being present in the specialized ligaments of joints, though not in their capsules. They are high-threshold, slowly adapting receptors which apparently serve to prevent excessive stresses being developed at joints by the reflex inhibition of the adjacent muscular activity. Their innervation is from the large myelinated group Ib afferent nerve fibres.

Type IV endings are free, unencapsulated terminals of group III myelinated fibres and type IV non-myelinated fibres which ramify within the capsule, the adjacent fat pads, and around blood vessels particularly of the synovial layer. These are also high-threshold, slowly adapting endings which are thought to sense excessive joint movements and also provide a basis for the signalling of joint pain.

NEUROMUSCULAR SPINDLES

The *muscle* or *neuromuscular spindles* form an important sensory element in the control of muscle contraction, and as might be expected from the complicated nature of this control, the detailed structure and behaviour of spindles are also complex and not entirely understood. The precise anatomy of spindles varies greatly in submammalian species, and hence the present account applies only to mammals (Bowden 1966; Landon 1966; Matthews 1971; Barker 1974).

Basically, each spindle consists of a few, small, specialized *intrafusal muscle fibres*, which are innervated by both sensory and motor nerve endings (7.32A–C). This complex is surrounded in the equatorial region of the intrafusal fibres by an expanded *spindle capsule* formed of connective tissue, divisible into an *outer sheath* of flattened fibroblasts and collagen similar to those of the perineurium (p. 839), and also elements of an *inner axial sheath* (of Sherrington) which form delicate tubes around the individual intrafusal muscle fibres. The space between internal and external sheaths is occupied by fluid which is rich in hyaluronic acid.



The intrafusal fibres number from six to fourteen, varying from one muscle to another, and also with species. Two distinct types of fibre are present in most mammalian spindles, the *nuclear bag* and *nuclear chain fibres*, distinguishable by the arrangement of nuclei within the sarcoplasm in the equatorial region of the spindle. In nuclear bag fibres the equatorial nuclei are gathered together in a cluster to give a slight expansion of the fibre profile, whereas in the nuclear chain type the nuclei form a single longitudinal row in the centre of the fibre. The nuclear bag fibres are greater in diameter and much longer, extending beyond the capsule to attach to the endomysium of the surrounding extrafusal muscle fibres; the nuclear chain fibres are attached at their poles to the capsule or to the sheaths of the nuclear bag fibres.

The contractile apparatus of the intrafusal fibres is similar to that of extrafusal ones except that the zone of myofibrils is rather thin at the equator where they ensheath the nuclei. Ultrastructurally, the nuclear bag fibres are similar to 'slow' extrafusal fibres of amphibians, lacking the M lines, possessing little sarcoplasmic reticulum, but containing abundant mitochondria and oxidative enzymes: nuclear chain fibres are more like immature 'fast' twitch muscles of mammals, containing M lines, well-formed sarcoplasmic reticulum and T-tube elements, fewer mitochondria and lower oxidative enzyme levels. There is also evidence, of a histochemical and ultrastructural nature, of subtypes of muscle fibre in at least some species (Banks *et al.* 1975), termed 'second bag' or 'intermediate' intrafusal muscle fibres; this indicates that the organization of spindle fibres is even more complex than originally thought, and may provide even more subtle information concerning muscle activity. Nuclear bag fibres, when stimulated, contract more slowly than the nuclear chain type, supporting the ultrastructural findings.

Sensory innervation of muscle spindles is of two types, both of which are the non-myelinated terminal branches of two distinct classes of myelinated somatic sensory nerve fibres. The *primary* or *annulospiral* endings are placed centrally at the equator, and form spiral and sometimes annular terminals enwrapping the nuclear bag or chain portions of the intrafusal muscle fibre. A single large myelinated sensory fibre (group Ia), branches to provide the innervations of a number of intrafusal fibres in this way. Ultrastructurally, each terminal runs in a deep groove in the sarcolemma beneath the basement membrane, and it contains numerous mitochondria, vesicles, microfilaments, microtubules, and a pervading flocculent material. The *secondary* or *flower-spray* endings, which are largely confined to nuclear chain fibres, are branched terminals of slightly narrower myelinated group II afferents; these endings are beaded in appearance and spread in a narrow band on both sides of the primary endings near the equator. These beads, ultrastructurally, are expansions similar in content to the primary endings, and they lie in close apposition to the sarcolemma, although not in grooves. Electrophysiological studies have shown the primary endings to be relatively rapidly adapting whereas the secondary endings have a strongly regular, slowly adapting response to static stretch (*see* Matthews 1972; Hunt 1974).

Motor Endings in Muscle Spindles

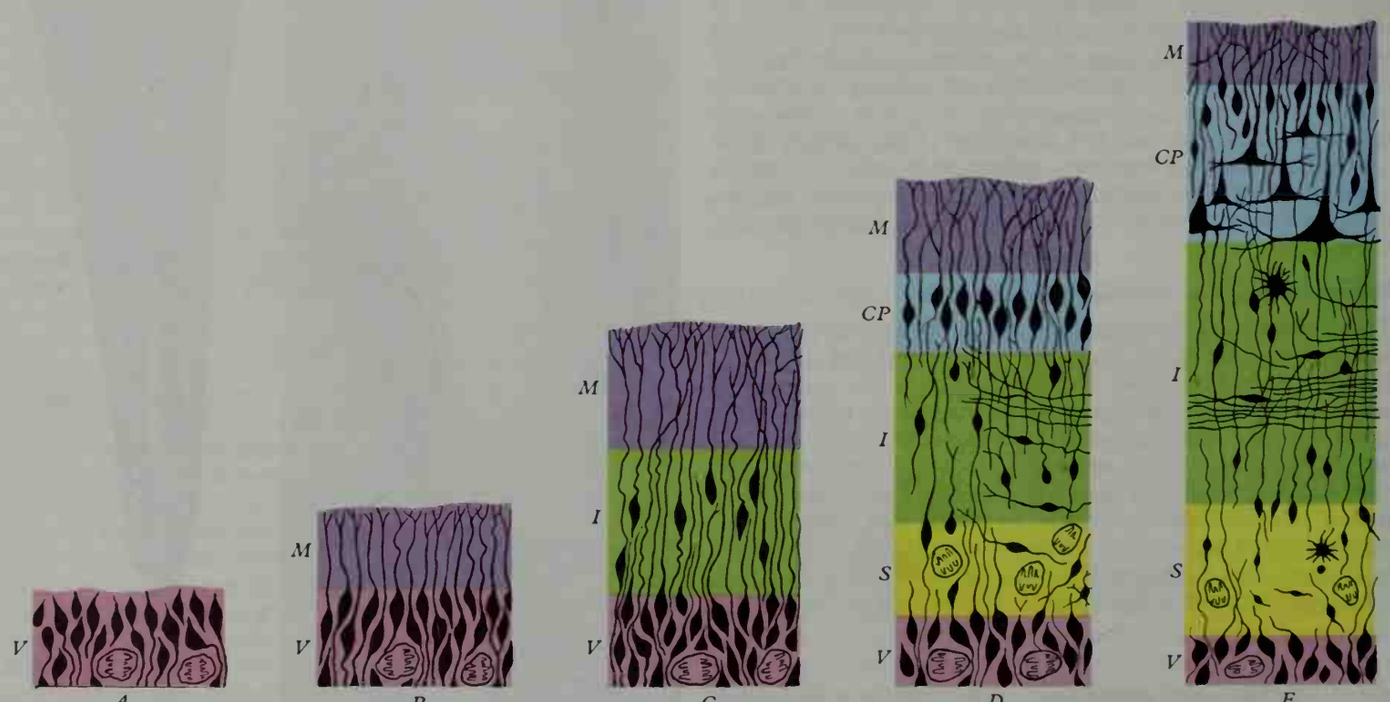
Three types of motor terminals have been distinguished, two being the endings of fine fusimotor (γ-) efferents and one of a β-efferent nerve fibre. The first two comprise the *trail ending* nearest to the equatorial region, ramifying to form unspecialized cholinergic motor terminals with no obvious end plate or sole, and further pole-wards the P_2 *ending*, with a typical 'en plaque' end plate and sole. At the extreme ends of nuclear bag fibres is the P_1 ending, likewise forming a typical 'en grappe' end plate (p. 514), whose efferent nerve fibre arises as a collateral branch of a myelinated fibre supplying the extrafusal slow twitch muscle in the neighbourhood of the spindle. Stimulation of the efferent

7.32C Schematic three-dimensional reconstruction of a mammalian neuromuscular spindle, showing nuclear bag, and nuclear chain fibres; these are innervated by the sensory annulo-spiral and 'flower-spray' terminals (blue) and by the γ and β fusimotor terminals (red). For further details consult text.

endings causes contraction of intrafusal fibres and corresponding activation of their sensory endings. There is some evidence that bag and chain fibres are stimulated to contract in rather different ways, and their fusimotor endings reflect this difference in the characteristic excitation of the two types of fibre. However, this duality is not entirely distinct, and further evidence of the functions of the bag and chain fibre is awaited.

The activities of the spindle appear to provide information on the length of the extrafusal muscle, its velocity of contraction, and changes in velocity, and it is thought that these modalities are related to the different behaviours of the two types of intrafusal fibres when stretched, either actively by their motor endings, or passively by stretching of the extrafusal muscle surrounding them. It is probable that because of the composition of sarcoplasm in the equatorial nuclear zone of the intrafusal fibres a passive stretch causes greater elongation in that region than in the fibres on each side where the myofibrils are more numerous, causing the response to deformation in the primary sensory endings to be different from that of the secondary endings which are placed further pole-wards. The equatorial region of nuclear bag fibres will also stretch more than that of the nuclear chain types because of the lower viscosity of the former, giving differential responses from the two. From physiological studies it is thought that *nuclear bag fibres* are concerned with *position*, *velocity*, and *acceleration* responses of a rapidly adapting, *dynamic* (phasic) nature, and the *nuclear chain fibres* with static, slow adapting ones (the *static response*). The fusimotor fibre can adjust the length of the intrafusal fibre, and therefore the activity of its sensory fibres by causing the polar regions to contract. This can compensate for shortening of the extrafusal fibres during normal muscle activity, or, as was formerly suggested, could be the normal means of causing extrafusal fibres to contract, these being stimulated by the intrafusal muscle. It was at one time envisaged that the γ fusimotor fibres, by causing contraction in the intrafusal fibres, could stimulate the sensory endings, which would then initiate contraction in the extrafusal muscle by reflex excitation of α-motor neurons (Granit 1970; Boyd 1962). More recent evidence, however, indicates that activity in the α-motor neurons may, in some cases of voluntary movement, precede that in γ-motor neurons during muscle contraction, so that the spindle probably monitors the *extent* of muscle contraction allowing *comparisons* to be made between *intended* and *actual movements* (Matthews 1971; Valbo 1974). It should be noted that although spindles have generally been considered to play no role in the conscious appreciation of limb position, this role being subserved by tendon, ligament and articular nerve endings, there is mounting evidence that spindles do indeed play a part in our awareness of muscle and limb movements and that spindle receptor activity is represented in the sensory cortex (Matthews 1977).

Development of neuromuscular spindles has been studied in detail by various investigators (*see* Zelená 1957; Landon 1972; Milburn 1973). The intrafusal fibres form by fusion of myoblasts in the usual manner, and the primary sensory endings are well established (in rodents) before birth, followed by the formation of fusimotor terminals, secondary sensory fibres, and the development of the capsular space. The early development of the spindle is absolutely dependent on the formation of the primary sensory ending (Zelená 1957), but later, spindles may survive denervation, although they may undergo marked changes even if crushed nerves are allowed to re-innervate them (Schiaffino and Pierobon Bormioli 1976).



The Natural History of Neurons

The structure of mature neurons considered in the previous paragraphs covers only a limited aspect of the total biology of these cells. Their mature structure must be considered in the context of the development, maturation, reactions to morphogenetic and pathological influences, senescence, and final death of these cells.

ORIGIN AND DEVELOPMENT OF NEURONS

Neurons originate from two main embryonic regions. Central nervous neurons stem from the neural plate and tube, whilst those of the cerebrospinal and autonomic ganglia arise from the neural crest (p. 161). The neural plate also gives rise to the ependymal and macroglial cells, whilst the neural crest produces the Schwann cells of the peripheral nervous system, and to the chromaffin cells of the suprarenal medulla.

The development of the cells of the central nervous system has attracted much attention since the first detailed descriptions by His (p. 157), and many conceptual schemes have been advanced to

7.32D Schema of five sequential stages (*A to E*) in the development of part of the neural tube's wall in section, to form cerebral cortex. (Modified from: Boulder Committee recommendations, *Anat. Rec.*, **166**, 1970.) Abbreviations: *V*—ventricular zone; *M*—marginal zone; *I*—intermediate zone; *S*—subventricular zone; *CP*—cortical plate. See accompanying text and also pp. 157 *et seq.*, for details.

explain the complex series of changes involved. Recently many of the difficulties of interpretation have been resolved by the use of autoradiographic methods, which demonstrate the origin and subsequent fate of the various cell types involved in the development of the nervous system.

In the central nervous system, the earliest observers considered the wall of the neural tube to be divided into ependymal, mantle and marginal zones (p. 157). This was later modified to include the concept of a matrix cell layer (p. 157). More recently (Sidman 1970), however, the latter has been further diversified into a fourfold division of the wall of the early neural tube, into *ventricular*, *subventricular*, *intermediate* and *marginal* zones (7.32D).

As described previously (pp. 157 *et seq.*), the neural plate and early neural tube consists of a single layer of pluripotent epithelial stem cells which give rise to all the cell types of the central nervous system except the microglia. The nuclei of these stem cells are situated near the ventricular surface in the *ventricular zone* of the tube, with an anuclear cytoplasmic marginal zone consisting of the laterally extending 'tails' of the cells. As these cells undergo mitotic division they change shape, contracting during the act of mitosis so that the nucleus moves first towards, and then subsequently away from the ventricular surface within the ventricular zone. Since the mitoses do not occur synchronously the nuclei appear at varying levels on histological section. Later, some of the progeny of these cell divisions cease mitosis permanently, and move deep to the ventricular zone to form an *intermediate* (mantle) *zone* where they differentiate into neuroblasts. Others, however, form a *sub-ventricular zone* between the ventricular and intermediate zones, where they continue to multiply, giving rise to further generations of neuroblasts and, later, glioblasts. Both of these cell types subsequently migrate into the intermediate and marginal zones. However, in particular regions (e.g. the cerebellar cortex, *see* p. 919), some of these mitotic subventricular stem cells migrate across the wall of the neural tube to assume a sub-pial position, where they establish a new zone of cell division and differentiation. Many of the cells formed remain in this sub-surface position, but others migrate, yet again, through the developing nervous tissue to their various deeply-placed definitive positions where final differentiation into neurons and macroglia occurs.

During the genesis of these various cell types, neuroblasts are the first to be formed, followed later by glioblasts. The timing of these events differs in the various parts of the central nervous system and also varies between species. The majority of neuroblasts are formed before birth in mammals, although a number of examples of postnatal neurogenesis are also known, namely, the granule cells of the cerebellar cortex, olfactory bulb, and hippocampus. In contrast gliogenesis continues after birth both near the ventricular surface and in other more deeply placed regions.

Autoradiographic studies have shown that particular classes of neurons develop at specific times. Usually large neurons differentiate before small ones; however, the subsequent pattern of migration appears to be independent of the time of initial formation. For example, the cerebellar Purkinje cells form before the main body of granule cells, which arise in the sub-pial zone and later migrate towards the ventricle via the zone of maturing larger neurons. Other studies have shown that neurons can migrate for considerable distances through populations of maturing, relatively static cells, before arriving at their final destination. It is considered that the early migration and differentiation of neurons is determined by intrinsic factors, or factors in their immediate vicinity, since at this stage they have no afferent connexions which might determine their paths of migration. Later, however, the final form of their neurites, cell volume, and indeed the continuance of the cell itself, depends upon the establishment of the correct patterns of connexion with other neurons. (*See* also pp. 802–816.)

STRUCTURE OF DEVELOPING NEURONS

Initially the neuroblast is a rotund or fusiform cell, the cytoplasm of which bears a prominent Golgi apparatus, many lysosomes, glycogen deposits and numerous unattached ribosomes (Tennyson 1969). As maturation proceeds the cell sends fine cytoplasmic processes (neurites) into the surrounding regions. The latter are rich in microfilaments and microtubules, and centrioles frequently occur at the bases of the neurites where microtubules are being formed (p. 16). Internally, further maturation is marked by the development of the membranes of the endoplasmic reticulum, and the proliferation of attached ribosomes and mitochondria; glycogen is progressively reduced in maturing cells. With development one of the neurites becomes differentiated as the axon, whilst the other cell processes extend to establish the early dendritic tree. The growth of axons has been extensively studied, particularly in tissue culture; the rate of longitudinal growth is initially quite rapid—up to 1 mm per day. The tip of growing axons and dendrites is marked by a bulbous enlargement, the *growth cone*, containing many microfilaments (p. 162) and membranous vesicles, with small surface filopodia ('microspikes') growing out in an 'exploratory' manner into the surrounding intercellular spaces (Tennyson 1970; Bunge 1976; Pfenninger and Rees 1976). Thus, like many other morphogenetic processes, axonal growth appears to depend upon the presence of microfilaments (*see* p. 16).

The direction taken by a growing axon appears to be governed in part by mechanical factors such as the micellar architecture of neighbouring intercellular matrix, or the presence of other axons and Schwann cells along which further generations of axons grow to form bundles, and hence central nerve fibre tracts, or peripheral nerve trunks (*see* p. 161). The final direction and termination of axons, however, appear to be related to the overall fundamental plan of the nervous system, and much evidence is available to indicate that their growth patterns are determined by embryonic chemical concentration gradients, 'field effects', the chemical recognition of the surfaces of other cells, and so forth (*vide infra*). Experimental work, particularly on lower vertebrates, in which it is possible to graft or manipulate parts of the embryonic nervous system such as the visual pathway from the retina to the optic tectum, indicates that axons are able to establish precise relationships with various target regions of the brain in spite of mechanical interference, as though they are guided both by their relationship to surrounding axons, and also by a chemical recognition in their areas of termination. Similar considerations apply to the motor innervation of skeletal muscle. The mechanisms whereby such specific connexions are established are as yet unknown in detail, but may involve the sensing of metabolites such as 'nerve growth factor' produced by the target tissues, and the recognition of particular cells by the composition of their surfaces (Sidman 1974; Moscona 1976), impulse firing characteristics, and so on (but see also pp. 161, 162). There is also evidence (Hughes 1968) that if, during embryonic development, the axon fails to establish the correct contacts, its parent perikaryon atrophies and finally disintegrates; such mechanisms may explain the close numerical relationship between the number of neurons in a given motor pool, and the number of muscle cells which it innervates (Tennyson 1969).

The final growth of the dendritic tree is also influenced by its pattern of afferent connexions and their activity, and, if deprived of these experimentally, the dendrites fail to develop fully, and may be permanently affected, e.g. in the visual system of young animals lacking a normal type of visual environment (Blakemore 1974). Various metabolic factors are also known to affect the final branching pattern of dendrites; for example, thyroid deficiency in perinatal rats results in cerebral cortical neurons which are smaller and have less profuse branching of their dendrites than those of control animals. This is probably analogous to the mental retardation of cretinism (Eayrs 1955).

Once established, however, the dendritic tree in broad outline appears to be remarkably stable, and partial deafferentation affects only the detailed organization of dendritic spines or similar surface projections. If, however, cells lose their afferent connexions completely or are deprived of the normal sensory input (*see* Guillery 1974), atrophy and degeneration of much of the dendritic tree, and even of the whole neuron may ensue, although different regions appear to vary in the quantitative nature of such deprivative responses (*anterograde transneuronal*

degeneration—see p. 815). Similar effects are also often seen in retrograde transneuronal degeneration. Thus, as development proceeds there is a gradual loss of plasticity so that soon after birth the neuron is a stable structure with a reduced rate of growth. After this two main types of alteration occur. The first follows physical or chemical trauma to any part of the neuron, the second involves the ill-understood changes which accompany the establishment of temporary or permanent memory traces.

Reaction of neurons to physical trauma has been studied most extensively in motor neurons with peripheral axons, which are convenient of access, but also centrally where their axons form well-defined tracts, and incidentally the latter provides the basis for the various degenerative techniques for exploring neuronal connectivity (*see* p. 815). When an axon is crushed or severed, changes occur on both sides of the lesion (Nauta and Ebesson 1970). Distally, the axon initially swells, and subsequently breaks up into a series of membrane-bound spheres; the process begins near the point of damage and progresses distally. These *anterograde* changes, which also involve the axon terminals (*terminal degeneration*), continue to total degeneration and removal of the cytoplasmic débris (see also p. 820). Proximally, a similar series of changes may occur close to the point of injury, followed by a number of sequential (*retrograde*) changes in the cell body (Cragg 1970). The latter are firstly directed towards the removal of much of the original protein-synthesizing apparatus by autophagic lysosomal action. There is first a rise in cytoplasmic RNA which is associated in part with the increased synthesis of lysosomal acid phosphatases; this is followed by a dispersion of the large Nissl granules with a loss of affinity for stains in the cytoplasm (*chromatolysis*), reflecting a reduction of cytoplasmic RNA (*see* the review by Lieberman 1974). Subsequently, this is followed by the formation of new protein-synthesizing organelles which produce distinctive proteins, many of which are destined for the regrowth of the axon. This is further indicated by the movement of the nucleoli to the periphery of the nucleus, and the restoration of polysomal clusters in the cytoplasm, and the consequent return of staining affinity in the cytoplasm when prepared with Nissl's technique for light microscopy. During this process the synapses on the cell body may be temporarily retracted away from the neuronal surface membrane and glial processes invade the gap so formed (Matthews and Nelson 1975).

Where regrowth of the axon is possible, as in the peripheral nervous system, the presence of an intact endoneurial sheath near to and beyond the region of injury, is important if the axon is to re-establish satisfactory contact with its previous end-organ, or a closely adjacent one. The degeneration of the myelin sheath which occurs distal to the point of injury has already been mentioned (p. 815), and this is accompanied by mitotic proliferation of the Schwann cells, their progeny filling the space inside the basal lamina of the old endoneurial tube (Webster 1964). Further, where a gap is present between the severed ends of the nerve, proliferating Schwann cells emerge from the stumps (mainly the distal stump) and form a series of nucleated cellular cords (the *bands of Bungner*) which bridge the interval. These may persist for a long time, even in the absence of satisfactory nerve regeneration. The proximal part of the axon develops a terminal swelling from the surface of which many small axonal sprouts develop which grow into the surrounding tissues. The majority of these are ultimately abortive, but the successful one enters the proximal end of the endoneurial tube and grows distally in close contact with the surfaces of its contained Schwann cells. A process of *contact guidance* (p. 91) is involved between the growing tip of the axon and the Schwann cell surfaces in the endoneurial tube and, when present, those which form Bungner's bands. When the axon tip has reached and successfully reinnervated an end-organ, the surrounding Schwann cells commence to synthesize myelin sheaths, including typical junctional nodes of Ranvier and internodal Schmidt-Lanterman incisures. However, if regeneration is occurring in a mature animal in which general growth of the body and limbs has virtually ceased, there is no increase in the lengths of the internodal segments of myelin, which remain uniformly short (often about 200 μm). Before full *functional regeneration* can occur, however, a considerable period of growth of both axonal diameter and myelin sheath thickness is necessary. When a high proportion of effective peripheral connexions has been established, the nerve fibre population eventually recovers a virtually normal nerve fibre diameter spectrum, but this does not occur with a lack of appropriate peripheral connexions or if the onset of regeneration is long delayed. Regeneration of central axons does not normally occur in mammals, perhaps because of the absence of definite endoneurial tubes, and the disorganized proliferation of macroglial cells which follows central nervous injury.

A second series of changes occurs in nerve cells throughout the life of the individual. In addition to the normal turnover and replacement of the cytoplasm and surface of the neuron which occurs continuously, there are the constantly changing patterns of afferent nerve fibre activity, circulating hormone levels and other factors which are important to changes in neuronal behaviour in different parts of the brain. In the normal individual, cyclic or intermittent processes such as those involved in feeding, reproduction, aggression and so on, are obviously connected with such alterations of activity. It may be envisaged that changes in the chemical micro-environment of the cell can alter its electrical firing pattern in a probabilistic manner and thus change the characteristic responses of whole cell populations. More subtle changes are probably involved at the biochemical level so that the neuron modulates its responses (and structure) with reference to its previous history. This is a probable basis of certain aspects of memory formation which have received much attention in recent years. Changes in RNA content and composition have been reported to accompany the learning of conditioned responses, and claims have been made that experimental inhibition of protein synthesis also specifically inhibits certain types of memory formation (Barondes 1969). Despite the interest of such findings, it is by no means clear what relevance they have to learning processes in the intact nervous system.

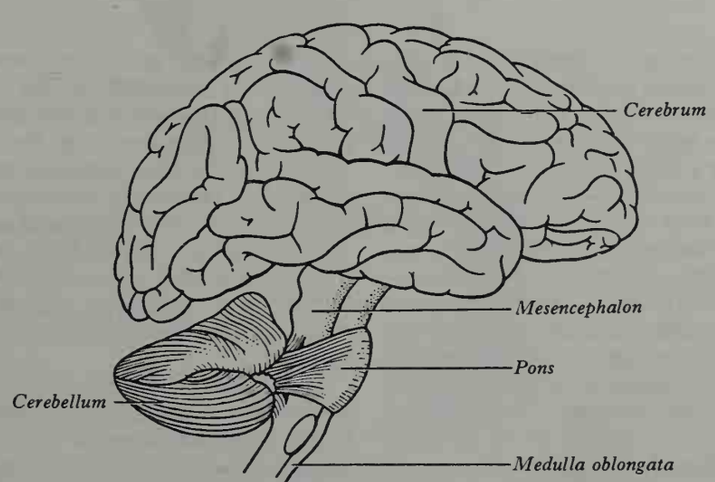
Finally, more drastic changes may occur; it is known that during fetal development many neurons degenerate and die. This process continues into post-natal life so that in senescence it has been estimated that up to 20 per cent of the original population of neurons is lost. In the embryo the loss of neurons can be seen as a process of 'thinning out' those which fail to establish proper functional connexions (Prestige 1970), or lose the competition with other neurons to innervate structures such as muscles (Hamburger 1975). In post-natal life the loss of neurons is not so easily understood; it has been suggested that it may be a similar process, perhaps related to the stabilization of behaviour patterns formed during the early years. Certainly, with increasing age, the logical efficiency of the nervous system and its reaction speeds deteriorate, and it seems probable that this is related in some way to the loss of neurons, although whether as a direct result is unknown.

TROPHIC INFLUENCE OF NEURONS

In addition to the functions of neurons in conduction and transmission, they have other important functions in the integration of the body during development, and in the continued post-natal maintenance of the other tissues. Of course, nervous tissue is not unique in this respect since most tissues influence the metabolism of surrounding cell masses in some fashion, but the effects of nervous tissue are perhaps more dramatic and far reaching than that of many other cellular components.

The most obvious relationship of this kind is the mutual dependence of motor neurons and the muscles which they innervate. If, during the course of development, a nerve fails to connect with a muscle, the nerve degenerates and likewise, if a muscle is denervated the muscle degenerates. If, however, the innervation of a slow (red) and a fast (white) skeletal muscle, each of which has distinct metabolic and physiological properties, is exchanged, the muscles change their structure and properties in accordance with the innervation, showing that the nerve determines the type of muscle and not vice versa (Buller 1970). However, in this case, the type of muscle is apparently determined chiefly by the firing pattern in its efferent nerve fibre, rather than by the release of a trophic chemical (Lomo and Westgaard 1974).

Trophic influences are best known in lower vertebrates, however, which are capable of regenerating whole limb structures after amputation, but only if the nerves to the limb are not destroyed (Hamburger 1968). In higher vertebrates, also, the trophic influences of axonal growth on dendritic trees is well known (p. 861), and it seems likely that many phenomena of sensory cell development, such as the specificity of gustatory sensory cells in the tongue, are under direct trophic influence from the afferent nerves (Rosenthal 1977).



It is interesting that in many invertebrates, also, regeneration of metameric segments is under direct neurosecretory control, and it has been suggested that the nervous system may have originated in the ancestral metazoans chiefly as a system for coordinating the regeneration and development of the body as a whole. Seen in this light, the neurosecretory activity of the hypothalamohypophyseal neurons may be a primitive survival from the distant past, other neurons being a subsequent specialization for more rapid types of communication.

MAJOR DIVISIONS OF THE NERVOUS SYSTEM

Although in essence a continuum, the nervous system may be divided for convenience of study into a number of parts, regions, or sub-systems. The *encephalon* or brain (7.33) and the *medulla spinalis* or spinal cord together form the *central nervous system*. Extended from this in pairs are twelve cranial and thirty-one spinal nerves, constituting a *peripheral nervous system*. This itself includes not only all the ramifications of these nerves, which mediate *somatic sensory* and *motor* functions, but also the entire complex of *visceral* or *splanchnic* nerves, connected to the central nervous system through the somatic channels, thus forming a *peripheral autonomic nervous system*. This division into central and peripheral parts of the nervous system is basically justifiable, for the latter consists of relatively simple conductors connecting the peripherally situated receptor and effector organs to each other through the complex intermediation of the brain and spinal cord. Though the latter also contains certain further extensions of the long afferent and efferent pathways deployed through the peripheral nerves, the particular significance of the whole central nervous system resides in extremely complex networks of interconnected neurons in which arise the appropriate patterns of response to the stimuli of both the external and the internal environment. This same highly intricate area of intermediation, between incoming patterns of afferent information and the emergence of suitable arrays of 'commands' to the effectors, is also the domain in which learning, memory and consciousness are intrinsic, each to a degree dependent upon the level of development of the central apparatus. Indeed, the elaboration of these activities, which clearly has increased along the lines of evolution, and especially along that leading ultimately to the human animal, is equally clearly related to a vastly increased population of central interneurons, rather than to changes in the peripheral afferent and efferent conductors. Nevertheless, the essential continuity and interdependence of all parts of the nervous system should never be overlooked.

The elements of which the nervous system is composed have already been described (p. 820). Whereas the peripheral nerves largely consist, except in their somatic and autonomic ganglia, of parallel and unconnected fibres, the central nervous system contains not only the terminations or beginnings of these peripheral axons but also very large numbers of nerve cells, together with their dendritic processes, the ramifications and synapses of which make up the greater part of the volume of the brain and spinal cord. Both parts of the nervous system also contain, of course, considerable amounts of either connective tissue and Schwann cells or neuroglia, and numerous blood vessels. The central nerve fibres and cells are distributed in an organized manner, and one or the other frequently predominates in particular regions. The somata of neurons are usually (but not always) gathered together into masses, which are called *nuclei* and sometimes *ganglia*; since they are devoid of any covering of myelin they appear darker to the unaided eye than do collections of nerve fibres, except where the latter are non-myelinated. This difference is accentuated by fixation, and with alcohol treatment nerve cells aggregations appear somewhat grey, and myelinated nerve fibres almost white, giving rise to the crude but useful terms 'grey' and 'white matter' or substance, although their colours are more nearly buff and cream in material fixed by the more commonplace formalin technique. It is not to be supposed that 'grey matter' contains no myelinated fibres; a large proportion of central axons are myelinated, and since every group of nerve cells will contain at least their own fibres, the grey or buff colour is merely due to the relatively low proportion of myelin. Similarly, tracts of myelinated nerve fibres, identified by the unaided eye as 'white matter', may nevertheless contain small numbers of nerve cells, and where the fibres are largely or entirely non-myelinated the colour will be 'grey'. With these provisos the two terms are usefully employed in the grosser descriptive topography of the central nervous system.

The spinal cord occupies approximately the cranial two-thirds of the vertebral canal, and it is arbitrarily considered to be continuous with the lowest part of the brain, the medulla oblongata, just below the level of the foramen magnum. The first pair of spinal nerves emerge from the spinal cord immediately caudal to this. The walls of the cord are thick, the cavity of the

7.33 Semi-diagrammatic scheme of the main divisions of the brain.

central nervous system being here reduced to an almost microscopic *central canal*, extending nearly the full length of the cord.

The encephalon or brain (7.33), which is wholly within the cranial cavity, is itself described as consisting of a number of regions, which are of considerable morphological and functional significance. These are—in ascending order from the spinal cord—the **rhombencephalon** or hindbrain, the **mesencephalon** or midbrain, and the **prosencephalon** or forebrain. The rhombencephalon includes the **myelencephalon** or medulla oblongata, the **metencephalon** or pons, and the **cerebellum.** The prosencephalon is also subdivided into the **diencephalon** ('between brain'), which is the central connecting part of the forebrain, corresponding approximately to the thalamus and hypothalamus, and the **telencephalon**, which comprises the two so-called cerebral 'hemispheres' or cerebrum. The midbrain, pons, and medulla oblongata are collectively termed the *brainstem*, connecting the forebrain and spinal cord. The relation of these divisions of the brain to each other will be appreciated more clearly if their development is considered (p. 170). The pattern of fore-, mid-, and hind-brain is not only an expression of ontogenetic growth in the individual, it is also phylogenetic, inasmuch as it represents the basic central nervous hierarchy of vertebrates. These three successive levels are sometimes regarded as the 'segments' of the brain, and in extension of this idea the telencephalic part of the forebrain, the cerebrum, and particularly the cerebral cortex and its connexions, is described as 'suprasegmental', a term also applied to the cerebellum. Both are phylogenetically later outgrowths upon the basically elongated form of the primitive vertebrate brain.

The *medulla oblongata* is the most caudal part of the brainstem. It is immediately above the basilar region of the occipital bone, and is continuous with the pons above and the spinal cord below. The *pons* is also related to the basi-occiput and to the dorsum sellae of the sphenoid bone. It is markedly greater in transverse and anteroposterior dimensions than the medulla, from which it is easily distinguished by the large lamina of transverse nerve fibres protruding from its ventral apsect. The *cerebellum*, consisting of paired lateral parts, or *hemispheres*, united by a median *vermis*, is dorsal to the pons and medulla, occupying most of the posterior cranial fossa. Ventrally it is continuous with the midbrain, pons, and medulla. The cavity of the rhombencephalon or hindbrain is expanded as the *fourth ventricle*, which occupies the dorsal parts of both the pons and the cranial half of the medulla, being continuous with a fine canal in the caudal part of the medulla, and through this with the central canal of the spinal cord. The fourth ventricle contracts at its cranial end into a narrow channel in the mesencephalon, somewhat inappropriately termed the *cerebral aqueduct*. The *midbrain* is a relatively short part of the brainstem and somewhat constricted in comparison with the pons. The *diencephalon*, which is almost completely embedded in the cerebrum and thus largely hidden from surface view, contains a narrow, vertical *third ventricle*, which communicates caudally with the aqueduct.

The *cerebrum* is the most cranial or rostral part of the brain, and it accounts in mankind for much the major fraction of its volume. It occupies the anterior and middle cranial fossae and is directly related to almost the whole concavity of the vault of the skull. It is described as consisting of two large convoluted *cerebral hemispheres*. In fact, the halves of the cerebrum are *not* hemispherical; *together* they do form roughly a hemisphere, and perhaps the term was originally used in the singular, but the plural usage, however unsuitable as regards shape, is customary. Each hemisphere is roughly equal to a quarter of a sphere in shape and contains a large, crescentic *lateral ventricle*, continuous medially with the third ventricle in the diencephalon. Each hemisphere has an external layer of grey matter, the *cerebral cortex*, and a central core of white matter, or *medullary substance*, in which are several large masses of grey matter, the *basal nuclei* or *'ganglia'*.

As already mentioned, the *peripheral nervous system* contains a somatic component, the *cerebrospinal nervous system*, and a visceral component, the *autonomic nervous system*. In the former the efferent nerve fibres pass directly from their cells of origin in the central nervous system to the effector organs, muscles. The efferent autonomic fibres, however, do not do so, but terminate in ganglia outside the central nervous system, where they form synapses with neurons whose axons pass onwards to innervate non-striated muscle and glandular tissue. Autonomic efferent pathways thus consist of two orders of neurons termed, for obvious reasons, *preganglionic* and *postganglionic* (although the variety of neuron types in automatic ganglia is now known to be much greater than this simple dualistic terminology implies, *see* p. 1124). The arrangement of afferent fibres is, on the other hand, similar in both cerebrospinal and autonomic systems.

The autonomic nervous system consists of *sympathetic* and *parasympathetic* divisions. Preganglionic sympathetic efferent fibres issue from a region of the spinal cord limited to the segments between the first thoracic and second or sometimes third lumbar levels. Preganglionic parasympathetic efferent fibres emerge from the central nervous system only in certain cranial nerves (oculomotor, facial, glossopharyngeal, vagus and accessory) and in the second, third and fourth sacral spinal nerves. These two groups of autonomic efferents are therefore usually designated the *thoracolumbar* (sympathetic) and *craniosacral* (parasympathetic) *outflows*. A detailed description of the autonomic system appears on p. 1121.

THE CENTRAL NERVOUS SYSTEM

THE SPINAL MEDULLA OR CORD

The spinal cord (medulla spinalis) is the elongated, approximately cylindrical part of the central nervous system which occupies most of the diameter of the cranial two-thirds of the vertebral canal. Its average length in the European male is 45 cm and its weight about 30 gm. (For a recent confirmation of these values, and comparison of length, weight and thickness at various levels, consult Barson and Sands 1977.) It extends from the level of the cranial border of the atlas to the caudal border of the first or cranial border of the second lumbar vertebra. This level of termination is, of course, subject to variation, showing also some correlation with the length of the trunk, especially in females (Jit and Charnalia 1959). The cord's termination may be as high as the lower third of the twelfth thoracic vertebra or as low as the disc between the second and third lumbar vertebrae. The position of the termination is elevated slightly by flexion of the vertebral column. The spinal cord is enclosed in three membranes or *meninges*; these are, from without inwards, the *dura*, *arachnoid*, and *pia maters*, which are separated from each other by *subdural* and *subarachnoid spaces*, the former being merely potential, the latter being occupied by the cerebrospinal fluid (p. 1050). Continuous cranially with the medulla oblongata, the spinal cord narrows caudally to a sharp tip, the *conus medullaris*. From the apex of this the *filum terminale*, a fine connective tissue filament, descends to the dorsum of the first coccygeal segment (7.34).

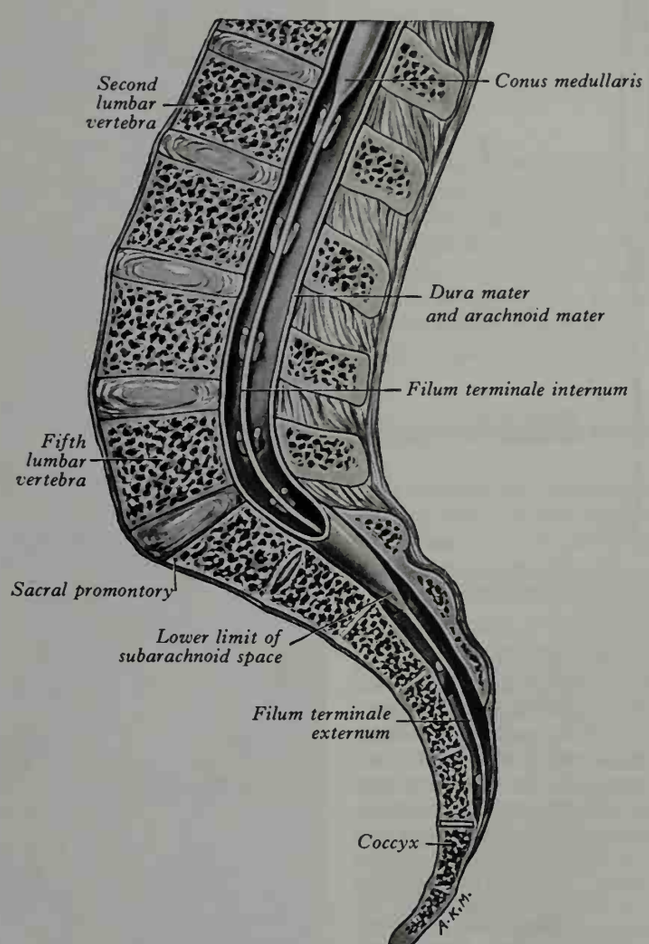
In *transverse width* the spinal cord varies from level to level. It shows a general tapering from cranial to caudal extremities, but this is obscured to some extent by enlargements at cervical and lumbar levels. Moreover, it is not cylindrical, being greater in its transverse dimension at all levels, and especially so in its cervical segments.

The *cervical enlargement* is the more pronounced and corresponds to the large spinal nerves supplying the upper limbs. Hence it extends from the third cervical to the second thoracic segment, its maximum circumference (about 38 mm) being in the sixth cervical. (A spinal cord segment is the region of attachment of one pair of spinal nerves.)

The *lumbar enlargement* similarly corresponds in level to the segmental innervation of the lower limbs, beginning at the first lumbar segment and extending to the third sacral, the equivalent *vertebral* levels being ninth to twelfth thoracic. Its greatest circumference (about 35 mm) is level with the lower part of the twelfth thoracic vertebra, beyond which it rapidly dwindles into the conus medullaris.

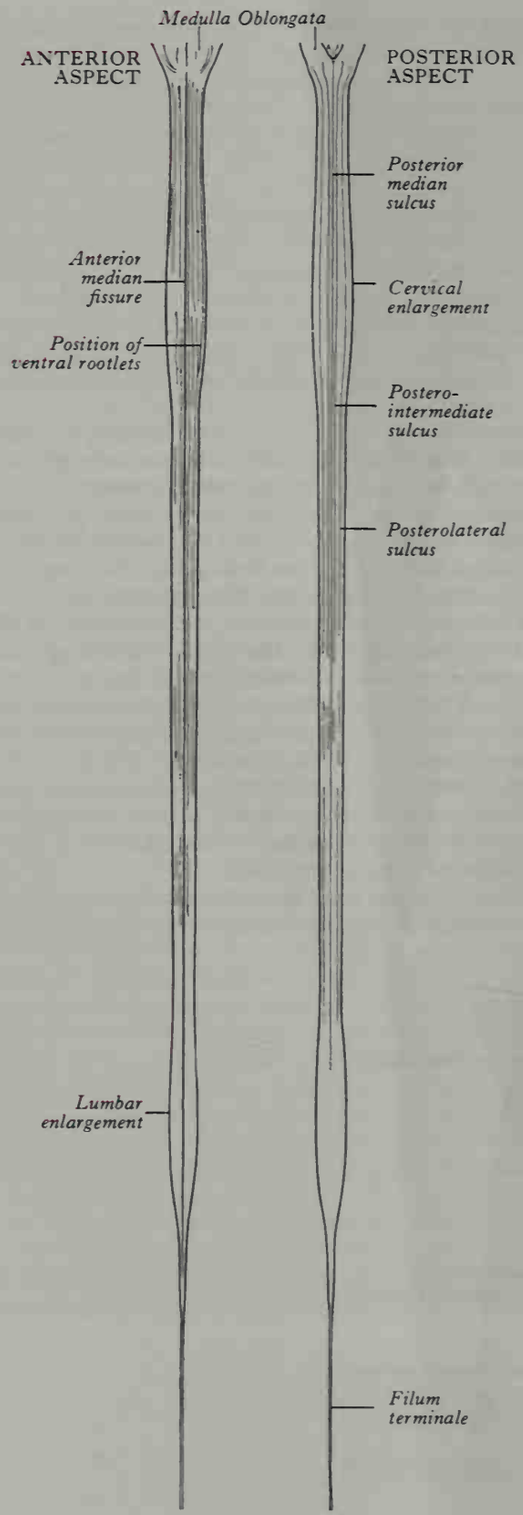
Fissures and *sulci* mark the external surface of the spinal cord through most of its length. An anterior median fissure and a posterior median sulcus and septum almost completely divide the cord into symmetrical right and left halves, joined across the midline by a commissural band of nervous tissue, in which is the central canal (7.35, 36).

The *anterior median fissure*, traversing the whole length of the ventral surface of the spinal cord, has an average depth of 3 mm, being deeper than this at more caudal levels. It contains a reticulum of pia mater, and immediately dorsal to it is a lamina of nerve fibres, the *anterior white commissure*. Perforating branches of the spinal vessels pass from the fissure into the commissure to supply the central region of the spinal cord.



The *posterior median sulcus* is much shallower, and from it a *posterior median septum* of neuroglia penetrates somewhat more than half way into the substance of the cord, reaching almost to the central canal. The septum varies in its anteroposterior extent from 4 to 6 mm, diminishing caudally as the canal becomes more dorsal in position and the cord itself contracts.

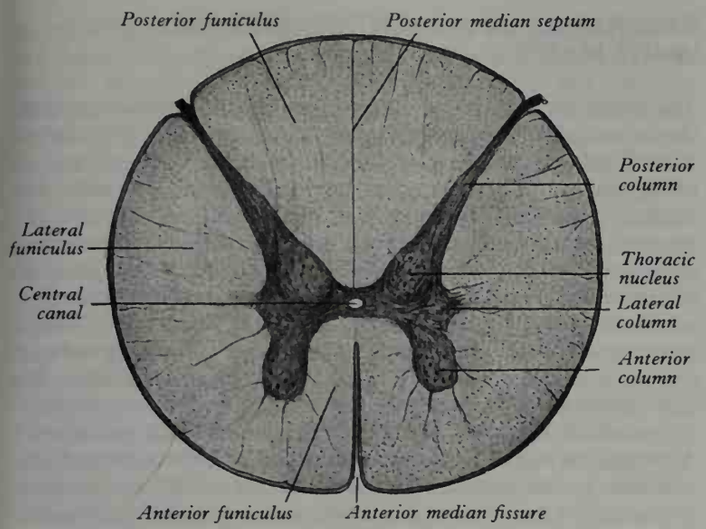
A *posterolateral sulcus* exists on each side of and a short distance from the posterior median sulcus, and along it the dorsal spinal nerve roots enter the cord. The white substance of the cord between the posterior median and posterolateral sulci on each side is the *posterior funiculus*. Through the cervical and upper thoracic segments the surface of this funiculus presents a further longitudinal furrow, the *postero-intermediate sulcus*, which marks the position of a septum extending into the posterior funiculus and dividing it into two large tracts of fibres, the *fasciculus gracilis*, which is medial, and the *fasciculus cuneatus* which is lateral.



The region of the spinal cord between the posterolateral sulcus and anterior median fissure is the *anterolateral funiculus*, and this is further subdivided into *anterior* and *lateral funiculi* by the issuing anterior roots of the spinal nerves. The anterior funiculus lies medial to (and includes) the zone of emergence of the ventral roots, whilst the lateral funiculus lies between the roots and the posterolateral sulcus (7.36, 38). In the upper cervical segments a series of nerve roots emerges through the lateral funiculus on each side to form by their union the spinal part of the accessory nerve, which ascends in the vertebral canal lateral to the spinal cord to enter the posterior cranial fossa through the foramen magnum (7.59). It is composed of fibres which supply the sternocleidomastoid and trapezius muscles.

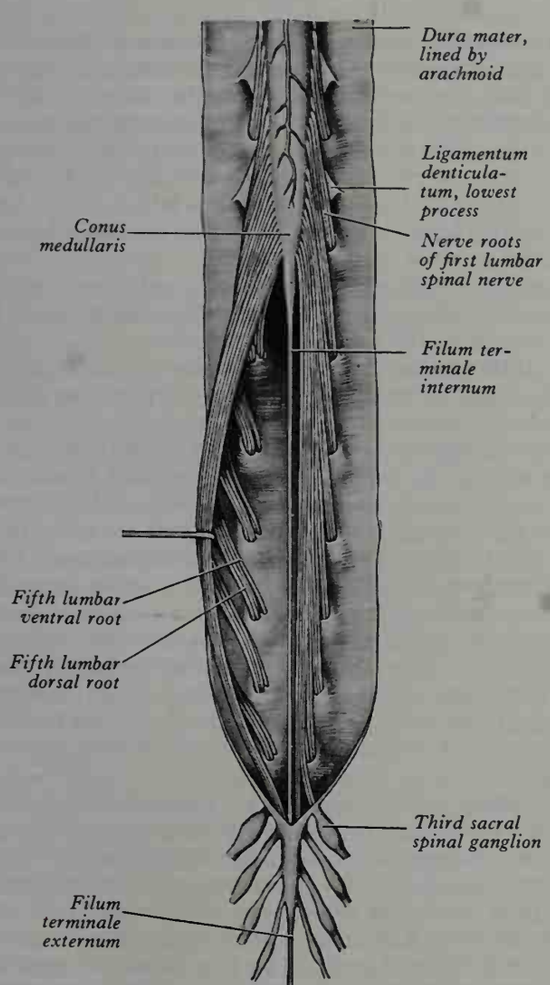
The *filum terminale* (7.34, 37), a fine filament of connective tissue about 20 cm long, descends from the apex of the conus medullaris. Its cranial 15 cm, the *filum terminale internum*, is surrounded by tubular extensions of the dural and arachnoid meninges and reaches as far as the lower border of the second sacral vertebra. Beyond this its final 5 cm, the *filum terminale externum*, is closely united with the investing sheath of dura mater, descending to an attachment to the dorsum of the first coccygeal vertebral segment. The filum, consisting mainly of fibrous tissue, is continuous at its cranial end with the pia mater of the spinal cord; adherent to the upper part of its surface are a few strands of nerve fibres which probably represent the roots of rudimentary second and third coccygeal spinal nerves. The central canal of the cord is also continued into the filum terminale for 5 or 6 mm. A particularly roomy part of the subarachnoid space surrounds the internal part of the filum; it is the site of election for spinal (lumbar) puncture.

Continuous with the cord at intervals along it are the paired dorsal and ventral roots of the spinal nerves (7.38). These cross

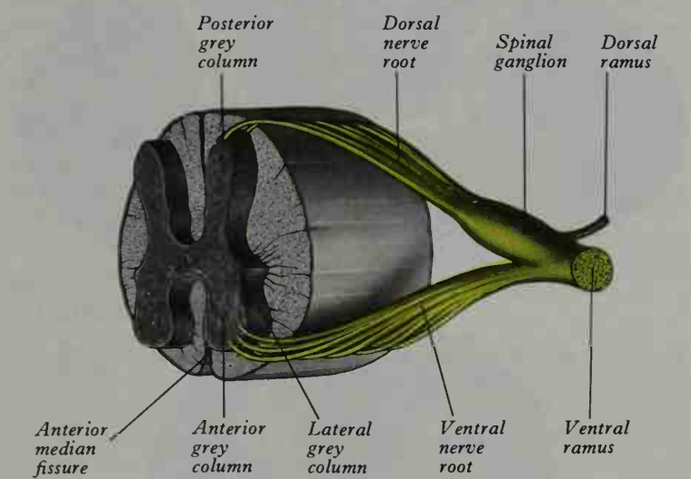


7.34 Median sagittal section of the lumbosacral part of the vertebral column to show the conus medullaris and filum terminale. The section has opened up the subarachnoid space as far as the first sacral vertebra. Note the difference in levels between the inferior limits of the spinal cord and its meninges.

7.35A Diagram to show the main features of the spinal cord.



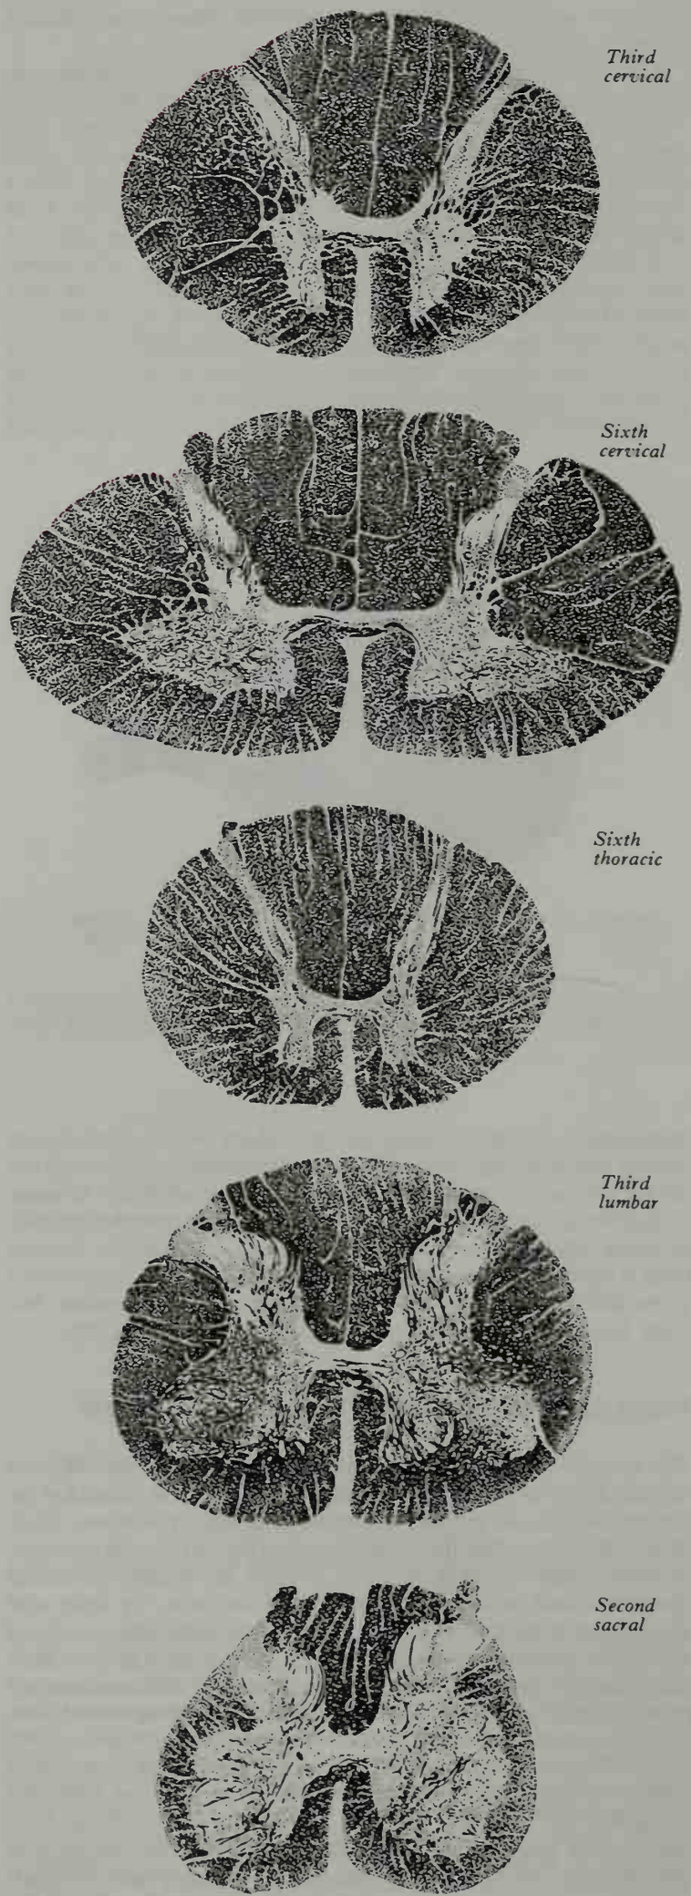
7.35B The brain and spinal cord with attached spinal nerve roots and dorsal root ganglia, photographed from the dorsal aspect. Note the relative sizes of the cerebral and cerebellar hemispheres, and the fusiform cervical and lumbar enlargements of the spinal cord. The median longitudinal fissure between the hemispheres which receives the falx cerebri and falx cerebelli is visible, together with the horizontal cleft between cerebrum and cerebellum which receives the tentorium cerebelli. Contrast the irregular pattern and dimensions of the cerebral gyri and sulci with the more regular, largely transverse pattern of the smaller cerebellar folia, and their intervening fissures. Note also the changing obliquity of the spinal nerve roots in their rostrocaudal progression, the stouter roots attached to the limb enlargements and the formation of the cauda equina and filum terminale. The cauda is undisturbed on the right, and has been fanned out on the left to facilitate identification of its individual components. (Dissection by Dr. M. C. E. Hutchinson, Department of Anatomy, Guy's Hospital Medical School.)



7.36 Typical transverse section of the spinal cord at a mid-thoracic level. Magnification about × 8.

the subarachnoid space, traverse the dura mater separately, and then unite in or close to their intervertebral foramina to form the spinal nerves. Since the spinal cord is markedly shorter than the vertebral column, the more caudal spinal roots descend for varying distances around and beyond the cord to reach their corresponding foramina; and in so doing they form, largely caudal to the apex of the cord, a divergent sheaf of spinal roots, the *cauda equina*, gathered around the filum terminale in the spinal theca. (For the developmental changes which occur in the human embryo's spinal cord consult p. 157 and Pearson and Sauter 1971.)

The *ventral spinal roots* consist of efferent somatic and, at certain levels, visceral (sympathetic) nerve fibres, the axons of which are emerging from their sources in the spinal cord. The *dorsal spinal roots* are characterized by ovoid swellings, the *spinal ganglia*, one on each root just proximal to its junction with a corresponding ventral root in its intervertebral foramen. Each dorsal root fans out into six to eight rootlets which enter the cord in a vertical series along the posterolateral sulcus. The dorsal roots are generally regarded as consisting entirely of afferent nerve fibres derived from unipolar nerve cells in the spinal root ganglia, but it has been suggested that a small number of them (3 per cent) are efferent (Young and Zuckermann 1936), and that autonomic vasodilator fibres may issue in dorsal roots (p. 1121). These views have not received wide support. Each ganglionic neuron has a single very short process which almost immediately divides into a medial process entering the spinal cord through the dorsal root and a lateral one which passes peripherally to some form of sensory end-organ. The central process is morphologically an axon, whereas the lateral or peripheral extension is derived from a dendrite. The region of the spinal cord associated with a given pair of spinal nerves is described as a *spinal segment*, but there is no clear indication of segmentation apart from this.



7.37 The lower end of the spinal cord, the filum terminale and the cauda equina exposed from behind. The dura mater and the arachnoid have been opened and spread out.

7.38 Diagram of a spinal cord segment showing mode of formation of a typical spinal nerve, and the gross relationships of the grey and white matter.

Internal Structure of the Spinal Cord

The internal structure of the spinal cord may be considered from several different but complementary points of view. Ignoring for the present the all-pervading supply and support tissues, blood vessels and neuroglia, the arrangement of the nerve cells and their processes can be studied by a variety of means, including dissection and unaided observation of sections, by light and electron microscopy, and by experimental techniques, and, of course by combinations of these. The first method reveals little more than the general layout of nerve fibres and cells; microscopy provides much more detailed information of cell types and fibre calibres and of their intimate disposition in the substance of the cord. While both light and electron microscopy have contributed greatly to knowledge of the interconnexions between neuronal elements, the potential of these techniques can only be fully exploited in conjunction with experimental manœuvres, such as degeneration, microelectrode and many other methods. We shall therefore consider spinal organization in a series of steps: (*a*) the large-scale arrangement of the grey and white matter, (*b*) the distribution of nerve cells in the grey matter, (*c*) the white substance and the deployment of tracts of fibres in it, and (*d*) the more detailed organization of the spinal neurons.

7.39 Transverse sections through the spinal cord at representative levels. Magnification about × 5. Note changes in overall profile, and the relative changes in grey and white regions.

GENERAL ARRANGEMENT OF GREY AND WHITE MATTER

The grey matter of the spinal cord is central in situation and has the form of a fluted column throughout, except where this pattern is modified at its continuation into the medulla oblongata and in its tapered caudal extremity, the conus medullaris. In transverse sections (7.39) this column consists of symmetrical right and left comma-shaped masses connected by a transverse *grey commissure*, the whole somewhat resembling a letter H. The commissure is traversed by the central canal, which may be just visible by unaided vision. Each of the lateral crescentic masses has a concavity directed laterally and can be regarded as having *anterior* and *posterior* parts or *columns* relative to the grey commissure. At some levels a small *lateral column* projects from the intermediate region of the concavity. In transverse sections of the spinal cord these various columns appear as more or less pointed projections and are hence commonly called 'horns'. This picturesque nomenclature is misleading and unnecessary, and the elongated divisions of the grey matter will be referred to as *columns* in this account. The central grey matter is surrounded by the white matter of the cord, the latter consisting largely of nerve fibres, many of which are longitudinal in direction and are therefore grouped appropriately into *funiculi* (little cords) or *white columns*. The general arrangement of these as dorsal, lateral and ventral funiculi has already been described above, and further details of the types and arrangements of nerve fibres in these white columns will be the concern of a subsequent section (pp. 874 *et seq.*).

The anterior or ventral grey column projects ventrally and somewhat laterally with respect to the grey commissure. It is comparatively short and broad and does not reach the surface of the spinal cord, being separated from this by the lateral part of the anterior funiculus (7.39). Its anterior and posterior limits are sometimes named its head and base—arbitrary terms of little value.

The posterior or dorsal grey column projects dorsolaterally, and in contrast to the anterior column it is transversely narrow and also extends almost to the surface near to the posterolateral sulcus, from which is it separated by a thin lamina of nerve fibres, the *dorsolateral tract* (p. 881). It also is considered to have a base, where it is continuous with the intermediate grey region, a constricted neck which expands into an oval or fusiform head, and an apex, which is capped by a mass of somewhat translucent nervous tissue, the *substantia gelatinosa* (*Rolandi*). This crescentic mass of small nerve cells and fibres is intimately concerned with the connexions of incoming afferent nerve fibres, further details of which appear later (p. 887).

The lateral grey column is a small, angular projection extending from the second thoracic to the first lumbar segment of the cord and does not appear at other levels.

The boundary between white and grey matter is in most places definite, but in the cervical region of the cord strands of grey matter invade the lateral funiculus from the base of the dorsal grey column; these strands are separated by interlacing groups of nerve fibres, and this gives the arrangement the appearance of a loosely interwoven net, whence its name, the *reticular formation*, or formatio reticularis. Similar regions appear, in a less developed form, at more caudal spinal levels; and more recently reticular formations have been identified in the brainstem, in connexion with which physiological investigations have led to the concept of an extensive *reticular 'system'*, of great functional importance, widely deployed throughout the neuraxis. See pp. 943–953 for details.

The respective positions of the main masses of white and grey matter are what might be expected in simple terms of peripheral conductors and longitudinally arranged spinal tracts of fibres, but this general structure is also an expression of the development of the cord (p. 157). The dimensions of the spinal cord and the relative volumes of peripheral fibres and centrally aggregated nerve cells at different levels (7.39) can, in part, be explained by the amounts of muscle, skin and other tissues innervated by different segments, and by consideration of the fact that the fibres in the longitudinal tracts are on the whole inevitably more numerous as the cord is traced in a cranial direction. In the

thoracic region the grey matter is absolutely and relatively small in volume, while the white substance shows a progressive increase in the ascending direction. In the cervical and lumbar enlargements the amount of grey matter, especially in the ventral columns, is much increased by the presence of large accumulations of nerve cells concerned in the innervation of the limbs; but, while the amount of nerve fibres at cervical levels is marked, in the lumbar enlargement and particularly the conus medullaris the white funiculi contain very many less fibres passing through these segments; 7.39 shows these details in several representative segments of the spinal cord, and it is obvious that various levels can easily be distinguished from each other. It is, however, more important to recognize the explanation of these differences in terms of the criteria noted above.

The central canal exists throughout the spinal cord and also extends into the caudal half of the medulla oblongata, opening out above this into the fourth ventricle (p. 932). In the caudal part of the conus medullaris it expands into a fusiform *terminal ventricle*, triangular in section with its base ventrally directed. It is about 8 to 10 mm in length, but tends towards obliteration above the age of forty years. At cervical and thoracic levels the canal is slightly ventral to the midpoint of the cord, central in the lumbar enlargement, and more dorsal in position in the conus medullaris. It extends for 5 or 6 mm into the filum terminale. During life it contains cerebrospinal fluid, and it is lined by a columnar, ciliated epithelium, the *ependyma*, which is encircled by a zone consisting principally of neuroglia but also containing a few nerve cells and fibres, the *substantia gelatinosa centralis*. This is traversed by processes spreading centrifugally from the basal aspects of the ependymal cells. The grey matter surrounding the central canal external to the gelatinous substance is the *grey commissure*. Ventral to the canal the commissure is thin, and further ventral still is a slender lamina of decussating nerve fibres, the *ventral white commissure* (p. 875). The grey commissure is traversed by two longitudinal veins (p. 896). The part of it dorsal to the canal is contiguous with the ventral edge of the posterior median septum; it is thinnest in the thoracic region of the cord and thickest in the conus medullaris; it is permeated by a variable number of transverse white myelinated nerve fibres which, collectively, are sometimes termed the *dorsal white commissure*.

Internal Structure of the Grey Matter

Like other parts of the central nervous system the spinal grey matter (7.40) consists of a complex intermingling of nerve cells and their processes with neuroglia and blood vessels. The predominance of the somata of neurons in relation to their myelinated processes, which are also present, is responsible for the so-called grey appearance, as we have seen above. The neuroglia (p. 834) forms a most intricate lattice among the nerve cells and their neurites, being particularly condensed in the central gelatinous substance around the central canal. The processes of the nerve cells will be described in detail later in this section in connexion with the tracts of the spinal cord (p. 875) and with the organization of its interneuronal networks (p. 882); they include axons arriving from or departing to the fibre tracts of the white funiculi, the commencement of efferent and the termination of afferent peripheral nerve fibres, together with collaterals from these sources and a most complex neuropil, the latter being composed of the innumerable neurites of nerve cells which are largely confined to the grey matter or at least to the spinal cord itself. Many cell processes cross the midline in the commissures, and the right and left halves of the cord, including its grey matter, are a functional continuum. The nerve cells in the grey substance are multipolar, varying much in size and other characteristics, and particularly in the length and morphology of their axons and dendrites. Many are Golgi types I and II nerve cells (p. 821), the axons of the former being long and passing out of the grey matter into the ventral spinal roots or the fibre tracts of the white matter. The axons and dendrites of the Golgi type II cells are largely confined to the neighbouring grey matter. Some neurons are *intrasegmental*, being deployed within the limits of a single segment; others spread through several segments, being *intersegmental* in distribution. Details of this kind will, however, be described later (p. 895). We shall here be concerned only with the mode of arrangement of the actual nerve cell bodies or somata in the different regions of the grey matter.

In many parts of the central nervous system nerve cells are gathered together in groups, often in large numbers; and this usually indicates involvement in some particular common function. In some instances a large group exhibits division into smaller subgroups sufficiently constant in occurrence in different individuals to justify description and the application of specific names. The existence of such constant patterns of nerve cell distribution inevitably suggests functional implications, though the influence of developmental or growth processes may be of even greater signifance in many places. The nerve cells of the spinal grey matter are not distributed evenly or at random; they also occur in major and minor aggregations, some of which have obvious broad functional significance, while the meaning of others remains obscure or a subject of controversy. The following details of the cytoarchitecture of the spinal grey substance are described in the first place as purely topographical arrangements, and in doing this it is convenient to divide this account into sections dealing with the ventral and dorsal columns and with the intermediate region between them, including with the latter the lateral grey column. After this the functional interpretations of some of the subgroups in these columns will be considered in the light of the available evidence.

NERVE CELL GROUPS OF THE ANTERIOR GREY COLUMNS

The nerve cells of the ventral columns vary greatly in size; most prominent are large multipolar elements exceeding 25 μm in average dimensions of their somata, and with axons emerging as the fibres of ventral roots which innervate striated skeletal muscles as α-efferents. Large numbers of smaller nerve cells, of the order of 15 to 25 μm, also occur and the axons of some of these are the γ-efferents which innervate the intrafusal muscle fibres of neuromuscular spindles. On the evidence of retrograde degeneration experiments and other considerations, not all the smaller nerve cells in this column produce such efferents, and most in fact are interneurons (see also p. 883).

As in other parts of the spinal grey matter, the ventral column cells are basically arranged in elongate groups, a number of separate longitudinal columns extending through characteristic series of segments in the cord. This arrangement is perhaps seen most easily in transverse sections (7.40A) and is usually so studied; longitudinal sections are rarely described or depicted. In the latter, however, it is clear that these columns of nerve cells are themselves not uniformly continuous through the cord (7.40B), but are clustered in small aggregations, which are too diminutive to bear any segmental significance (Laruelle and Reumont 1933). The basic division of the ventral grey region is into three columnar groups—*medial*, *central*, and *lateral*—but all of these exhibit further subdivision at certain spinal levels, usually into dorsal and ventral parts. Thus a considerable nomenclature has accumulated, and while there is a satisfactory measure of agreement regarding the organization of the ventral column into cell groups, some confusion persists in the naming of these. The terms employed here are derived from an authority widely consulted (Crosby *et al.* 1962) but only recently (1977) have these terms been officially established in *Nomina Anatomica*. As will be more easily appreciated from illustration 7.41, the **medial group** extends through most segments of the cord, being perhaps absent from the fifth lumbar and first sacral. Through all the thoracic and the upper three or four lumbar segments it is divided into subsidiary **ventromedial** and **dorsomedial groups**, and in segments cranial and caudal to this the medial group is represented only by its ventromedial moiety, except in the first cervical segment, where only the dorsomedial group is considered to exist.

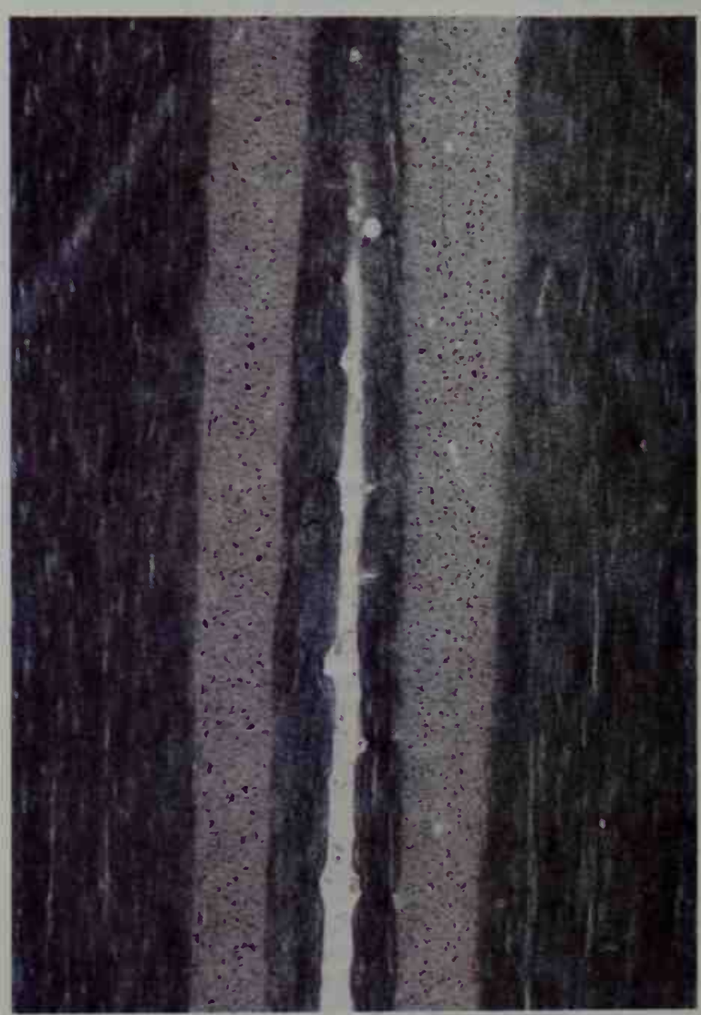
The **central group** of the ventral grey column is the least extensive and is identifiable only in some cervical and lumbosacral segments. In the cervical cord, through the third to seventh segments, is a centrally situated columnar group termed the

phrenic nucleus; there is abundant experimental and clinical evidence that these nerve cells innervate the diaphragm, probably constituting the least controversial individual motor pool in the entire spinal cord. For experimental evidence in various mammals, including primates, *see* Kohnstamm (1898); Sharrard (1955); Keswani and Hollinshead (1956); Warwick and Mitchell (1956); Ullah (1978). The **lumbosacral nucleus**, traversing the second lumbar to first sacral segments, is also central in the ventral column, the distribution of its axons being unknown. Nerve cells whose axons are considered to enter the spinal part of the accessory nerve form an irregularly shaped **accessory group**, in the upper five or six cervical segments, occupying the ventral border of the anterior grey column in an intermediate or central position. They are, however, lateral to the dorsomedial group in the first cervical segment; the ventral siting of this nucleus may be coupled with the absence of the lateral groups from the first three cervical segments (7.41).

The **lateral group** of the ventral column can be further divided into **ventral**, **dorsal**, and **retrodorsal groups**, all of which are largely confined to spinal segments innervating the limbs. Their individual extents are indicated in illustration 7.41, and the significance of their arrangements will be discussed below (p. 872).

Onufrowicz (1899) described a ventrolateral group of motor neurons, in the first and second sacral segments, which he considered to innervate the perineal striated muscles. This so-called *nucleus of Onufrowicz* has been confirmed in mankind by Mannen *et al.* (1977) and by Konishi *et al.* (1978) in the cat.

NERVE CELL GROUPS OF THE POSTERIOR GREY COLUMNS



The cell groups of the dorsal region of the spinal grey matter comprise two which extend through the whole length of the cord and two limited to the thoracic and upper lumbar segments.

The **substantia gelatinosa** (of Rolando), present at all levels, consists chiefly of small Golgi type II neurons with some larger nerve cells. The connexions of these with incoming fibres from dorsal roots and with spinothalamic tract fibres have long been accepted, but somewhat drastic review of this teaching in its details is occasioned by recent experimental work (pp. 888, 890). Also extending throughout the cord is a column of rather large cells, ventral to the gelatinous substance, the **dorsal funicular group** or *nucleus proprius*. As in the case of the anterior column, a thin lamina of nerve cells, distinguishable from those of the substantia gelatinosa by their larger size, is described by some authorities as a *marginal zone*, dorsal to the substantia (7.40, 41). (For further structural details and earlier postulated roles of the substantia gelatinosa *see* pp. 887, 890.)

The **nucleus dorsalis** or *thoracicus* (of Clarke) occupies the basal region of the posterior grey column, immediately dorsal to the intermediate zone in laminae VI–VII (but *see* also p. 883). At most levels it is close to the dorsal white funiculus and may project slightly into it. There are variable accounts of its extent, but in the human spinal cord it can usually be identified from the eighth cervical caudally to the third or fourth lumbar. Similarly situated groups of nerve cells have been described as occurring at cervical

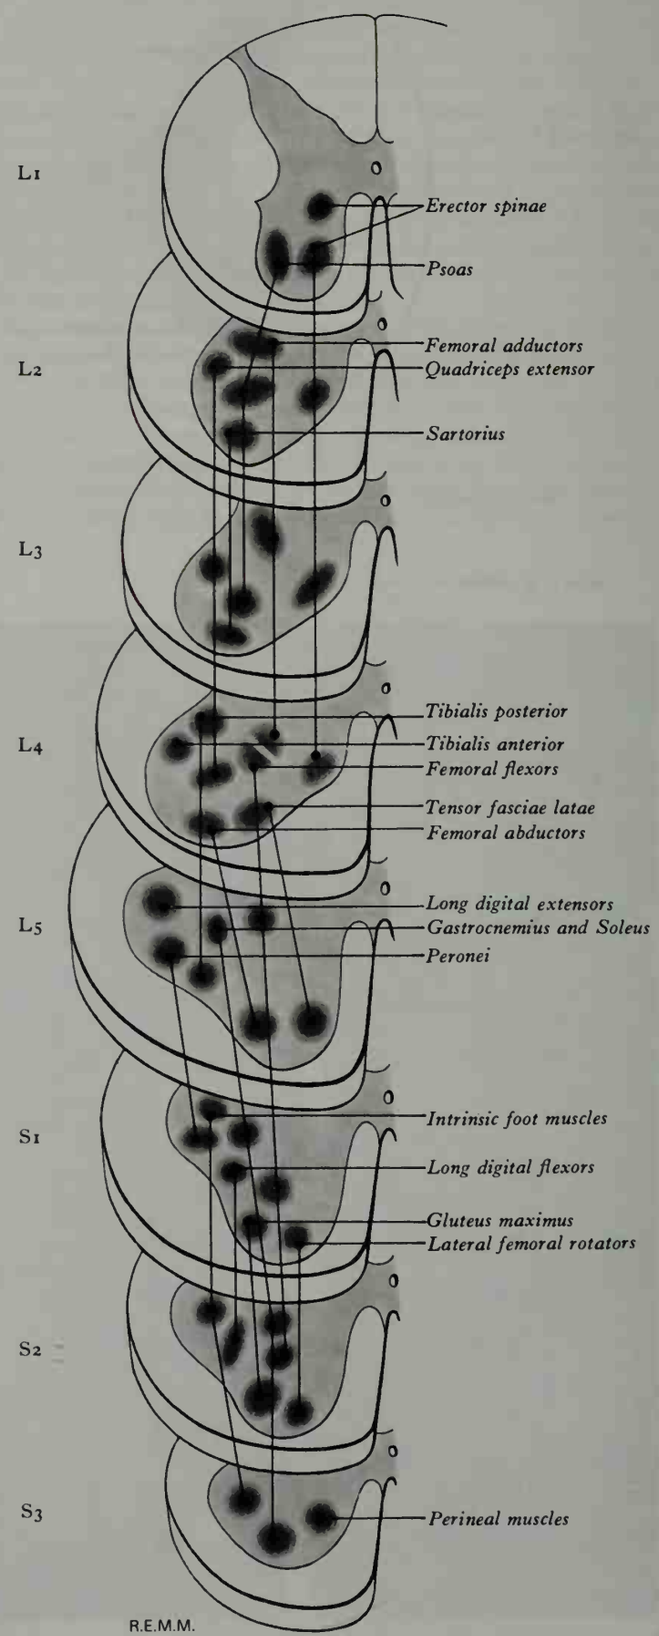
7.40A and B Transverse and longitudinal sections of spinal cord. A Transverse section of left half of human spinal cord at a mid-lumbar level. Note dorsal and ventral grey columns and commissural grey mass. The larger motor neurons in the ventral grey column are visibly grouped. For details see text. (Stained with cresyl fast violet.) B Longitudinal section of feline spinal cord showing the anterior median fissure, and anterior white columns, and lateral to these the ventral grey columns, in which motor neurons show some degree of grouping into longitudinal columns. (Material prepared by the late Professor L. Laruelle and kindly supplied by Professor J. André-Balisaux, Institut Neurologique Belge, Brussels.)

7.41 The groups or nuclei of nerve cells in the grey columns of the human spinal cord as generally accepted. Relative positions of these columnar groups, as well as their extension through varying series of spinal segments, are as indicated. (Adapted from data in *Correlative Anatomy of the Nervous System*, by E. C. Crosby, T. Humphrey and E. W. Lauer, Macmillan, 1962, with the permission of the authors and publishers.)



levels cranial to the nucleus dorsalis, and extensive prolongations in caudal levels of the cord appear to exist in some long-tailed monkeys (Chang 1951). But since these 'cervical' and 'sacral' nuclei consist of cells of considerably different characteristics, and have only been described in other mammals, it is premature to extrapolate such observations to the human spinal cord (*see*, however, p. 891). The cells of the dorsal nucleus itself vary in size, most being comparatively large, especially in the lower thoracic and lumbar segments. Some of these cells send axons into the dorsal spinocerebellar tract (p. 879), some are interneurons. Petras and Cummings (1977) have described the cells of this nucleus and their connexions in some detail in neonatal dogs, also confirming its role as a 'relay' group on the dorsal spinocerebellar pathway. The same workers demonstrated a similar role for the **nucleus centrobasalis**, which occupies a similar position in the dorsal grey column to the nucleus thoracicus but appears in the lower cervical and lumbosacral segments of the spinal cord. These groups have not been clearly established in the human cord.

Lateral to the nucleus dorsalis, and dorsal to the intermediolateral column (7.41), is a small region of nerve cells of medium size, extending throughout the same segments (approximately first thoracic to third lumbar) as the intermediate columns (Takahashi 1913). This columnar group is identifiable in the human cord, but its functional status is uncertain, though it has naturally been associated with the neighbouring autonomic nerve cells.

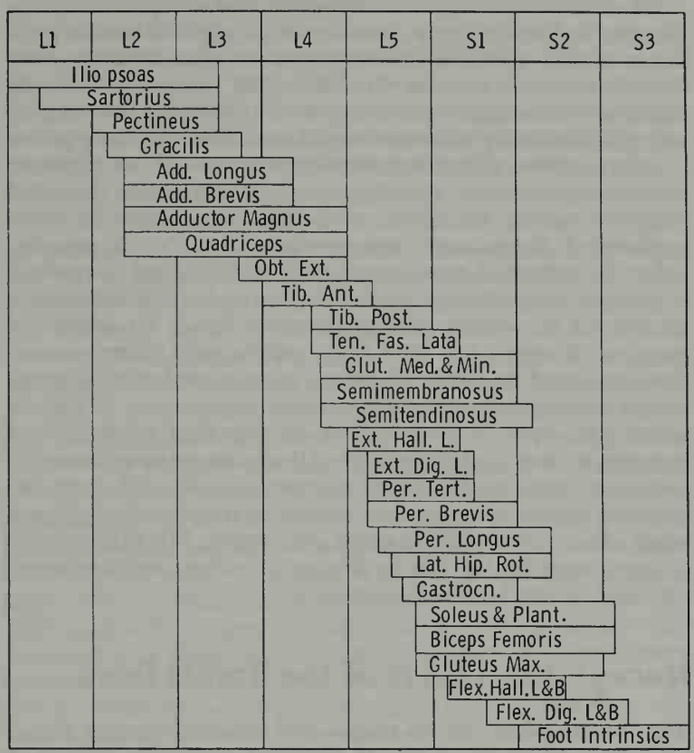
NERVE CELL GROUPS OF THE INTERMEDIATE GREY MATTER

The intermediate region of the spinal grey matter (7.40, 41), which includes the lateral grey column, is composed of relatively small nerve cells, many with the features of autonomic preganglionic cells, which develop from elements in the embryonic cord at first dorsolateral to the central canal. Many of these migrate to a position lateral to it and at some little distance from it; these nerve cells constitute the **intermediolateral group**. An **intermediomedial column** is formed from nerve cells which remain nearer to the central canal. The intermediolateral group forms the projecting lateral grey column proper, and a large proportion of its cells send axons into the ventral spinal roots and via the white rami communicantes to reach the sympathetic trunk (p. 1123); preganglionic nerve fibres are similarly derived from some of the cells of the intermediomedial group (the remainder being interneurons). Both groups extend from the eighth cervical or first thoracic segment as far as the second or third lumbar, thus corresponding approximately to the thoracolumbar outflow. In the second, third and fourth sacral segments a similar group of nerve cells, intermediate in position, is the source of the pelvic or sacral outflow of parasympathetic preganglionic nerve fibres (p. 1123). This **sacral parasympathetic grey column** is lateral to the central canal and substantia gelatinosa centralis, in the junctional zone between the bases of the anterior and posterior grey columns. It shows no division into medial and lateral parts, nor does it project from the intermediate grey zone like the thoracolumbar lateral grey column. The emergence of parasympathetic preganglionic nerve fibres from other segments of the cord has been described by Kuré *et al.* (1930), and Sheehan (1933), their cells of origin being ascribed to the basal region of the dorsal grey column and perhaps to be associated with the intermediate grey zone. Such fibres were stated to issue from the cord in *dorsal* roots, to be vasodilator in function, and to form synapses with small multipolar nerve cells in corresponding dorsal spinal root ganglia (Kiss 1932; Kuré *et al.* 1934). These interesting views have not, however, received general acceptance nor any substantial confirmation.

The foregoing description of the arrangement of nerve cells in the spinal cord, which is largely dependent upon the study of material specifically stained to show the *somata* of neurons rather than their processes, has of late been considerably amplified by a *laminar concept* of spinal grey matter organization, an account of which follows below (p. 882). This concept is more widely based upon the interconnexions of nerve cells, and its structural data have been correlated with the results of degeneration experiments to a much greater degree than in the case of the older mode of description outlined above, combining also more aptly with the observations of microelectrode studies. The laminar pattern of organization has thus helped to establish a more precise definition of spinal cord activities, but the two modes of description are not exclusive and, as will become apparent, the older scheme of

7.42A Diagram of the approximate location in the transverse plane, and in longitudinal extent, of the nerve cell groups innervating muscles, chiefly in the leg, in the lumbosacral segments of the human spinal cord. (Based on clinicopathological studies of poliomyelitis, by W. J. W. Sharrard, *J. Bone Jt Surg.*, 1955.)

columnar grouping of nerve cells is in most of its features adaptable into the newer laminar pattern. The latter does, nevertheless, involve some important modifications in regard to the structural relationships between the nerve cells of the dorsal grey column and the fibres of the dorsal roots and spinal tracts, and also involves more precise concepts of functional implications.



There is one aspect of the spatial relationships of nerve cells in the spinal grey matter which so far has scarcely been mentioned; this concerns the significance of cell grouping in the ventral grey columns in relation to individual muscles and movement, and to this attention must now be directed.

THE FUNCTIONAL IMPLICATIONS OF ANTERIOR GREY COLUMN CELL GROUPS

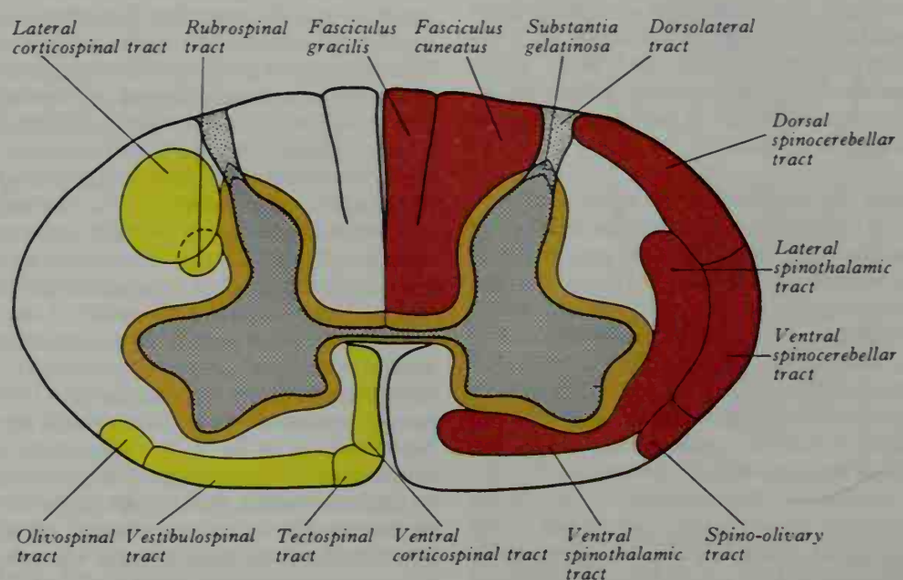
Even in the earliest accounts of the columnar arrangement of nerve cells in the spinal cord—most of which were based on Nissl stained material studied only in transverse sections, and derived from a truly extraordinary miscellany of animals (including tapoles, an ostrich, a gorilla, and occasionally man!)—a somatotopic interpretation of cell grouping in the ventral column was advanced with some confidence (Elliot 1942). Thus, it was an early tenet of such speculations that the medial groups innervate axial musculature (supplied by posterior primary rami), the limbs being innervated from the lateral groups. This attractive hypothesis, originally based entirely on structural data, has in fact been confirmed to some degree by subsequent experimental work, as will appear below. The criticism has been made that few of the investigators in this field have observed the grouping of ventral grey column cells in longitudinal sections, and that the errors which may arise in tracing elongated aggregations of cells through transverse series of sections probably account for at least some of the disagreements and variations between the topographical results of many earlier workers. Obviously an agreed pattern of cell groups, free at least from major discrepancies, is a necessary prelude to any attempts to assess how far such grouping might represent, for example, the neurons innervating an individual muscle. Considerable agreement in this regard is apparent in the more recent work on this problem, particularly among observers who have examined the distribution of ventral grey column cell groups in fetal material, where it is agreed that the groups are more discrete and hence more easily identified (Romanes 1941; Elliot 1943). It is also of importance to note that results of this kind were markedly similar in cat and human material, though only one human fetus was examined. On the other hand, the degree of motor cell grouping in the ventral column is much less developed in amphibians and reptiles, or even mammals such as the bat and mole, all of which possess a fairly complex forelimb musculature, than in the whale, in which the same muscle system is much simplified (Romanes 1953). It must be added that these comparative observations are of limited value, having been carried out on a somewhat heterogeneous collection of vertebrates, usually in extremely small series and often single animals, with little reference to taxonomic relationships. Moreover, little new information appears to have been recorded during the last few decades and certainly no major series of observations.

These difficulties must be mentioned in some detail to introduce some element of caution into further consideration of the functional interpretations of the motor neuron groups which undoubtedly occur in the ventral grey column, and not to deny the existence of such patterns. Pattern is always significant, and a topographical pattern certainly exists in the ventral column. The question in the present context is—What is the physiological meaning of cell grouping in this region? That it concerns the innervation of skeletal muscles seems inescapable, and it would appear a relatively simple, if tedious, undertaking to cut the nerves supplying individual muscles and to observe the distribution of the resultant retrograde degeneration in the motor neurons of the ventral columns. Few experimental studies of this kind have in fact been carried out—at least, on an extensive scale—and since they have involved the use of different species of animal and sometimes different levels of the spinal cord, they provide only limited checks upon each other. In an investigation of the lumbosacral region of the cord in cats, in which various peripheral nerves were divided in the hind limb (Romanes 1951), the affected groups of nerve cells were all in the lateral part of the anterior column, and the cells innervating the more distal muscles in the limb were dorsal to the 'motor columns' for proximal muscles. In general terms these findings corroborated the speculations of earlier topographical observers, and limited

THE INNERVATION OF THE LOWER LIMB MUSCLES

7.42B The segmental arrangement of the innervation of the lower limb muscles. (According to W. J. W. Sharrard, *Ann. R. Coll. Surg.*, **35**, 1964.)

experimental confirmation, also in the cat, has been recorded with regard to the anterolateral group of leg muscles (Balthasar 1952). In the former investigation it was concluded that the cell groups identifiable topographically were not usually individual *motor pools*, but more often (but not always) represented a somatotopic grouping of the motor nerve cells innervating muscles involved together in some *common effect on a joint*.



Another investigator has interpreted his experimental results in monkeys as indicating that the ventral column cell groups can be accounted for not only on the above basis, but also and equally well in terms of peripheral nerves, limb segments, and muscles grouped on a morphological or developmental basis (Sprague 1948). In this investigation the effects of division of dorsal and ventral primary rami of spinal nerves were studied both in the segments innervating limbs and at thoracic levels; and this led to a denial of the differentiation of the ventral grey column into medial and lateral groups in thoracic segments. Even in the limb enlargements of the cord, where both groups were admitted to be present, both appeared to be sources of fibres entering dorsal and ventral rami, a direct confutation of the classical view assigning the innervation of axial and limb musculature respectively to the medial and lateral groups (Kaiser 1891). The same worker, in a later communication, re-emphasized his view that the concept of columnar organization of the ventral grey region had become so ingrained as to be a serious source of error in functional interpretation of this part of the spinal cord. While this is perhaps an extreme view, it does at least underline the unsatisfactory state of knowledge in these matters, which require a wider re-investigation in primate animals, a formidable undertaking. More precise and reliable description of the motor neuron groups in the ventral grey column might, of course, prove to be of rather limited interest in functional interpretation, though it would clearly be of

some value when applied in clinical situations involving spinal lesions in mankind. In this connexion it is interesting to note that the effects of poliomyelitis on motor neurons in the ventral column have been correlated by several clinical observers with the distribution of the resultant paralysis. The most detailed report of this kind (Sharrard 1955, 1956) is of special interest, being concerned with human conditions and also a confirmation to a considerable extent of some of the experimental findings in cats referred to above (7.42). It is much to be hoped that further data will be forthcoming from such clinicopathological correlation.

To summarize, it must be admitted that, despite a copious literature reporting a large number of topographical studies and a much smaller succession of experimental investigations, very considerable uncertainties remain to be clarified. That the topographical arrangement of the nerve cells of the ventral grey columns is basically columnar is well established, but many points of imprecision require further study; and perhaps the columnar mode of organization—to some extent inevitable in an elongated structure such as the spinal cord—has been somewhat over-emphasized. Somatotopic organization with respect to muscles, either in individual representation or in functional groupings, appears to be confirmed in general terms; but the evidence is against the occurrence of discrete motor pools for individual muscles, of which few have been satisfactorily demonstrated. Overlapping of the nerve cell groups of associated muscles seems to be a commoner pattern of functional organization. It may be added that most of the workers in this field of study and experiment have apparently allowed their concentration upon the *somata* of neurons to divert consideration too far from the *dendritic regions* between them, which in simple ratio occupy a much greater volume in the spinal grey matter. It is to this aspect of spinal organization that we shall return after consideration of the 'white matter' in the next section.

Nerve Fibre Tracts of the Spinal Cord

The 'white matter' of the spinal cord consists of nerve fibres, neuroglia and blood vessels. It surrounds the fluted column of grey matter and its whiteness is, of course, due to the large proportion of myelinated nerve fibres. Its arrangement into anterior, lateral and posterior funiculi has already been described (7.36). Its constituent fibres vary much in calibre, large numbers being small and non-myelinated. Some tracts are characterized by fibres of a small diameter, for example the dorsolateral tract, the fasciculus gracilis and the central part of the lateral funiculus. The nerve fibres in the fasciculus cuneatus, anterior funiculus, and the peripheral zone of the lateral funiculus all contain many large diameter fibres. Most regions of the white substance of the spinal cord contain a considerable *spectrum of fibre diameters*, extending from 1 μm or less up to about 10 μm. Fibres with a diameter of 3 μm or less predominate, and those at the upper end of the spectrum (a few of which may exceed 10 μm) form only a small fraction of the total. Detailed studies of the distribution of fibres of differing diameter in the human spinal cord have been few (Häggqvist 1936; Giok 1956), but it has been claimed that many tracts can be identified on this basis alone. The proportion of fibres of particular diameters has been estimated in a few instances (Szentágothai-Schimert 1941), but in general precise data of this kind are lacking. In any case, delineation of tracts by such observations in transverse sections of normal material can only be regarded as valid when confirmed by the results of experimentation. Most of the available information regarding the tracts of the spinal cord is derived from the results of controlled selective damage of fibres in the cord itself, in experimental animals, but the effects of damage to dorsal nerve roots and of lesions placed in the brainstem, cerebellum and cerebrum have also provided much information. In all such experiments retrograde degeneration indicates the nerve cells from which particular fibres proceed, while anterograde terminal degeneration provides the evidence for their sites of termination. Suitable staining to reveal Wallerian degeneration of the fibres at intermediate levels demonstrates the position of a tract and the degree to which its fibres are compacted together, dispersed, or overlapped with others. It must be emphasized at once that, while certain tracts are relatively discrete and the central regions of most are located regularly in definable parts of the funiculi, reciprocal overlapping at least of their fringes (and often much more) is usual (*vide infra*). This accounts in part for the variation in their extent, as seen in diagrams of transverse sections of the cord according to different authorities; in all such diagrams arbitrary boundaries must necessarily be set to delineate the supposed limits of tracts. This is especially true in regard to the human spinal cord; deliberate experimentation is here impossible, and the only data available are the results of disease and injury, neither of which produce the selective and clear-cut kind of lesions possible in animal experimentation. The results of such investigations, particularly when derived from experiments on other primates, can be regarded as likely to be closely similar to the human arrangements; but it would obviously be unwise to accept them as being identical. The evidence collected from examination of the human spinal cord for degenerating nerve fibres resulting from disease or injury does in general support the presumption that the layout of tracts in the human primate is very much the same as in others. The amount of information accumulated from this source is surprisingly large, though usually less precise; it was in fact the

7.43 Simplified diagram of the main tracts of the spinal cord. The ascending tracts are shown in red on the right side of the figure; the descending tracts are shown in yellow on the left side; the 'intersegmental' tracts are in orange on both sides. Many tracts are omitted (see 7.44).

principal source of information at first (p. 817), and a very large number of reports of this kind are scattered through neurological literature (*see* Nathan and Smith 1955, 1959).

The very predominance of data derived from clinical sources has produced a curious vicious circle in associating an observed grouping or *syndrome* of sensory and motor disturbances with injury to or disease in particular regions of the cord—the exact extent of the latter being not invariably assessed with precision. Because some tracts are undeniably concentrated in certain parts of the white funiculi, their delineation has become artificially crystallized. The fringe overlap mentioned above may be quite extensive; some tracts are in fact almost completely mingled, and others are merely a concept, rather than a circumscribed reality, their fibres being scattered far and wide. Experimental observations, pursued in parallel with clinical deductions, have now far outstripped the latter in their recognition of the intermingling of spinal tracts, whose supposed discrete nature is still widely accepted in clinical practice, but this can become an impediment rather than an aid to accurate diagnosis.

The account of spinal tracts which follows is primarily concerned with their arrangement in the human spinal cord, but inevitably reference to findings in animal experimentation must be made at many points where adequate clinicopathological or other data based on human material are not available. In the succeeding section (p. 882), dealing with the finer details of neuronal organization and activity in the spinal cord, evidence derived from animals other than man predominates, but it is improbable that the deductions from this are not largely applicable to the human spinal cord.

As a convenient simplification, the nerve fibres in the white matter of the spinal cord may be assigned to five groups: (*a*) afferent fibres from the cells in the dorsal root ganglia which have entered by the dorsal roots and extend for longer or shorter distances in the cord; (*b*) long ascending fibres, derived from nerve cells in the cord and conducting afferent impulses to supraspinal levels; (*c*) long descending fibres from supraspinal sources which synapse with cord cells; (*d*) fibres effecting intrasegmental and intersegmental connexions; and (e) fibres from the motor neurons in the ventral and lateral grey columns which issue in the ventral spinal nerve roots. Fibres in all these categories except the last form the *longitudinal tracts* of the spinal cord. Arrangements are not, however, as simple as this. Examination of the cord in different planes reveals that many fibres proceed for considerable distances in oblique and even horizontal directions, particularly when crossing the midline, as many do in the grey and white commissures. Many of these are *decussating* fibres, that is to say they are crossing to the opposite side of the cord to continue to some more distant point. Many others are *commissural*, being intrasegmental connexions which link nerve cells in the grey columns on one side of the cord to cells on the other. Moreover, some of the longitudinal tracts are polysynaptic, that is, composed of a train of neurons. Most, if not all, of the fibres entering by the dorsal root divide into ascending and descending branches which both give off a series of collateral branches extending into the grey matter. In the latter the number of nerve cells which either send axons into the ventral roots or into the tracts in the white funiculi is a mere fraction of the total, the majority being local interneurons (p. 885).

In the following account of the spinal tracts an arbitrary order has been adopted, those in the anterior, lateral and posterior funiculi being described in that order; in each region the descending, ascending and intersegmental tracts are successively considered. This is done primarily to present a relatively orderly topographical picture of the arrangement of tracts which is useful in the context of medical diagnosis, and in phylogenetic studies. However, tracts vary somewhat in their relative positions at different levels in the cord, and in different species. For a detailed analysis of tracts in the cat and monkey, and a critical review of some of the difficulties in their determination; *see* Verhaart (1953, 1954); van Beusekom (1955); Verhaart and van Beusekom (1958). The general positioning of the major tracts is illustrated in a simplified form in 7.43 and in greater detail at two spinal levels in 7.44A and B. Some features are further summarized in 7.47A, B and C.

TRACTS IN THE ANTERIOR FUNICULUS

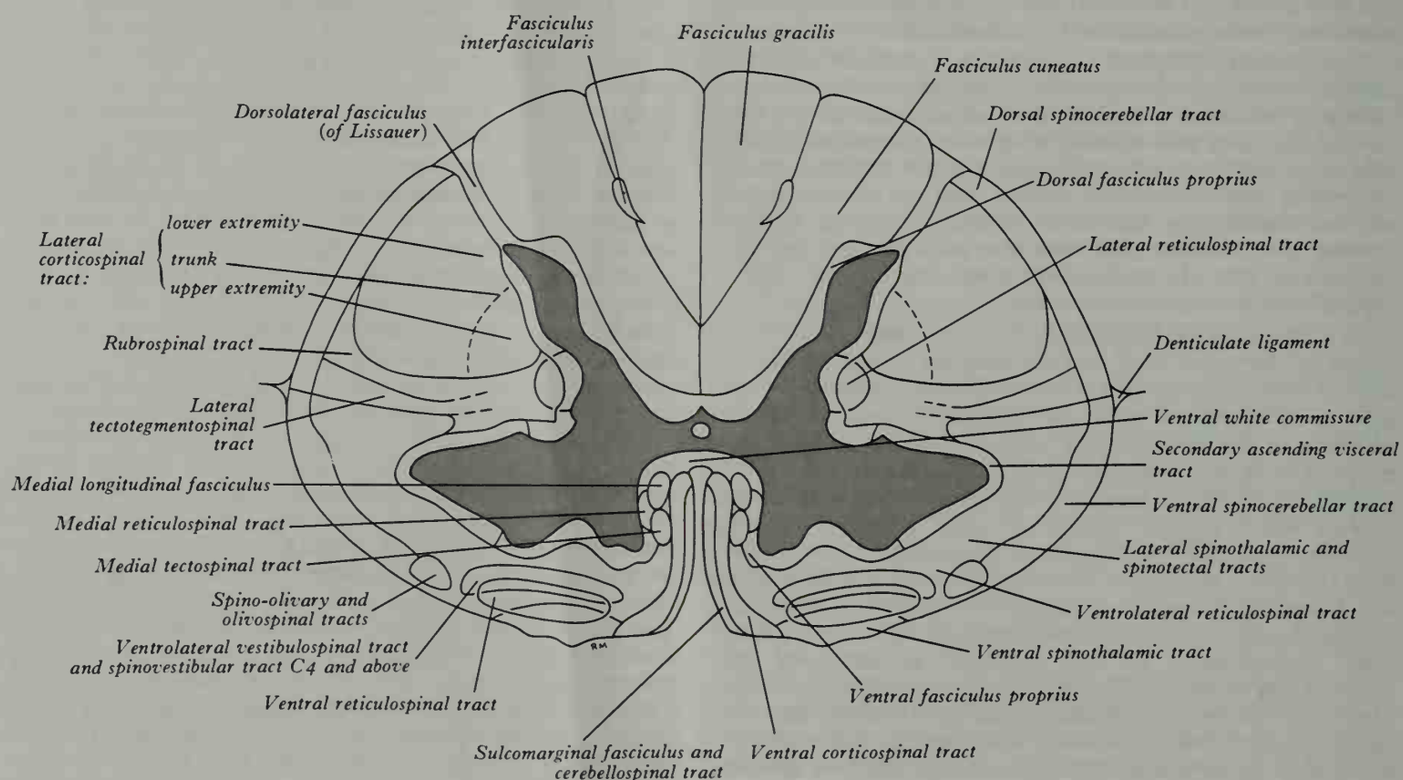
1. Descending Tracts

(*a*) **The anterior corticospinal tract** is usually small, but varies in size inversely with the lateral corticospinal tract. It lies alongside the anterior median fissure, from which it is separated by the sulcomarginal fasciculus (*vide infra*). It is present in the upper part of the spinal cord, gradually diminishing in size as it descends; it cannot be traced below the middle of the thoracic region. The origin and termination of its constituent fibres are considered with those of the lateral corticospinal tract (p. 877). This tract is found only in primates; its precise significance is unknown; it is subject to much variation (Nyberg-Hansen and Rinvik 1963); it may be absent or it may, very rarely, contain all the corticospinal fibres. Usually it is composed of about 10–30 per cent of them. Its variations have been said to accord with its late phylogenetic and ontogenetic development (Humphrey 1960).

(*b*) **The vestibulospinal tract**, which is principally derived from both the large and small cells of the lateral vestibular nucleus (p. 908), descends along the periphery of the anterior funiculus; its fibres end around cells in the anterior grey column. This tract is uncrossed and brings the anterior column cells under control of the vestibular nuclei of the same side, serving as an efferent pathway for equilibratory control. The most medially situated fibres of the vestibulospinal tract have, however, been described as starting from cells in the medial and perhaps also the lateral and inferior vestibular nuclei (Rasmussen 1932), though more recent work suggests that only the medial nucleus is a source (Pompeiano and Brodal 1957). These fibres, which pursue a different course in the medulla oblongata, descending in the medial longitudinal fasciculus (p. 939), constitute the *medial vestibulospinal tract*. This tract is partly crossed and probably does not reach lumbar segments of the cord, and may therefore be concerned with the upper extremity and neck alone. In the white funiculus it is dorsal to the tectospinal tract and immediately adjacent to the anterior median fissure (7.43, 44) in the position of the so-called *sulcomarginal fasciculus*. The remainder of the vestibulospinal fibres (i.e. the majority, which are uncrossed and descend from the lateral nucleus) may hence be regarded as a *lateral vestibulospinal tract*, which extends to all levels in the cord. The fibres of both tracts terminate in the medial part of the anterior grey column (laminae VII and VIII, *see* p. 883), and they influence both α and γ motor neurons through interneurons (Gernandt 1959), but there is physiological evidence that some fibres end monosynaptically on motor neurons. Both tracts have been widely regarded as uncrossed, but, as we have seen, decussating fibres have been described in the medial tract. There is some degree of somatotopic representation in the lateral vestibular nucleus.

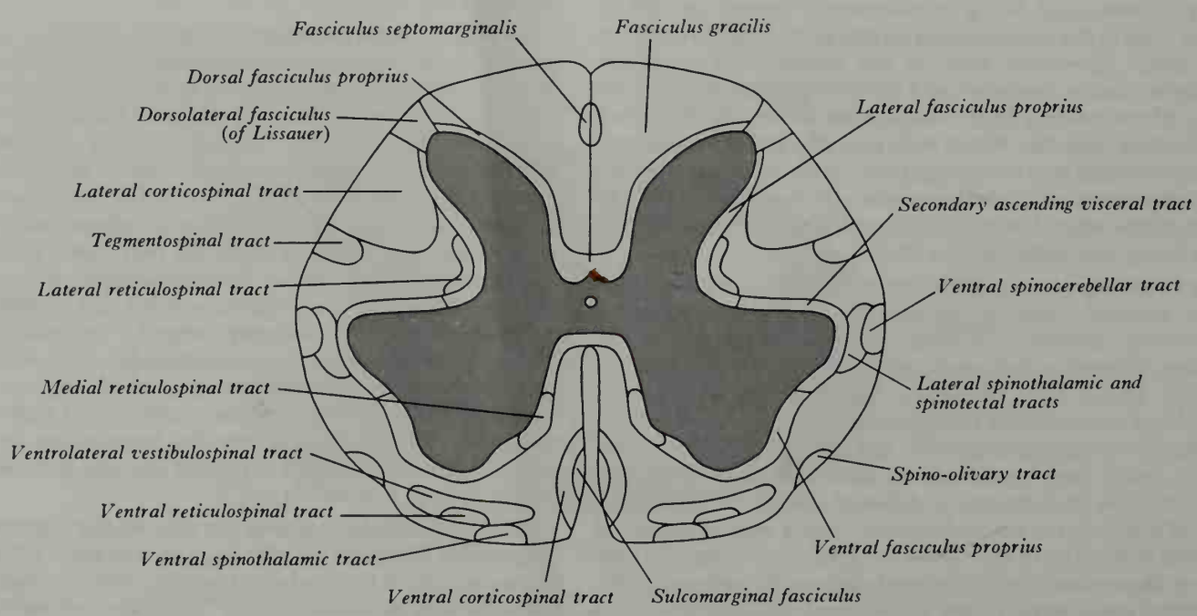
(*c*) **The tectospinal tract** is variably disposed lateral to the anterior median fissure. Its fibres arise in the superior colliculus of the opposite side (p. 941) and end by forming synapses with cells in the anterior grey column, especially in the cervical segments of the cord. These fibres influence motor neurons through interneurons (Szentágothai 1948), their terminations being probably in laminae VI–VIII (p. 883). The contralateral origin of this tract now seems well established; suggestions of a bilateral origin from the superior colliculi may have arisen through confusion with the *lateral tectotegmentospinal tract* of some authors. When the latter is recognized, the tectospinal fibres which descend in the anterior funiculus are often termed the *medial tectospinal tract*. Autoradiographic fibre-tracing experiments in primates (Frankfurter *et al.* 1976) suggest that only a minority of the fibres in this descending tectal pathway actually reach the spinal cord, the majority terminating in relation to various brainstem nuclei. For further discussion of the tectospinal systems *see* pp. 879 and 941.

(*d*) **Reticulospinal fibres** are also widely scattered through the anterior funiculus, chiefly in its medial part. They arise from the nerve cells of the ipsilateral pontine reticular nuclei (p. 945), but some may decussate shortly before their spinal terminations (Torvik and Brodal 1957). They descend throughout the cord in the anterior funiculus and probably end as synapses with interneurons in the medial part of the ventral grey column



(laminae VII and VIII; *see* Nyberg-Hansen 1965, and p. 888), through which they possibly exert a facilitatory effect on motor neurons. This tract is commonly known as the *medial* (pontine) *reticulospinal tract*, its origin in the pons corresponding in level to the 'facilitatory area' of many physiologists. (Contrast the lateral reticulospinal tract—p. 879.) These details are entirely derived from observations in non-human tissues; for a discussion of the reticulospinal tracts in man *see* Nathan and Smith (1955), Brodal (1957), Webster (1978); further details are also furnished on pp. 946, 947.

(*e*) **The interstitiospinal tract** has its origin in the interstitial nucleus (p. 939) and its fibres descend without crossing into the medial longitudinal fasciculus (p. 939), and thence into its spinal continuation, the ipsilateral fasciculus proprius (anterior intersegmental tract). In the cat the tract is claimed to be traceable to sacral levels (Nyberg-Hansen 1966), but no such details are available for the human spinal cord, although the tract as an entity has long been recognized (Muskens 1914).



(*f*) **The solitariospinal tract** (of Cajal 1909) is a small group of descending fibres which may originate in the neurons of the caudal part of the solitary nucleus (p. 903); it has been best demonstrated in the cat (Torvik 1957), and has been equated with part of the medial reticulospinal tract by another authority (Crosby *et al.* 1962). It was named by Cajal and may be involved in visceral reflexes involving the oesophagus and stomach.

2. Ascending Tracts

The anterior spinothalamic tract is in fact continuous with the lateral tract of the same name, but may be considered to be the part of this complex in the anterior funiculus, medial to the fibres

A

B

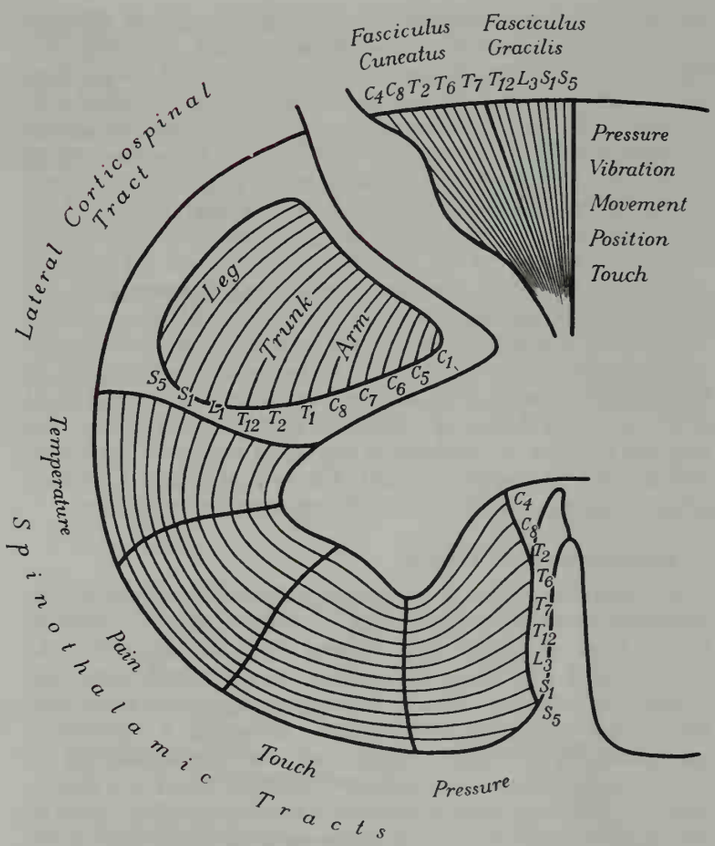
of the ventral nerve roots and dorsal to the vestibulospinal tract (7.43), which it overlaps, as it does all its neighbours. It has been claimed, largely on clinical evidence, that it is chiefly concerned with crude tactile and with pressure sensibility (but this does not wholly accord with recent physiological investigations—pp. 890, 958). According to Applebaum *et al.* (1975) segregation upon a modality basis, within the anterior/lateral spinothalamic complex is not supported by experimental data, and the two tracts are to be considered as a continuum, both structurally (as stated above) and also in the functional sense. However, as noted below, the neurons from which spinothalamic axons are derived are diverse in distribution and in the modalities which they subserve. It is therefore no longer possible to consider simple segregations of sensory mediation either in the spinothalamic system or other ascending tracts. Nevertheless, the physiological characteristics associated with the neurons in the laminae of origin of spinothalamic projections provide some indications. Thus, cells in laminae I and V respond to 'noxious' mechanical and thermal stimuli, applied cutaneously, and some lamina V cells are associated with non-noxious cutaneous stimuli. Laminae VII and VIII are concerned with muscular and articular receptors, and some show responses on cutaneous stimulation. The precise locations of the nerve cells of origin of this tract are subject to much controversy; they have usually been described as 'secondary neurons' situated in the dorsal grey column which receive direct synapses from the axons which enter via the dorsal roots from the primary sensory neurons in the dorsal root ganglia. Since the investigations of Cajal it has been known that some neurons in all regions of the grey matter (dorsal and ventral columns, and the intermediate zone) have axons which cross the midline and ascend in the anterolateral white funiculus. More recently, investigators using Golgi techniques have claimed that these are particularly concentrated in spinal cord laminae IV–VII and especially lamina V; but there are also contributions from the pericornual cells superficial to the substantia gelatinosa (lamina I) and also from lamina VIII (*see* Webster 1977, for literature). Physiological experiments have corroborated some of these details in the cat and the rat (Dilly *et al.* 1968). Electrical stimulation of the region where the medial lemniscus and spinothalamic systems enter the thalamus was accompanied by intracellular recording of antidromic responses from the various grey matter laminae in the cord. Responsive cell somata were identified in laminae V and VI, and this provides some confirmation of the origin of the spinothalamic tracts; but it should be noted that with the limited sampling inherent in such a technique, responding cells in other laminae may well have been missed. Further, it is by no means certain that all spinothalamic fibres are the axons of 'secondary neurons'; in some cases one or more interneurons may be interposed between the primary dorsal root afferents concerned and the spinothalamic tract neuron.

The evidence from cordotomies in man and from other sources suggests that most of the fibres cross the cord, probably within a single segment above their origin, the decussation being in the anterior white commissure. Although physiological studies (p. 890) suggest some spatial separation of neuronal elements concerned with different combinations of the sensory modalities associated with the spinothalamic tracts in the dorsal grey column, the arrangement of the ascending fibres in these tracts has long been regarded as somatotopic (Nathan 1963; Morin *et al.* 1951). Fibres crossing at any particular level join the medial aspect of those already ascending on the contralateral side of the cord, so that both tracts are segmentally laminated (7.45), fibres originating in lower segments, and therefore of greater total length, being most superficial. In addition a slight spiral twist is said to occur, the more superficial fibres being progressively more dorsal in position as the tracts ascend the cord. This arrangement is continued through the medulla and pons to the nucleus ventralis posterior lateralis of the thalamus (p. 958). However, the precise mode of arrangement of these fibres, whether somatotopic, dermatomic, or otherwise is by no means certain. Intermingling with the anterior spinothalamic fibres are not only descending *reticulospinal fibres*; already mentioned, but also numbers of ascending *spinoreticular fibres*. It is possible that the spinothalamic fibres give off collaterals to the brainstem reticular nuclei, but it is now considered that the majority of their afferents form separate spinoreticular pathways, some of which are probably polysynaptic in nature. As in the case of other ascending tracts, there is definite physiological evidence that the spinal cells of origin of the spinothalamic tracts, or their associated interneurons, may be selectively inhibited by fibres descending from nerve cells in the sensory and motor parts of the cerebral cortex, in the anterior cerebellar lobe, and certain regions of the brainstem reticular formation; but the spinal distribution and sites of termination of these inhibitory fibres have not yet been clarified. Consult Carpenter *et al.* (1963) and Webster (1977) for details. Finally, mention should be made of a small *spinovestibular tract* which is intermingled with the vestibulospinal system, and which conveys both exteroceptive and cutaneous information to the vestibular nuclei. This tract may be confined to cervical levels of the cord; the degree of crossing of its fibres is uncertain, but they are thought to terminate in restricted regions of the lateral and descending vestibular nuclei. The cells of origin of the tract probably correspond to those of the spinocerebellar system.



3. Intersegmental Tracts

The remaining fibres of the anterior funiculus constitute the **anterior intersegmental tract**. It consists of intersegmental fibres, some of which have crossed from the opposite side. Intermingled with them are believed to be reticulospinal and descending autonomic fibres. The tract is continuous above with the medial longitudinal fasciculus. Although it is perhaps preferable to combine together all the intersegmental or propriospinal fibres in the anterior funiculus under one term, a number of separate entities have been described in this region by the classical neuroanatomists of the past, as in the case of the propriospinal tracts elsewhere in the cord (Nathan and Smith 1959), and the finer details of distribution of such fibres will be briefly considered with the dorsolateral tract (p. 881).

TRACTS IN THE LATERAL FUNICULUS

1. Descending Tracts

(*a*) **The lateral corticospinal tract** extends throughout nearly the whole length of the spinal cord. It gradually diminishes in size as it descends, and it ends about the level of the third or fourth sacral segment. On transverse section it occupies an oval area anterolateral to the posterior grey column and medial to the posterior spinocerebellar tract (7.44); in the lumbar and sacral regions, where the posterior spinocerebellar tract is absent, the lateral corticospinal tract reaches the surface of the spinal cord. The anterior and lateral corticospinal tracts are widely accepted as important motor pathways in the spinal cord, but in recent years physiological experiments have focused attention on other important functional associations of these pathways (pp. 890, 891). They contain about a million fibres of varying diameter, 70 per cent of which are myelinated. About 90 per cent of the fibres have a diameter of 1–4 μm, about 9 per cent are from 5 to 10 μm and less than 2 per cent range from 11 to 22 μm. However, it should be noted that here, as at many other points in the nervous system, these figures, and particularly those concerning the small-diameter fibres, may well need substantial revision in the future, when systematic quantitative studies using the electron microscope have been carried out. Many of the fibres arise from cells in the motor area (area 4 of Brodmann) in the frontal lobe; the thicker fibres (11–22 μm in diameter) are believed, from cell and fibre counts, to be the axons of the giant pyramidal cells of Betz (p. 1007). Some of the fibres come from other layers in area 4, but experimental evidence shows that at least two-thirds of the corticospinal fibres arise elsewhere. A number start from other cortical areas in the frontal and parietal lobes, especially areas 3, 1, 2 and 6 of Brodmann. However, the origin of about 50 per cent only of the total number of fibres can be thus explained (Lassek 1954). All the fibres descend through the internal capsule of the cerebrum, traverse the cerebral peduncle and pons and enter the pyramids of the medulla oblongata. In the lower part of the medulla oblongata a variable number, usually about two-thirds, cross the median plane and turn caudally in the lateral funiculus of the spinal cord as the *crossed lateral cortiospinal tract*, while the

7.45 Diagram to illustrate the general plan of segmental organization of the fibres in the posterior funiculus, the lateral corticospinal tract and the lateral and anterior spinothalamic tracts. The probable cross-sectional areas of these tracts are enlarged to provide adequate space. (After Dr. O. Foerster, by kind permission of Springer Verlag, Berlin.)

remainder do not cross but are continued into the same side of the spinal cord, where they form the *anterior corticospinal tract*. The lateral corticospinal tract also contains some fibres which are derived from the cerebral hemisphere of the same side (*uncrossed lateral corticospinal fibres*)–*see* Fulton and Sheenan (1935).

The corticospinal tracts, anterior and lateral, thus defined, have commonly been described as the *pyramidal* pathway, a usage which is likely to persist. It is true that they consist of the fibres which pass through the pyramids of the medulla oblongata (p. 898), but the same expression is sometimes also made to include *corticobulbar* fibres which diverge cranial to this level to terminate in association with the motor nuclei of the cranial nerves (p. 996). But the chief objection to the continued use of the term 'pyramidal' lies elsewhere. The corticospinal tracts have a single distinction, in that they descend without interruption from cerebral cortex to a termination in the spinal grey matter; and in this they have become contrasted with a group of other descending tracts, such as the rubrospinal and vestibulospinal and others, the fibres of which form intermediate synapses with nerve cells in the cerebrum and brainstem, and which have been collectively labelled as 'extrapyramidal'. The functional distinction between these so-called 'systems' is rapidly becoming blurred, and clinical concepts based upon them are in process of gradual dissolution. The more recent revelation of the reticular system (p. 943) has added further confusion, because in both structural and functional details it overlaps much of the 'extrapyramidal' system. The latter concept is probably to be regarded as obsolescent, and for this reason the term 'pyramidal' is perhaps also better avoided.

Throughout its course in the cerebrum and brainstem, with the possible exception of the pons, somatotopic arrangement of its fibres has been established, chiefly as a result of clinical observations in man (7.45). The details of this arrangement will be described in the appropriate sections below. Whether the same kind of distribution obtains in the medullary pyramids and spinal cord is a matter of controversy (Foerster 1936; Barnard and Woolsey 1956), but in the cord the longer fibres are said to be most superficial, the shorter ones being internal to them. The majority of the corticospinal fibres, in both ventral and lateral tracts, probably terminate in synapses with interneurons situated in the basal part of the dorsal grey column and spreading ventrally from this through the intermediate zone into the ventral grey column, laminae IV–VII (*see* p. 883; and Hoff and Hoff 1934; Chambers and Liu 1957; Nyberg-Hansen 1969). In these experimental investigations, mostly in cats, no corticospinal fibres were traced as far as motor neurons; but monosynaptic connexions of this kind have been described in monkeys (Liu and Chambers 1964), and it is presumed that such findings indicate similar arrangements in the human spinal cord, perhaps in greater numbers. Nevertheless, it appears certain that the majority of corticospinal fibres, which influence motor neurons innervating skeletal muscle, do so through polysynaptic chains of interneurons. Physiological evidence suggests that this influence is facilitatory with regard to flexors and inhibitory in the case of extensors—the reverse of the effects mediated by the lateral vestibulospinal tract (p. 875). Both α and γ motor neurons are influenced by corticospinal fibres. There is some evidence that corticospinal fibres from the precentral or motor cortex terminate in a more ventral position than those from the postcentral or sensory area (Scheibel and Scheibel 1966), and a considerable number of them (perhaps up to one quarter in some cases) reach their termination without crossing the midline. The influence of corticospinal fibre activity on the transmission of sensory information has been mentioned elsewhere (pp. 890, 892). The nature of the modifications of sensory input thus effected have been discussed *in extenso* by Schmidt (1973), Gordon (1973), Tone (1973), and McCoskey and Torda (1975).

For the most detailed review of the evolutionary status, neuroanatomy, electrophysiology and possible functional roles of corticospinal neurons in general consult Phillips and Porter (1977).

Ascending spinopontine and *spinocortical fibres* have been described in both the anterior and the lateral corticospinal tracts in the cat (Walberg and Brodal 1953) and in man (Nathan and Smith 1955), derived from all levels of the spinal cord, but especially from cervical segments. They may be concerned in the transmission of cutaneous afferent information (Brodal and Walberg 1952). These circumstances add further confusion to the traditional concepts of 'pyramidal' and 'extrapyramidal' systems.

(*b*) **The rubrospinal tract** is composed of nerve fibres of variable diameter which descend from large and small cells in the red nucleus; immediately caudal to this they decussate, and in the lateral funiculus they form a relatively compact band ventral to the lateral corticospinal tract (7.43, 44). Similar fibres have been said to be derived from other nerve cells in the tegmentum of the midbrain caudal to the red nucleus, constituting a *tegmentospinal tract* associated with the ventral border of the rubrospinal tract (Woodburne *et al.* 1946). The latter was first established in the cat, in which animal it has been most extensively studied; but it is also well authenticated in the macaque monkey, and in both these species it descends through the whole cord to lumbosacral levels. It is important to note that fibres from the smaller nerve cells of the red nucleus reach the most caudal segments of the cord. Because an erroneous view was at one time current that only the largest cells in the nucleus (p. 938) were the source of such long fibres, and since there are few large cells in the human red nucleus, a persuasion has gradually developed that the rubrospinal tract is negligible in man, an opinion doubtless aided by the dearth of information from clinical observation (Nathan and Smith 1955). Since the tract is well attested in the monkey and chimpanzee, it may exist in mankind; and although the details stated here apply to other mammals, it is wiser to maintain an open verdict as regards the human condition.

In their origins from the red nucleus the rubrospinal fibres show, in the cat (Pompeiano and Brodal 1957), a somatotopic arrangement on a dorsoventral plan, the shortest fibres arising in the most dorsal cells and proceeding to cervical levels in the cord to influence, presumably, the muscles of the neck and upper limb—probably through intermediary neurons. The axons of the most ventral rubral nerve cells are considered to be concerned

with the movements of the lower limbs. Some of the fibres leave the tract in the brainstem to influence the motor neurons of cranial nerves, possibly through interneurons in the reticular formation, and some of these *rubrobulbar* axons may reach the ipsilateral inferior olivary nucleus (Walberg *et al.* 1958).

The distribution of the terminals of the rubrospinal fibres is similar to that of the corticospinal tract, largely to laminae V–VII (7.47B), except that the rubrospinal terminals do not extend quite so far ventrally, none reaching the motor neurons. This spatial overlap of the terminals of the two tracts suggests a close interaction of their effects on the motor neurons through a common interneuron pool. It is worthy of note here (see also p. 938) that the red nucleus receives afferent fibres not only from the cerebellum but also from the cerebral cortex, including the 'motor' cortex (area 4) and other areas which are concerned in the origins of the corticospinal pathway. This corticorubral projection displays a somatotopic arrangement in the cat (Mabuchi and Kusama 1966) and in primates (Kupyers and Lawrence 1967) similar in its details to the corticospinal pathway. Both tracts appear to exercise somewhat similar effects on the spinal motor neurons, such as facilitation of those concerned with flexor musculature; and it is therefore probably misleading to separate them, either in physiological or clinical thinking, as 'pyramidal' and 'extrapyramidal'. However, it would be premature to formulate a revised outlook upon these tracts and their funcitoning *in man*, despite the highly suggestive data available from investigations in other primates.

It is appropriate to mention here that the cells of origin of the *tegmentospinal fibres* mentioned above are thought to receive the synaptic terminals of *tectotegmental fibres* from the superior colliculi of both sides. Further, some direct tectospinal fibres from both colliculi may accompany the tegmentospinal fibres. This complex of descending fibres (which are closely associated topographically with the rubrospinal system) are accordingly often grouped as the *lateral tectotegmentospinal tract*.

(*c*) **The lateral reticulospinal tract** is usually described as medial to the rubro- and corticospinal fibres, but its constituent fibres are to some degree dispersed among those of the neighbouring tracts, and in some experimental mammals, reticulospinal fibres have been demonstrated descending lateral to the rubro- and corticospinal fibres (*see* 7.47C). This description applies to experimental animals, for although there is little doubt that reticulospinal pathways exist in the human spinal cord, there is as yet little direct evidence of this. The lateral reticulospinal tract differs in several characteristics, anatomical and physiological, from the medial tract (p. 875). Its axons are largely derived from large nerve cells in the medullary zone of the brainstem reticular formation (*nucleus reticularis gigantocellularis*), but also from smaller cells, this origin according with the varying diameters of the reticulospinal fibres. In contrast with the pontine reticulospinal fibres in the anterior funiculus, the lateral tract is largely crossed, but some fibres also remain on their side of origin. Each half of the medullary reticular formation hence exerts a distinctly bilateral effect on the spinal cord. The terminals of the lateral, like the medial reticulospinal tract, form synapses with interneurons in the intermediate grey region and the medial zone of the anterior grey column, but they are more dorsal in position (chiefly lamina VII), though some may reach motor neurons (lamina IX). These details apply chiefly to the cat (Nyberg-Hansen 1965), and in the same study it was established that reticulospinal fibres descend to all levels of the cord, contrary to earlier views (Torvik and Brodal 1957). The medullary origin of the lateral reticulospinal tract approximates in extent to the brainstem 'inhibitory area', and this again contrasts with the facilitatory effect of the medial tract. In addition to these motor influences, which extend to both α and γ neurons in the activities of the medial and lateral tracts, the reticulospinal axons may also modify the transmission of afferent impulses. (See also 7.47C and pp. 943–953 for details and bibliography concerning the pontobulbar origins of reticulospinal tracts, their aminergic/non-aminergic status, and further comments concerning possible functional roles.)

(*d*) **Descending autonomic fibres**, mediating both direct and crossed connexions between brainstem visceral 'centres' and the preganglionic nerve cells of the spinal cord, must obviously exist, as is attested by an abundance of physiological evidence. Nevertheless, accurate knowledge of their positions and terminations in the spinal cord is exiguous and conflicting. That such fibres are predominantly in the lateral funiculus is generally agreed, but it is likely that a smaller number also descend in the anterior funiculus. The failure of experimental efforts to define any compact groups of degenerating nerve fibres in the spinal cord as a result of hypothalmic or brainstem lesions has naturally led to the concept that descending autonomic connexions are diffusely dispersed through the cord. But individual investigations have associated them with the lateral corticospinal, reticulospinal and intersegmental tracts, and have also assigned some of them to a superficial position in the lateral funiculus (Enoch and Kerr 1967). The descending pathways are considered to consist for the most part of small-diameter fibres, probably arranged in polysynaptic chains. Since lesions which were supposed to interrupt reticulospinal fibres have been associated with disturbances of visceral function, such as vasomotor and sudomotor control (Johnson *et al.* 1952), it is probable that some of these fibres are to be regarded as autonomic. Vasomotor changes can be elicited by stimulation of the precentral area of the cerebral cortex, and there is thus a possibility that some corticospinal fibres are autonomic in function. In sum the evidence, much of it negative in character, suggests that the descending autonomic fibres are dispersed through much of the anterolateral region of the cord; hence lesions in any part of this are likely to be associated with disturbance of visceral control.

(*e*) **The olivospinal tract** (of Helweg) is described in considerable detail in most textbooks, and these descriptions are markedly uniform in assigning it to a small triangular area, as seen in transverse spinal sections, immediately lateral to the most lateral of the issuing ventral root fibres. It is said to be confined to upper cervical segments, and to contain fibres which end in the ventral grey column, and also fibres which form an ascending *spino-olivary tract* (*see* p. 881, and Jansen and Brodal 1954). The olivospinal tract was identified in the human spinal cord, but there appears to be no experimental evidence that its axons are in fact derived from the nerve cells of the inferior olivary nucleus (Brodal 1969). Because of this uncertainty it has been suggested that the tract be named *bulbospinal*, but this merely displaces the uncertainty elsewhere. These conflicting views serve to emphasize the need of further evidence in this matter.

2. Ascending Tracts

(*a*) **The posterior spinocerebellar tract** is a flattened band situated at the periphery of the posterior region of the lateral funiculus; medially it is in contact with the lateral corticospinal tract, dorsally with the dorsolateral tract. It begins about the level of the second or third lumbar nerve, increases in size as it ascends, and finally passes into the cerebellum through the inferior cerebellar peduncle. Its fibres are the axons of the cells of the ipsilateral thoracic nucleus. This nucleus receives *afferent* impulses from two sources. (1) Many of the long ascending fibres of the posterior funiculus give off collaterals which form synaptic connexions with the cells of the thoracic nucleus. (2) Terminals of the intermediate ascending fibres of the posterior column may behave in the same way, especially in the thoracic segments of the spinal cord. It is uncertain which of these two sources preponderates in the formation of the posterior spinocerebellar tract.

(*b*) **The anterior spinocerebellar tract**, as identified in transverse section, is a crescentic, flattened tract which occupies the periphery of the lateral funiculus, in front of the area occupied by the posterior spinocerebellar tract. The precise origin of its constituent fibres cannot be regarded as settled, but they are usually said to be derived from the large cells of the posterior grey column. They are therefore secondary neurons on the spinocerebellar pathway. The primary neurons concerned are probably similar to those described above in connexion with the posterior spinocerebellar tract, but the ascending axons of the secondary neurons are mostly derived from the opposite side of the spinal cord, only a small proportion ascending on the ipsilateral side (Jansen and Brodal 1954). Experimental evidence indicates that

the 'secondary neurons' are in fact sited dorsolaterally in the *ventral* grey column (Ha and Liu 1968). The tract commences in the upper lumbar region and extends upwards to cranial pontine levels, where it turns to descend dorsally in the superior cerebellar peduncle to reach the cerebellum.

The fibres in the spinocerebellar tracts have a laminated arrangement, with those carrying impulses from the lower limb being placed most superficially (Yoss 1952/3; Smith 1957). They convey to the cerebellum both exteroceptive and proprioceptive impulses arising in receptors of the skin and locomotor apparatus which are essential for the adjustments of muscle and for synergic control during the performance of voluntary movements. As already stated (p. 870), the thoracic nucleus diminishes in size as it is traced upwards, and does not extend cranial to the first thoracic or last cervical segments. It would appear, therefore, that the posterior spinocerebellar tracts are concerned chiefly with the trunk and lower limbs, and evidence has been adduced to show that the corresponding proprioceptive impulses from the upper limbs travel by the posterior external arcuate fibres which originate in the accessory cuneate nucleus in the medulla oblongata (p. 899), forming a *cuneocerebellar tract*. In addition to the classical spinocerebellar pathways there is considerable evidence for at least two indirect projections, interrupted by synapses in the inferior olivary and lateral reticular nuclei of the medulla, both of which have been shown to project to the cerebellum, receiving their afferents respectively from the dorsal funiculi and the spinothalamic tracts. Consult Brodal (1969) for further details and discussion.

It has long been established that the spinocerebellar tracts convey proprioceptive information; more recently physiological evidence has demonstrated that the posterior, or dorsal, tract also mediates impulses from touch and pressure endings. Both tracts display a marked somatotopic termination in the cerebellum in experimental animals, including monkeys, and in man an arrangement which will be considered in greater detail later (p. 928). The posterior spinocerebellar tract ends in an area of cerebellar cortex concerned with the hind limb, while its associated cuneocerebellar tract reaches a fore-limb area. Ventral spinocerebellar fibres end only in the hind-limb area; but physiological evidence (Oscarsson and Uddenberg 1964; Oscarsson 1965) indicates the existence of ascending fibres functionally associated with the anterior spinocerebellar tract and serving tendon stretch receptors in fore-limb muscles; this has been tentatively named the *rostral spinocerebellar tract*. A spinocerebellar projection concerned with proprioceptive information from neck muscles has been described as originating in the *nucleus cervicalis*. This entity, chiefly identifiable in young animals and not satisfactorily described in the human spinal cord, exists at high cervical levels only. According to Cummings and Petras (1977) cerebellar ablations in newborn dogs are followed by a retrograde response in cells of this nucleus, and in particular in the *nucleus cervicalis centralis*, and not in the *nucleus cervicalis lateralis*, as was claimed by Rexed and Brodal (1951). Petras (1977) has investigated the spinal origins of spinocerebellar tracts in monkeys, by parallel observations of retrograde degeneration and retrograde horseradish peroxidase transport; these studies yielded similar results. (See also below.)

Some of the neuronal somata which contribute to the spinocerebellar tracts have been studied using intracellular recording techniques. Some receive the termination of only one type of exteroceptive or proprioceptive afferent, whilst others show a convergence and interaction of different types of afferent upon single cells. Their impulse transmission characteristics are modified by activity in tracts which descend from the brainstem.

(*c*) **The lateral spinothalamic tract**, which lies medial to the anterior spinocerebellar tract in the lateral funiculus of the spinal cord, as noted above (p. 879), is continuous with the anterior spinothalamic tract. As in the case of the ventral part of the tract, in the anterior white column (p. 876), it should be noted that the simple zonal, 'modality-specific' pattern of fibres, still widely ascribed to be spinothalamic tracts, contrasts sharply with the great variation in physiological responses of the cell types investigated in the grey matter laminae IV–VII, some of which probably give rise to spinothalamic fibres. As we shall see (pp. 890, 891), these variations include marked differences in the size, characteristics, specificity and somatotopic mapping of the receptive fields of the different cells, and in the degree of convergence of different functional types of primary afferent fibre on to single interneurons. In view of this, it seems likely that some, at least, of the spinothalamic fibres transmit complex patterns of information, and the assumption that they are all modality-specific is certainly an oversimplification. (Reference is made to the possible role of the substantia gelatinosa in the pain pathway on p. 890.)

The somatotopic lamination of the anterior spinothalamic tract is also evident in the lateral. This arrangement is of considerable practical importance to the neurosurgeon, and it is maintained throughout the passage of the lateral tract through the medulla oblongata and the pons. In the midbrain, however, the fibres from the lower limbs extend dorsally, and in this part of their course it is possible for the surgeon to divide the pain and temperature fibres from the upper limb and trunk without injury to the corresponding fibres of the lower limb (Earl Walker 1942).

Although it is generally accepted that the lateral spinothalamic tract is the predominant pathway for somatic pain and thermal sensibilities, it has not infrequently been suggested that an alternative pathway may exist and is provided by a series of intersegmental fibres with their neuronal bodies situated in the grey matter of the spinal cord (p. 946). In addition, the spinotectal tract has been regarded by others (e.g. Earl Walker 1943) as an alternative pathway for painful and thermal sensibility.

It is convenient to add at this juncture a brief reference to the *spinocervical tract* and an associated *spinocervico-thalamic system* of connexions. The *lateral cervical nucleus*, though small in man, is an accepted entity and is situated in the lateral funiculus lateral to the dorsal grey column in the upper two cervical segments of the cord (*see* Truex *et al.* 1970). The tract is derived from nerve cells in the dorsal grey column, particularly from laminae IV to VI, among those giving rise to axons of the spinocerebellar tracts. It extends upwards from lumbosacral levels. The further projection from the lateral cervical nucleus was at first considered to enter the cerebellum, but the most recent anatomical and physiological studies indicate that the axons from the cells in this nucleus ascend with the medial lemniscus to the nucleus ventralis posterior lateralis of the contralateral thalamus, that they mediate light tactile and pressure modalities of sensation (and perhaps also joint sensibility), and are hence for the present to be associated with the spinothalamic system (Morin and Catalano 1955; Ha and Liu 1966). Some of these neurons may also respond to noxious stimuli (Brown and Gordon 1977). Interestingly, a column of nerve cells, considered to be identical with the lateral cervical nucleus, has been described in the rat as extending throughout the spinal cord (Gwyn and Waldron 1968).

Little definite information is available concerning the pathway followed by impulses arising in connexion with painful pathological conditions of viscera. It has been clearly shown that the first neuron fibres travel in the splanchnic nerves, and it seems certain that they enter the spinal cord via white rami communicantes and dorsal spinal roots. Whatever pathway they follow in the spinal cord they are all interrupted by the operation of bilateral cordotomy of the lateral funiculi carried out at the level of the first thoracic segment (Hyndman and Wolkin 1943) and on this account it has been suggested that they travel in the lateral spinothalamic tract. The reader should note that, although hitherto defined as being formed by the union of the lateral and anterior spinothalamic tracts, the spinal lemniscus may now be defined more accurately as the brainstem continuation of the lateral spinothalamic tract alone.

Owing to the fact that the fibres which form the lateral spinothalamic tract cross at once, decussating with the corresponding fibres of the opposite side, lesions affecting the commissural area, such as occur in the disease, *syringomyelia*, produce a bilateral loss of pain and thermal sensibilities for the areas represented in the particular segments involved.

(*d*) **The spinotectal tract** is medial to the anterior spinocerebellar tract and anterior to the lateral spinothalamic tract, the three tracts being intimately related throughout their ascending course in the spinal cord and brainstem. Its constituent

fibres start in laminae of the deeper contralateral grey matter and soon cross the median plane to reach the lateral funiculus. The tract is most easily identified at cervical levels. Its fibres ascend to the midbrain where they terminate in the superior colliculus of the tectum. They provide an ascending pathway for spinovisual reflexes. In this connexion it is to be remembered that the superior colliculi constitute a reflex centre in the visual path and are not concerned with the transmission of visual impulses to the cerebral cortex. Afferent impulses passing up the spinotectal tract result in movements of the head and eyes towards the source of stimulation. However, some fibres topographically associated with the tract pass onwards to the ventral thalamus, and have been considered to mediate cutaneous pain and perhaps other modalities.

(*e*) **The dorsolateral tract** (of Lissauer) is a small strand of fine myelinated and non-myelinated fibres situated between the tip of the posterior grey column and the surface of the spinal cord, close to the dorsal roots. It is formed in part by fibres of the lateral bundle of the dorsal roots which bifurcate into ascending and descending branches. The ascending branches travel one or two segments in the tract; they give collaterals to and terminate around cells in the posterior grey column (pp. 887, 890). Although the dorsolateral tract is present throughout the cord, no fibres travel more than a few segments in it, and it is hence more appropriate to regard it as a *fasciculus*. This is all the more desirable in view of the experimental confirmation (Poirier and Bertrand 1955; Earle 1952; Szentágothai 1964) of an old suggestion (Flechsig 1876) that the tract contains many propriospinal fibres, the contribution from entering dorsal root fibres amounting to no more than 25 per cent of the total at any particular level (Earle 1952). (It is interesting to note that Flechsig's suggestion considerably predated Lissauer's descriptions in 1886.) Many of the propriospinal fibres are axons of the small neurons of the substantia gelatinosa (laminae II and III, *see* p. 883).

(*f*) **Spinoreticular fibres** have been described in the lateral funiculus as a result of experiments in the cat (Brodal 1949), these are intermingled with spinothalamic fibres and hence do not form a discrete identifiable tract. The majority of these ascending fibres do not cross, but there appears to be a generalized and bilateral projection to nuclei at all levels of the brainstem reticular formation, though particularly to those at pontine and medullary levels. The existence of such spinoreticular connexions has also been demonstrated in the human brainstem (Mehler 1962).

(*g*) **The spino-olivary tract** is described as arising from neurons in the deeper laminae of the spinal grey matter, the axons of which cross the midline and then ascend near the surface of the cord at the junction of the anterior and lateral white funiculi, to terminate in specific 'spinal' regions of the dorsal and medial accessory olivary nuclei (Mizuno 1966). The tract conveys information derived from cutaneous as well as proprioceptive receptors—both muscle and tendon organs (Grant and Oscarsson 1966). A functionally similar pathway which constitutes a *dorsal spino-olivary system* has been suggested on physiological grounds as ascending with the dorsal white funiculi and then relaying in the dorsal column nuclei before projecting on to the accessory olivary nuclei (Oscarsson 1967). Interest in these pathways has heightened in company with the increased awareness of the importance of the olivocerebellar system of climbing fibres with their specific localized excitatory effects on the cerebellar Purkinje cells (pp. 916, 919).

3. Intersegmental Tracts

The lateral intersegmental tract constitutes the remainder of the lateral funiculus, separated ventrally from the anterior intersegmental tract by the emerging fibres of the ventral nerve roots. It consists of intersegmental fibres, some of which have passed from the opposite side of the spinal cord and, probably, reticulospinal and descending autonomic fibres.

TRACTS IN THE POSTERIOR FUNICULUS

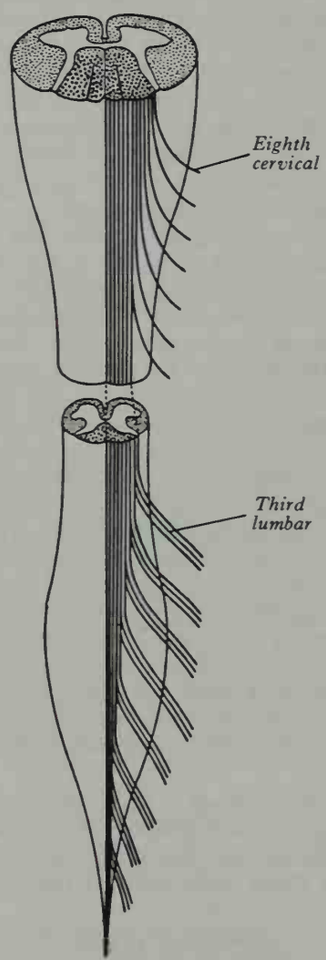
1. Ascending Tracts

This funiculus comprises two large ascending tracts, the fasciculi gracilis and cuneatus, which are separated from each other by the postero-intermediate septum. Essentially the dorsal funiculi mediate projections from the dorsal root ganglia *and* the dorsal grey columns upon the gracile and cuneate nuclei; but this simple description must be modified, because many of the fibres do not reach the nuclei, and many are *propriospinal*. Moreover, some ascending fibres reach the nuclei by other routes.

The fasciculus gracilis commences at the caudal limit of the spinal cord and is composed mainly of the long ascending branches of the medial bundle of fibres of the dorsal nerve roots; but a considerable fraction (15 per cent according to Rustioni and Dekker 1974) are axons of *secondary* neurons, whose perikarya are in the ipsilateral dorsal grey column (laminae III and IV). These remarks also apply to the cuneate fasciculus. They run upwards in the posterior funiculus, and as the tract ascends it receives accessions from each dorsal root. The fibres which enter in the coccygeal and lower sacral regions are thrust medially by the fibres which enter at higher levels. The fasciculus gracilis, which contains fibres derived from the lower thoracic, lumbar, sacral and coccygeal segments, occupies the medial part of the posterior funiculus in the upper part of the spinal cord (7.45).

The fasciculus cuneatus commences in the mid-thoracic region and derives its fibres from the dorsal roots of the upper thoracic and cervical nerves and, in consequence, is situated lateral to the fasciculus gracilis (7.45, 46).

Both fasciculi are myelinated, and the fibres are larger in the fasciculus cuneatus than they are in the fasciculus gracilis, probably due to the finding that proprioceptive fibres (which are of greater diameter) remain in the cuneate fasciculus, but leave the gracile fasciculus at lumbar levels (*vide infra*). Both fasciculi contain the central processes from cells in the spinal ganglia, i.e. receptor or *primary afferent* neurons, and some of these pass without interruption or decussation to the medulla oblongata, where they end in the *gracile* and *cuneate nuclei*, in which the second neurons of this pathway begin. The majority of the fibres of the second neurons sweep ventrally round the central grey matter (7.61) as the *internal arcuate fibres*, and take part in the *decussation of the lemnisci*. Thereafter, as the *medial lemnisci*, they ascend on each side to the ventral nucleus of the thalamus (p. 958) and are there relayed to the cortex of the post-central gyrus (areas 3, 1 and 2). Some of the second neurons form *posterior external arcuate fibres* (p. 902) which pass to the cerebellum. Presynaptic dendrites, which effect dendro-dendritic connexions, have been described in the cuneate nucleus of the macaque (Wen *et al.* 1977), but the origin of the fibres from which they branch remains obscure.



These two tracts, which occupy nearly the whole of the posterior funiculus, convey proprioceptive sensibility, including vibration and pressure and some elements of exteroceptive tactile sensibility. The fibres concerned all pass up to the medulla oblongata in the ipsilateral posterior funiculi, together with the fibres which convey sensations of posture and of movements, both active and passive. It should also be noted, however, that during their passage in the cord a number of the long ascending dorsal column fibres give rise to a series of collateral branches which enter the dorsal column of spinal grey matter.

The laminar somatotopic pattern of the gracile and cuneate tracts has been shown to be more intricate than the segmental arrangement described above; there is also a segregation of fibres on the basis of modality, those conducting impulses from hair receptors being most superficial, followed by fibres mediating tactile and vibratory sensibility in successively deeper layers (Uddenberg 1968). Physiological experimentation has also indicated that the somatotopic arrangement is carried through to the nuclei gracilis and cuneatus, and that these contain numerous interneurons; unit recording in the nuclei shows a high specificity in fibres arriving along the two tracts. Stimuli immediately outside the receptive field from which a single unit can be activated may show an inhibitory effect. There is evidence of a projection of descending fibres from the pre- and post-central cerebral cortex which travel in the corticospinal projection and exert facilitatory and inhibitory influences on the interneurons of the gracile and cuneate nuclei. Similar projections also originate in the brainstem reticular formation (pp. 943–953). It is to such modulating effects that the highly discriminative nature of activity in the dorsal funicular pathways is probably due, and

these tracts, like others, can no longer be regarded as a simple through route for sensory information. (For further discussion see p. 891).

2. Descending Tracts

A somewhat confusing number of small tracts of descending fibres have been described in the dorsal funiculi by a variety of observers, who worked chiefly in the late nineteenth century and based their accounts on pathological appearances in human spinal cords. Thus, extending through cervical and upper thoracic levels, in the medial part of the cuneate tract, is the *comma tract* (of Schultze), also known as the *semilunar tract* or, more recently, the *interfascicular fasciculus*. In lower thoracic segments a thin superficial strand of fibres has been described, but this is almost certainly the cranial end of the *septomarginal tract*, which is ascribed to a deeper situation bordering the posterior median septum. The so-called '*oval field of Flechsig*' and the '*triangular field of Gombault and Philippe*' are also merely different levels of the septo-marginal tract, which appears to alter its shape and position remarkably as it descends in the cord from lower thoracic segments. It is tempting to assume that the interfascicular fasciculus and septomarginal tract are also continuous, but this remains a matter of doubt. They are reputed to differ in one respect; the former is said to consist only of the descending branches of entering dorsal root fibres, whereas the septomarginal tract is considered to contain also large numbers of intersegmental connexions. It must be emphasized that almost all the literature concerning these descending dorsal column fibres is based on clinical observation, experimental evidence being scant. For an exhaustive review consult Nathan and Smith (1959).

7.46 Diagram showing the lamination of the fibres in the posterior funiculus. The spinal cord is viewed from the dorsal aspect. The drawing shows that the posterior funiculus is formed (in part) by the long ascending fibres of the dorsal roots and that the sacral fibres adjoin the median plane, the lumbar to their lateral side, the thoracic more laterally, and the cervical most lateral of all. For dorsal fibres arising elsewhere *see* p. 881.

3. Intersegmental Tracts

Occupying the anterior or deepest part of the posterior funiculus is a small strand of fibres named the **posterior intersegmental tract**. It is somewhat crescentic on transverse section, and is just posterior to the grey commissure (7.43, 44); it is best marked in the lumbar region, but can be traced into the thoracic and cervical regions. Its fibres, which are intersegmental, are derived from the cells of the posterior grey column; they divide into ascending and descending branches which re-enter and ramify in the grey matter.

Further Aspects of Spinal Cord Organization

The more traditional and somewhat simplified account of spinal cord organization given in the preceding pages has been considerably expanded, complemented, and in a number of respects modified, in recent years following the intensive application by many investigators of both the classical and newer methods of neuroanatomy and neurophysiology (Eccles and Schadé 1964*a* and *b*; Lissák 1967; Ralston 1974). Their researches include more detailed comparative studies in a wide array of vertebrates, alternative schemes for the classification of the spinal cord grey matter based upon cytoarchitectonics, and more precise analyses of the dendritic patterns and axonal arborizations using modified Golgi techniques. The more recent degeneration techniques have added considerably to our knowledge of the sites of termination of dorsal spinal nerve root afferent fibres and their collaterals, the siting of terminals of fibre systems which descend from supraspinal levels, and some approach has been made to unravel the exceedingly complex intrinsic organization of the cord by placing minute focal lesions within the grey matter and following subsequent degenerative events in neighbouring regions. Many of these neuro-anatomical investigations, based upon light microscopical techniques, have been improved progressively by the application of quantitative histological methods, whilst detailed ultrastructural studies of the synaptic arrangements have provided new data; putative transmitter distribution studies progress rapidly.

This intensified interest in spinal cord structure has greatly assisted, and equally been assisted by, parallel studies in neurophysiology. In particular, the electrophysiological analyses of the dorsal and ventral spinal nerve root fibres under different conditions, recordings from different points within the grey matter, and unit recordings made with microelectrodes which have impaled single neuron somata, can with some success be correlated with the anatomical findings. As a result, whilst some of the classical views have been substantiated, others have needed a drastic revision and new concepts have been proposed.

LAMINAR ARCHITECTURE

For many years the *general outline* of the grey matter of the spinal cord as seen in transverse section provided an arbitrary terminological basis used by morphologists and experimentalists alike. In this manner, as we have seen elsewhere (p. 869), dorsal, lateral and ventral columns were recognized. The ventral column was considered to consist of a 'base' and a ventrolateral 'head', whilst the dorsal column was dignified with an 'apex', 'head', 'neck' and 'base' proceeding from dorsal to ventral. Between these, a rather imprecisely defined intermediate zone was recognized, whilst more easily defined subdivisions included the substantia gelatinosa, the thoracic nucleus (Clarke's column) and the various subgroupings of large motor neurons which, in considerable variety, characterize a part of the ventral column (p. 870). Whilst much valuable pioneering work was carried out using this scheme, the increasing volume of experimental analysis, both structural and functional, has revealed a relative lack of precision, proving a hindrance and prompting further attempts to classify cord structure (Rexed 1952, 1954, 1964). The most widely adopted scheme stemmed initially from extensive

studies using thick as well as the more usual thin sections, stained by the method of Nissl for cell somata, of new-born, young and adult specimens of the feline spinal cord. Based upon observations on the size, shape, packing density, and cytological features of the neurons in different regions of the grey matter, nine *cell layers* or *laminae* have been distinguished which are roughly parallel with the dorsal and ventral surfaces of the grey matter, and which extend throughout the length of the cord, together with a region surrounding the central canal. As an example, the disposition of the laminae as seen in a transverse section through the fifth lumbar segment of the cord is shown in illustration 7.48A. General confirmation of the laminar pattern in *human* material has subsequently been provided by Schoenen (1973).

Briefly the constitution of the cell layers is as follows:

Lamina I is an extremely thin layer with an ill-defined boundary adjoining the white matter (within which outlying cell groups occur). It presents a reticular appearance because of the presence of many coarse and fine nerve fibre bundles intermingling in a variety of directions. It contains small, intermediate and fairly large neuron somata, many being spindle-shaped. Alternative names proposed are *lamina marginalis* or the *layer of Waldeyer* (who recognized a similar zone in 1888).

Lamina II consists of tightly-packed small cells crossed, especially medially, by numerous fibre bundles which enter from the dorsal funiculus. An outer (dorsal) zone, which appears darkly stained because of its high density of the smallest cells, stands in contrast to an inner (ventral) pale zone.

Lamina III consists of neuron somata which are in general larger, more variable in shape and less closely packed than those in lamina II.

Lamina IV, thicker than the preceding layers, is a loosely packed, heterogeneous zone permeated by many fibres. The cell somata vary greatly in size and shape, from small and round, through intermediate and triangular, to very large star-shaped profiles.

Laminae I–IV correspond to the general term *head* of the dorsal column of previous workers. Lamina II (and some workers consider in addition part or all of lamina III) corresponds to the *substantia gelatinosa* of earlier accounts, whilst the imprecisely defined *nucleus proprius* of the dorsal column roughly corresponds to some of the cell constituents of laminae III and IV.

Lamina V, a thick layer which includes the *neck* of the dorsal column, is divisible into a lateral one-third and a medial two-thirds. Both have a mixed population of cell somata, but the former contains a large number of prominent well-stained cells interlaced by numerous bundles of nerve fibres running transversely, dorsoventrally and longitudinally—hence the restricted use of the term 'formatio reticularis' for this region, particularly well seen in the cervical region, and recognized for over a century (Deiters 1865). (It should be noted, however, that in modern neurology the term *reticular formation* is used much more widely—pp. 943–953.)

Lamina VI, most easily recognized in the limb enlargements, particularly of young animals, consists of a medial one-third of small tightly-packed cells and a lateral two-thirds which possesses larger triangular or star-shaped cells, more loosely packed. Accordingly, in lamina VI the medial zone stains more heavily than the lateral zone, in contrast to lamina V where the converse applies. Lamina VI corresponds roughly to the topographical *base* of the dorsal column.

Laminae VII–IX present a variety of complex forms in the limb enlargements (7.48A), and to assist understanding the simpler arrangement found at thoracic levels is included for comparison (7.48B).

Lamina VII—this corresponds to much of the intermediate grey column or *zone* of previous authors. Within its confines it includes the prominent cells of the *thoracic nucleus* (Clarke's column) and the *intermediomedial* and *intermediolateral cell columns* at appropriate levels in the spinal cord—these have been detailed elsewhere (p. 872). The remaining large areas of lamina VII (i.e. between these cell columns and, in the limb enlargements, extending ventrally between lamina VIII and the constituent groups of IX) consist of a rather homogeneous population of medium-sized triangular or star-shaped cell somata.

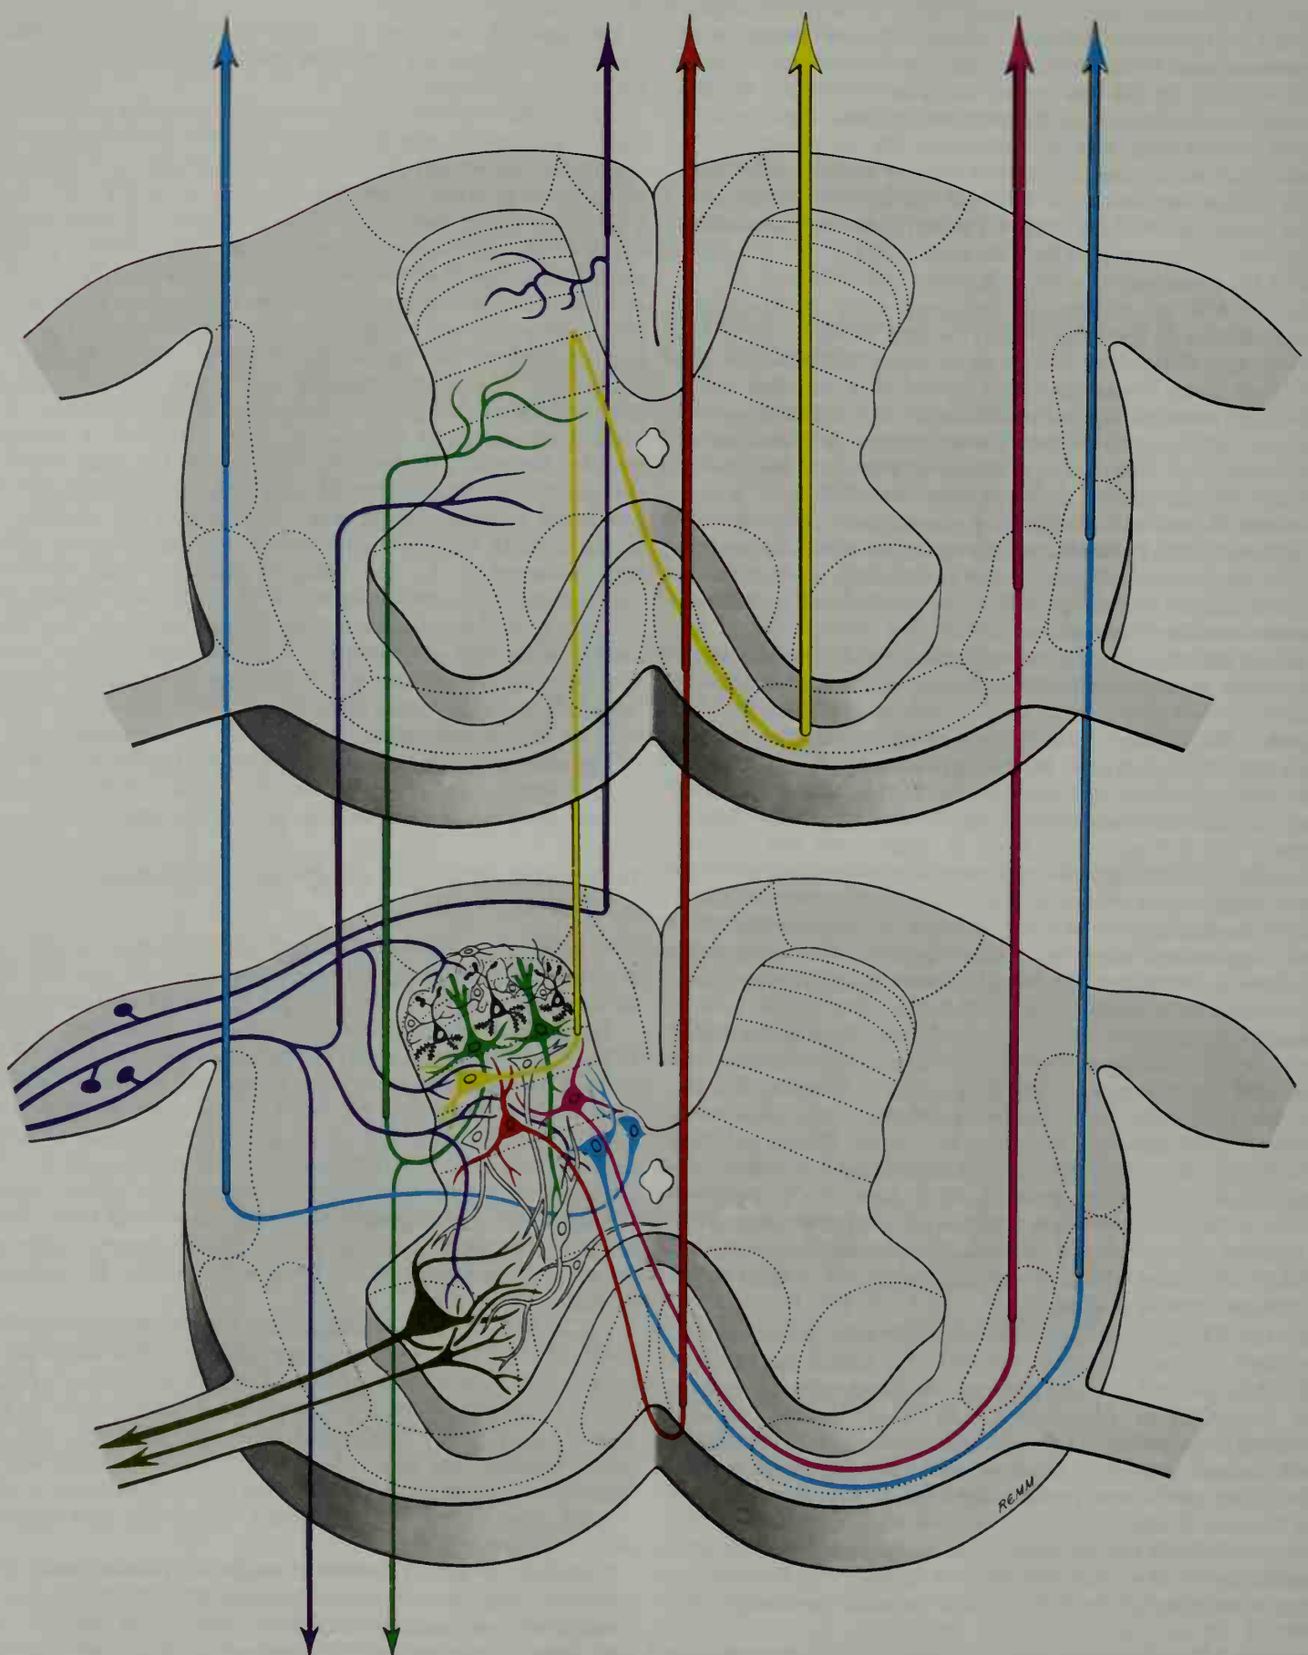
Lamina VIII spans the base of the thoracic ventral column, but in the limb enlargements it is restricted to its medial aspect. It consists of a heterogeneous mixture of cell sizes and shapes from small to moderately large.

Lamina IX comprises the complex array of cell columns (p. 870) which include the very large somata of the α motor neurons, and numerous smaller cells.

The smaller cells include motor neurons which give rise to the small-diameter efferent fibres (γ efferents) to the muscle spindles, and numerous interneurons some of which may be the inhibitory Renshaw cells (*vide infra*). The location of the γ motor neurons was long in doubt, but studies of the retrograde changes in the cell somata following section of peripheral nerves (Nyberg-Hansen 1965) and intracellular recording with microelectrodes (Eccles *et al.* 1960) have demonstrated that these cells are dispersed between the α motor neurons within the motor cell columns. The precise location and morphology of the Renshaw cells, however, is still admittedly uncertain. Intracellular microelectrode recordings have indicated the presence of inhibitory interneurons in the ventral extension of cell lamina VII, where it is insinuated between laminae VIII and IX (Willis and Willis 1966). Studies of this region with the Golgi technique (Scheibel and Scheibel 1966) has failed to demonstrate typical Golgi type II neurons (with profuse, short, local arborizations of their axons)—the cell type long assumed to be the basis of Renshaw loop inhibition. Nevertheless, another view has been expressed (Szentágothai 1967), namely that neurons with longer axons are not incompatible with such an inhibitory function, and further, that the ventral extension of lamina VII receives the greatest density of initial collateral branches from the axons of the α motor neurons (and which are assumed to synapse with the Renshaw cells).

The remaining area of grey matter **(lamina X)** surrounds the central canal, and consists of the *dorsal* and *ventral grey commissures* and the *substantia gelatinosa centralis*.

FURTHER ASPECTS OF SPINAL LAMINAR ARCHITECTURE



It must be emphasized that the preceding description is the barest outline of the proposed scheme of classification and for further details the extensive original papers quoted should be consulted.

It should also be noted that the original scheme only applied in full to the spinal cord of the *cat* and no comparably detailed study was for long carried out on the spinal cord of man or any other primate (*see*, however, the more recent analysis by Schoenen 1973). Nevertheless, the same general principles of laminar organization (with doubtless appreciable variation in detail) are *considered* to apply to the spinal cords of *all* higher mammals (Rexed 1964). *The originator* of the scheme *proposed* the following tentative functional analysis of the laminar pattern (although a number of his conclusions have been *revised* by subsequent workers— *vide infra*).

Laminae I–IV were considered the main receiving areas for the cutaneous exteroceptive primary afferent fibre terminals and collateral branches. (For further details of this sensory input, *vide infra*.) From this region are initiated many complex polysynaptic reflex paths, both ipsilateral and contralateral, and both intrasegmental and intersegmental. It was also considered that from this region arise many of the long ascending tracts to higher centres (but *vide infra* for further discussion and alternative points of view).

Laminae V and VI were thought to receive most of the terminals from proprioceptive primary afferents and also profuse connexions from corticospinal fibres descending from the motor and sensory regions of the cerebral cortex, and descending systems from other sub-cortical centres. Accordingly, these laminae were regarded as being of great importance in the detailed regulation of movement patterns.

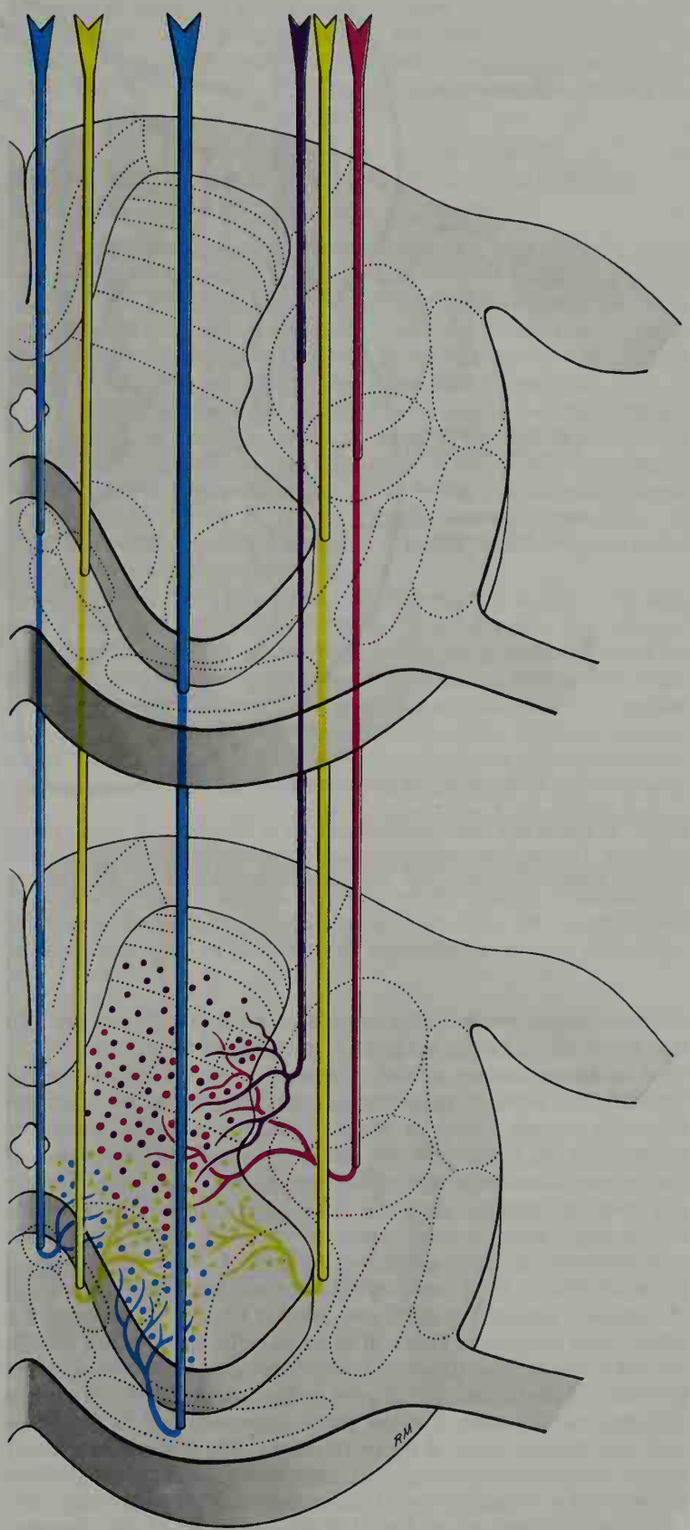
Lamina VII in its lateral part has extensive ascending and descending connexions with midbrain centres and the cerebellum (e.g. via spinocerebellar, spinotectal, spinoreticular, tectospinal, reticulospinal and rubrospinal tracts), and is hence of importance in the regulation of posture and movement. The medial part of lamina VII has a wealth of propriospinal reflex connexions with neighbouring regions of grey matter and adjacent segments

7.47A Simplified scheme of some of the major ascending tract systems of the spinal cord and some features of grey matter organization. Within the grey matter the dotted lines show the laminar pattern, within the white matter they are an approximate guide to the topography of the tracts. Attempts have been made to indicate in a simplified manner the overlapping of dendritic fields described in the text. An alpha and a gamma motor neuron (grey) are included, together with some of the structural features of the substantia gelatinosa which are described and illustrated more fully in 7.49. Some of the small substantia gelatinosa neurons are uncoloured, as are some interneurons in the deeper laminae. The larger substantia gelatinosa neurons are solid black. Large lamina IV cells, and associated ascending and descending intersegmental fibres are green. Primary sensory afferent fibres, including a fibre in the fasciculus gracilis, are purple. Spinotectal fibre—orange; anterior spinothalamic fibre—yellow; lateral spinothalamic fibre—magenta; and dorsal and ventral spinocerebellar fibres—blue. Compare with 7.47C.

concerned both with movement patterns and autonomic functions (p. 970). As we have seen, the ventral extension of lamina VII may be in part occupied by inhibitory interneurons (Renshaw cells—pp. 807, also *see* Renshaw 1941, 1946).

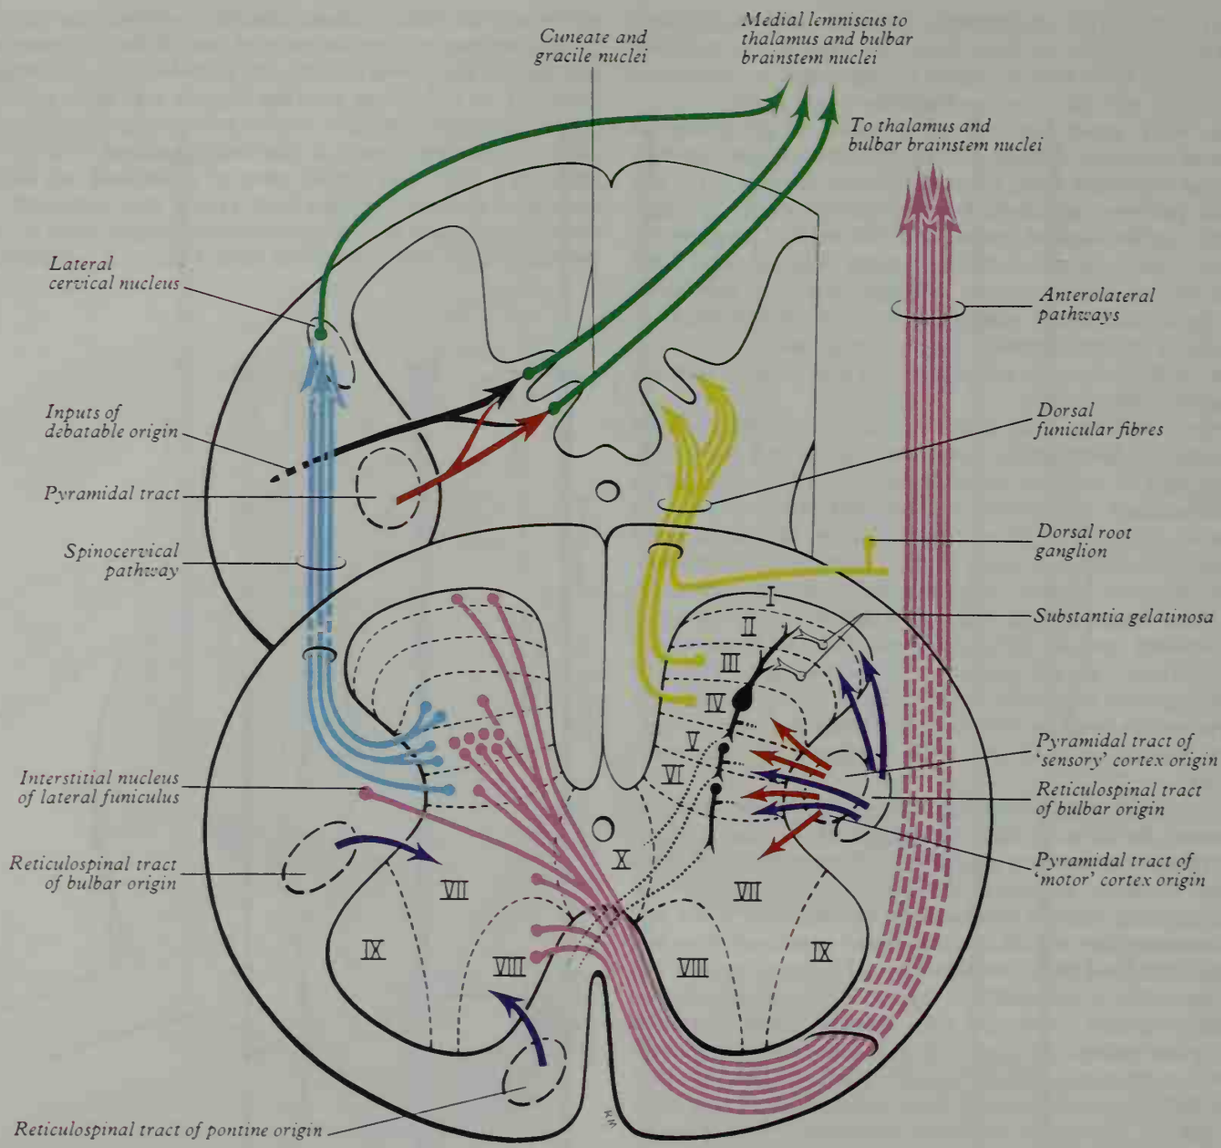
Lamina VIII again consists of a mass of propriospinal interneurons receiving terminals from adjacent laminae, profuse commissural terminals from the contralateral lamina VIII, and descending pathway terminals from interstitiospinal, reticulospinal, and vestibulospinal tracts, and the medial longitudinal fasciculus. Their axons influence both contralateral and ipsilateral motor neuron pools, perhaps directly, but more probably by an excitatory action on the small motor neurons which supply γ-efferent fibres to the muscle spindles.

Lamina IX consists of an admixture of α and γ motor neurons and also many interneurons.



The large α *motor neurons* supply the motor end plates of the extrafusal muscle fibres in the *motor units* of striated muscle (p. 514). They vary in size and physiological recording techniques have demonstrated two varieties, *tonic* and *phasic* α neurons (Granit *et al.* 1956). The former have a lower rate of impulse firing, a lower conduction velocity in their axons, and are assumed to be dimensionally smaller. Attempts have also been made to correlate these varieties with different structural and functional types of striated muscle fibre, e.g. *slow* and *fast* muscle—*see* p. 512. However, as yet there is no histological means of differentiating these types of α motor neuron. Additionally some of the large motor neurons (sometimes termed β *motor neurons*) have been considered to supply both extrafusal and intrafusal muscle fibres.

Similarly, there are at least two physiologically distinct types of γ *motor neuron*, the axons of which (fusimotor fibres) innervate the intrafusal fibres of the muscle spindles. It has been shown that the 'static' and 'dynamic' responses of muscle spindles (p. 860) are subject to separate control mechanisms mediated by *static* and *dynamic fusimotor fibres* which are distributed to *nuclear chain* and *nuclear bag* intrafusal fibres respectively. However, again it has proved impossible to differentiate the types of γ motor neuron somata histologically, although two types of neuromuscular junction—*plate endings* and *trail endings*—have been recognized, as have two varieties of γ-efferent myelinated nerve fibre (γ *1* and γ *2*) in peripheral nerves to muscle (Boyd 1962). How closely these varieties can be correlated has been disputed. For a detailed review of the motor innervation of muscle spindles and an extensive bibliography consult Barker (1974).



THE GEOMETRY OF SPINAL NEURONS

Since the unrivalled pioneering investigations of Cajal (1908), which foreshadowed so much of what was to follow and, indeed, remain today a primary source of information, there has gradually accumulated a volume of increasingly precise data on the form of spinal neurons. As we have seen, much has been learned from a study of the sizes, shapes, distribution, packing density and cytological characteristics of *cell somata* following staining by the Nissl technique or one of its modifications. However, as has been emphasized, such techniques provide only limited information and they must be supplemented by alternative techniques which allow analyses, preferably in quantitative terms, of the patterns of dendritic ramifications, and of the courses, arborizations and sites of termination of axons and their collateral branches. Furthermore, degenerative and other techniques (p. 815) are necessary for a precise determination of their connexions with other cells.

Excellent examples of such quantitative approaches may be found in (Aitken and Bridger 1961; Schadé 1964), in which the lumbosacral regions of the spinal cord of the cat were studied. Whilst the results cannot be examined in detail here, they contained the following kind of information. In the ventral zone of the ventral column of one complete spinal segment (lumbar 6) there was a total neuron population of about 7,000; of these 700 were considered to be the small cells from which the γ-efferent fibres to the muscle spindles originated; of the larger cells 3,276 were propriospinal (interneurons), 126 were classified as 'spinal border' cells, whilst 2,898 were α motor neurons. Thus, in this region about half the cells were interneurons and half motor neurons; if the whole ventral column is assessed, the ratio is about 7 interneurons to 1 motor neuron, and if the intermediate zone and base of the dorsal column are included also, the ratio rises to about 13 to 1. Neuron packing density was estimated and was highest in the intermediate zone of grey matter (7 cells per 100 μm cube of tissue) and lowest in the ventral column (1–2 cells per 100 μm cube). The *total* surface area of individual cell somata and associated dendrites ranged from 11,000 to 97,000 μm^2, whereas the surface area of the *cell somata* alone ranged up to 25,000 μm^2; the number of stem dendrites varied up to a maximum of 13,

7.47B A simplified scheme of some of the major descending tract systems of the spinal cord including their overlapping zones of termination in the grey matter. The significance of the dotted lines is the same as for 7.47A. Corticospinal tract—mauve; rubrospinal tract—magenta; reticulospinal tracts—yellow; vestibulospinal tracts—blue.

7.47C A recent and more detailed analysis of the principal somaesthetic pathways. Descending corticospinal and reticulospinal tracts involved in sensory modulation are also indicated. Modified from data kindly provided by Professor K. E. Webster, King's College, University of London.

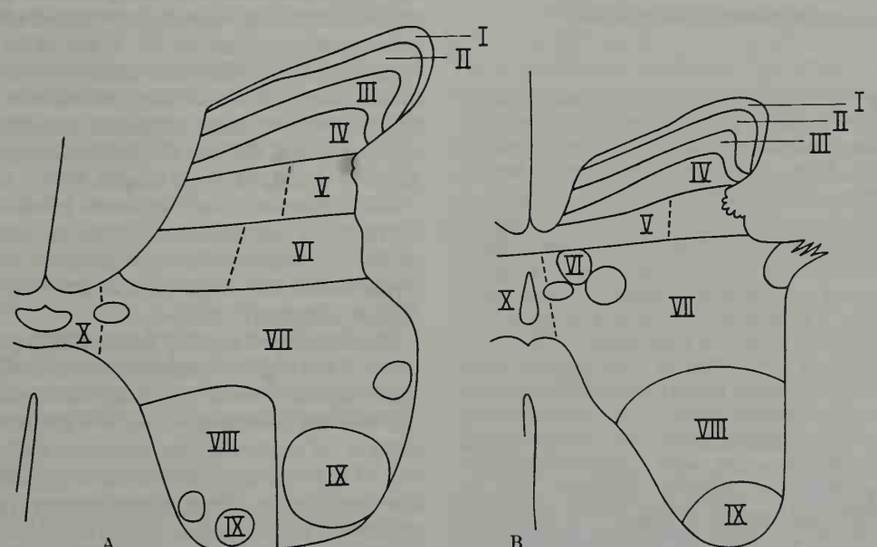
whilst *dendritic* surface area ranged up to about 76,000 μm^2. In this study the dendrite surfaces formed up to 80 per cent of the total *receptive* surface of the neuron (i.e. excepting the axonal surface), the dendrites sometimes extending as far as 1,000 μm from the parent soma, in which cases the terminal dendrites passed into the adjacent white matter, as much as 50 per cent of the estimated receptor surface of the neuron being more than 300 μm from the parent cell body. The latter figure is particularly interesting, since many types of neuron have very wide arborizations of their dendritic trees; but neurophysiological evidence (Eccles 1957) has cast doubt on the possible effectiveness of synapses situated at distances greater than 300 μm from the soma; their functional role still remains to be determined. In the second series of investigations cited (Schadé 1964) estimates were provided of the percentage of grey matter occupied by cell somata and their surface areas, and the percentage occupied by dendrites and *their* surface areas. A mean value of 7,500 μm^3 was estimated for the volume of the soma of an interneuron, and 29,000 μm^3 for the soma of a motor neuron. The surface area of the 'average' cell body ranged from 4·4 to $5{\cdot}9 \times 10^3$ μm^2 and that of the 'average' dendritic tree from 59 to 73×10^3 μm^2 in different specimens.

Other investigations (Romanes 1964; Sprague and Ha 1964) have also been concerned with the complex dendritic patterns of ventral column motor neurons and of interneurons located in adjacent cell laminae. Emphasis is placed upon the wide arborization of the dendrites of the motor neurons, seen to best advantage when both transverse and particularly longitudinal sections are examined. Not only do the dendrites of adjacent *cells* interlace horizontally in complicated patterns, but they also spread even more widely, overlapping the territories of other motor neuron cell *columns*; some penetrate adjacent cell laminae (VII and VIII), interweaving with their dendrites and cell somata, whilst still others pass quite deeply into the superjacent white matter, weaving between the longitudinal myelinated nerve fibres and terminating at varying depths (sometimes one-third to one-half the thickness of the white matter is traversed). Even more prominent is the longitudinal spread of dendritic branches from *a* motor neurons which occurs within their cell column of origin, and which may overlap the territories of many hundreds of neighbouring motor neurons. Again, these observations raise the question of the functional role of axodendritic synapses far removed from the cell soma. Clearly, the causal mechanisms responsible for the relatively circumscribed grouping of motor neuron *somata* into cell columns contrasts sharply with those related to the development of interlacing *dendritic fields*. The significance of the latter is by no means clear but attempts have been made to interpret the patterns of overlap in terms of the geometry of the terminals of primary afferent fibres from muscle nerves, and those of the interneurons in the adjacent cell laminae, both of which spread longitudinally for distances of three or four

spinal cord segments (for details consult Sprague and Ha 1964; Sterling and Kuypers 1967).

A further detailed study of the dendritic fields in spinal cord grey matter has been published (Scheibel and Scheibel 1968), whilst particular regions which have been the subject of intensive study include the *thoracic nucleus* or Clarke's column (Szentágothai and Albert 1955; Böhme 1962) and the *substantia gelatinosa* (Szentágothai 1964; Ralston 1965). For a more recent general survey of the neuronal organization of the spinal cord consult Ralston (1974).

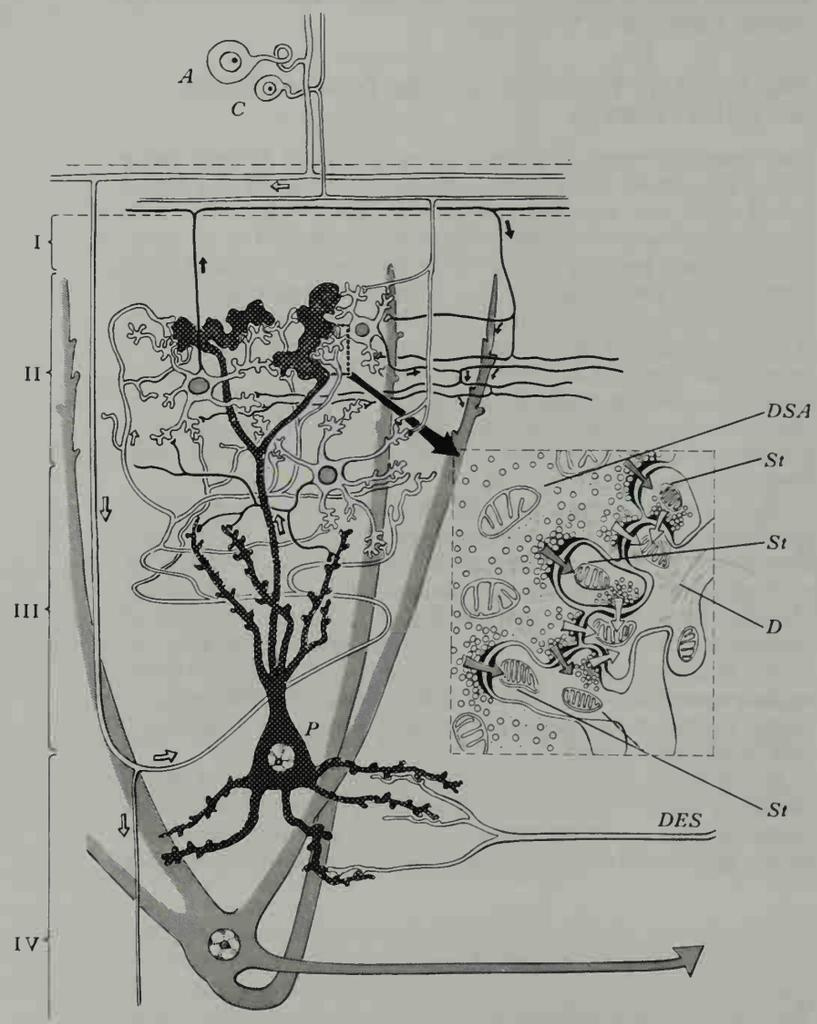
The general arrangement of neurons in the **substantia gelatinosa** is as follows. The neurons of the thin lamina I usually possess large dendritic networks which spread tangentially across the dorsal aspect of the dorsal grey column, where they interdigitate with the deepest fibres of the dorsolateral (Lissauer's) tract and some of the dorsal nerve root afferents; in the main their axons ramify in the subjacent laminae, but some are more lengthy, decussating and thereafter ascending to brainstem and diencephalic levels in the ventrolateral white columns of the contralateral side (p. 880). The small neurons of lamina II and the somewhat larger ones of lamina III have predominantly radially disposed dendrites (i.e. they occur in longitudinal 'sheets' which are perpendicular to the surface of the dorsal column); possibly a few of their axons may pass ventrally to the deeper laminae but the vast majority remain within the substantia gelatinosa (*vide infra*). These fine axons ramify immediately, either after ascending or descending a short distance within lamina II or after passing briefly into the dorsolateral tract and then returning to either lamina II or III. Between the radial dendrites of the small cells are two other principal components also radially disposed—the terminal parts of the long dendrites of the larger, more deeply situated cells of lamina IV and the terminal branches of many primary afferent cutaneous dorsal nerve root fibres. The small-diameter non-myelinated afferents approach the substantia gelatinosa from its dorsal aspect and their terminal branches point ventrally, whilst the larger diameter afferents curve around the substantia and approach it from its ventral aspect, their terminals point dorsally.



Another detailed study of the substantia gelatinosa was carried out, based upon the Golgi technique and ultrastructural methods, combined with either dorsal root transection or chronic surgical isolation of the dorsal grey column. The morphology of the neurons in laminae II and III were studied, and particular reference was made to a larger pyramidal type of neuron sited at the junctional zone between laminae III and IV. The latter possess recurrent axons which pass into lamina II, where they expand to form the core of large *glomerular synaptic complexes*. These glomeruli contain axodendritic synapses between the pyramidal cell axons and the dendrites of the small gelatinosa cells, and axoaxonic contacts between the pyramidal cell axons and the terminals of primary dorsal root afferent fibres. The principal structural features of these synapses, together with some synaptic details of the input from primary dorsal root afferents, the axonal ramifications and terminals of the small gelatinosa neurons, the main output channel via lamina IV neurons, and terminals of fibres descending from supraspinal sources, are summarized in illustration 7.49 which is taken from (Réthelyi and Szentágothai 1969); this should be consulted for further details. Consideration of *earlier* interesting proposals concerning the possible functional significance of this arrangement is given in subsequent paragraphs. However, it must be emphasized that in the light of further researches in the intervening years, it is evident that at present the detailed role of the substantia gelatinosa remains quite obscure (*see* comprehensive reviews by Nathan 1976, and by Wall 1978).

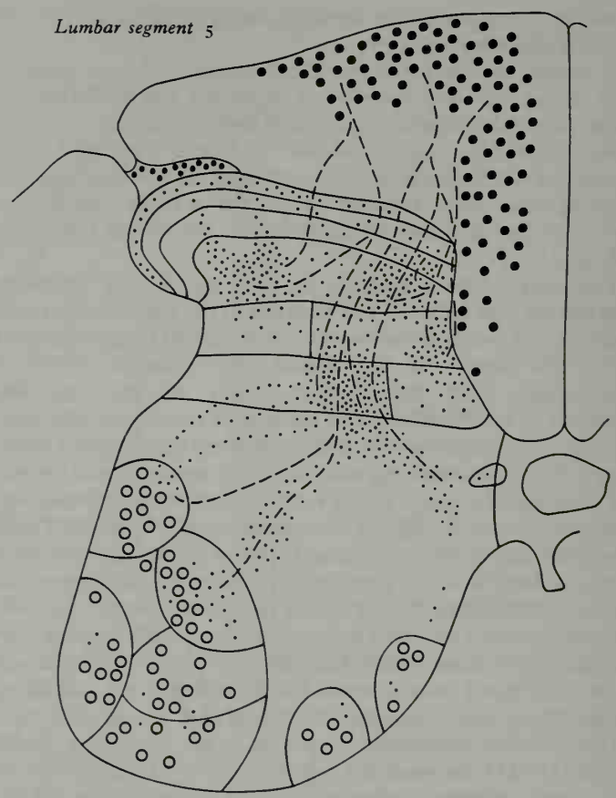
THE SITES OF TERMINATION OF DORSAL ROOT AFFERENT FIBRES

The mode of formation, general topography, and division into a lateral fine-fibred and a medial coarse-fibred bundle of a dorsal spinal nerve root have been described elsewhere (p. 887). This distribution has been confirmed in man by Sindou *et al.* 1974. Consideration has also been given to the manner in which these fibres divide into ascending and descending branches, each of which gives rise to a series of collateral branches which approach the grey matter of the dorsal column at various levels over a substantial length of the cord, the longest ascending branches of the medial division proceeding as far as the gracile and cuneate nuclei in the medulla. In the present section, the zones of termination of these dorsal root fibres in the various regions of the spinal grey matter are discussed.



There have been two principal approaches to this problem: anatomical and neurophysiological. In the former, the fields of termination of fibres at different levels have been followed by application of such techniques as those of Glees, Nauta, and Fink-Heimer after severance of individual dorsal roots and the elapse of appropriate time intervals to allow terminal degeneration to occur. In the latter, the focal electrical potentials generated in the spinal grey matter have been explored by using microelectrodes to record the results of stimulation of muscle and cutaneous nerves and dorsal nerve roots.

In relation to earlier degeneration studies a number of points should be noted. Extensive and informative studies of dorsal root terminals (Sprague 1958; Sprague and Ha 1964) were carried out on the spinal cord of the *cat* (although similar general principles



7.48A and B The pattern of lamination proposed by B. Rexed (*Progress in Brain Research*, Vol. II) for the spinal cord grey matter of the cat, viewed in transverse section. A the fifth lumbar segment. B the third thoracic segment. (With the permission of Prof. Rexed and the Elsevier Publishing Company.)

probably apply to all higher mammals, *details* cannot be applied without reserve to the spinal cord of man). The authors related their findings to the laminar architecture of the grey matter described previously (p. 882), and included a critical review of the limitations and advantages of the Nauta technique. It is pointed out that the degenerating terminals seen are only those in association with cell somata and dendrite trunks, whereas the branches of the dendrites of many neurons radiate widely from the cell (p. 887). Since the dendrites are encrusted with synaptic contacts throughout their length (Armstrong *et al.* 1956; Wyckoff and Young 1956; Rasmussen 1957; Young 1958; Illis 1964; Gelfan and Rapisarda 1964), numbering some thousands in large neurons, and since these are not revealed by the degeneration techniques mentioned, it is essential to correlate such studies with others carried out using the Golgi techniques.

7.49 Diagram of the arrangement of neurons and their interconnexions in a longitudinal section through the dorsal grey column of the spinal cord, which includes the substantia gelatinosa and adjacent neuronal laminae (Roman numerals I–IV). Inset (right) shows synaptic detail of the area indicated. Two primary sensory afferent fibres are shown: a cutaneous afferent of large calibre (A), and a small calibre non-myelinated afferent (C). Small substantia gelatinosa interneurons are in white with black outline; their axons are single black lines. A pyramidal cell with dendrites and spines, and a recurrent axon expanding into synaptic complexes is shown in black with white dots. A large multipolar neuron of lamina IV with long radial dendrites and initial axon is in cross-hatch. DES—axon descending from a supraspinal source. Arrows on main diagram show presumed direction of impulse conduction. Note (1) the different sites of synaptic termination of primary afferents A and C, (2) the axonal pattern and terminals of substantia gelatinosa interneurons, and (3) the synaptic complexes formed between the recurrent axon expansions of the pyramidal cell, the small gelatinosa interneuron dendrites, and the primary sensory axon terminals. See inset for details: DSA—pyramidal cell axon terminal; D—dendrite of gelatinosa interneuron; St—primary afferent fibre axon terminal; white arrows—axo-dendritic synapses; cross-hatched arrows—axoaxonic synapses. A

7.50A–C The pattern of degeneration of nerve fibres and their terminals, demonstrated with the Nauta-Laidlaw technique in the ipsilateral half of the spinal cord at various segmental levels, five days after surgical division of the *sixth* lumbar dorsal spinal nerve root of the cat. A the fifth lumbar

The fields of termination of fibres examined after section of the sixth right lumbar dorsal spinal nerve root in the cat is shown at three levels (spinal cord segments, lumbar 5, 6 and 7) in illustration 7.50A, B, C. These findings are briefly summarized as follows.

All the large calibred fibres of the dorsal funiculus (excepting some of the medially placed ones) have collaterals which pass through the medial two-thirds of laminae I, II and III, many curving around the medial aspect of these laminae and these form a dense plexus of degenerating fibres of passage (in transit to other regions) and degenerating terminals around the majority of the cells in the broad lamina IV. Many of the fibres of passage recurve to approach the substantia gelatinosa from its ventral aspect, into which they pass, forming numerous degenerating terminals between the radially disposed dendrites of the small cells of laminae II and III and the terminal segments of the long dorsally directed dendrites from lamina IV.

Degeneration occurs in some of the fine fibres of the dorso-lateral tract for distances of three segments both cranial and caudal to the level of the severed root, and from these, collaterals pass directly into laminae I, II and III, in all of which they form degenerating terminals.

From lamina IV many larger fibres pass to the medial zones of V and VI (a region containing commissural interneurons), whilst many others form a rich mass of degenerating terminals in the central zone of laminae V and VI. From this central concentration 'fingers' of degenerating terminals radiate through laminae VII and VIII and, running with them, are fibres of passage which then converge upon the various motor neuron pools and their associated interneurons, which constitute lamina IX. It has been demonstrated (Sprague 1958) that degenerating synaptic terminals from dorsal root afferents terminate both on the cell somata and the dendritic surfaces of the large multipolar motor neurons where they are interspersed between the numerous

segment; B the sixth lumbar segment; and C the seventh lumbar segment. The large dots indicate degeneration of fibres in the dorsal funiculus; smaller dots—degenerating fibres in the dorsolateral tract of Lissauer; smallest dots—degenerating nerve terminals; dashed lines—degenerating fibres of passage; circles—neuronal somata of motor neurons. (From J. M. Sprague and H. Ha, *Progress in Brain Research*, Vol. II, with the permission of the authors and the Elsevier Publishing Company.)

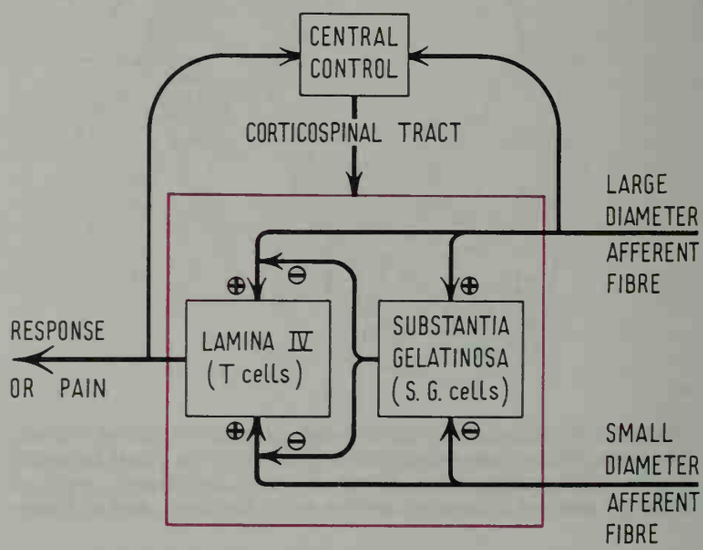
terminals derived from interneurons in other laminae and at other levels in the cord. In the cat such monosynaptic terminals of dorsal root afferents on motor neurons were found to extend for two segments cranial and caudal to the severed root, whereas terminals on interneurons in other laminae were also identified one or two segments even more cranial or caudal to this. Similar extensive studies have also been carried out on the spinal cord of the rhesus monkey (Shriver *et al.* 1968; Carpenter *et al.* 1968). In a number of respects the findings correspond with those in the cat, but a number of differences in detail have also emerged, but will not be discussed here; the interested reader should consult the references quoted.

In recent years there have been numerous attempts to correlate the architectural features of the spinal cord grey matter derived from Nissl, Golgi, and degeneration techniques, supplemented by the newer powerful methods employing tracers, of the kind detailed in the preceding pages (p. 819), with more critical analyses of the sites of origin and termination of the tract systems in the white matter, with the exceedingly complex array of propriospinal interneurons, and with electrophysiological studies of their functional activities. In relation to the latter a voluminous literature has accumulated which lies outside the scope of the present volume. Only a few points can be mentioned briefly and superficially here, and further details may be sought in the readily available review articles and original publications in this field, for example: Eccles (1957); Eccles and Schadé (1964 *a* and *b*); Ralston (1974).

SOME NEUROPHYSIOLOGICAL CORRELATIONS

In addition to providing a most convenient site in which to study the sequence of cytological changes which follow the severance of their axons (p. 862), the large multipolar neurons of the motor columns in lamina IX of the spinal cord formed the basis for Sherrington's classical study of the characteristics of reflex responses (Sherrington 1906). During this emerged the first clear evidence of *integrative* activities occurring at the contact points between neurons, and the foundations for the concepts of opposing *excitatory* and *inhibitory* action were laid. Subsequently the large size and position of the somata of these cells enabled investigators to impale them with microelectrodes. The additional fact that they can be caused to fire volleys of nerve impulses (or to be inhibited from so doing) *orthodromically* by the stimulation of appropriate peripheral nerves or dorsal nerve roots, and that they can be invaded *antidromically* by stimulation of ventral nerve roots was of great assistance to experimentalists. These means have made possible detailed analyses of the electrical and ionic events which occur at synapses during the generation of *excitatory* and *inhibitory postsynaptic potentials* (EPSPs and IPSPs). Similarly, the early recognition of inhibitory interneurons (Renshaw 1941, 1946), in the neighbourhood of the large motor neurons, has led to an increasing volume of enquiry into *lateral* and *feedback* inhibitory phenomena, not only in the spinal cord but at many other cell stations throughout the nervous system.

Since 1940 much evidence has accumulated concerning another form of inhibitory action, namely *presynaptic inhibition*, in which spinal neurons have, again, provided a major experimental source (for reviews *see* Eccles 1964). In presynaptic inhibition the synaptic terminals (A) which impinge upon a neuron (B) are themselves subjected to the action of synaptic terminals (C) from a neighbouring interneuron, i.e. there exist axoaxonic synapses. When the inhibitory terminals (C) are active they are held to cause a relative depolarization of terminals (A), thus reducing the effectiveness of the latter in causing a postsynaptic change in neuron (B). Usually two or more interneurons are interposed on a presynaptic inhibitory pathway. Further, in common with postsynaptic excitatory and inhibitory



phenomena, presynaptic inhibition may be mediated by fibre system terminals which have descended from supraspinal sources.

Once thought to be uncommon, *presynaptic inhibitory effects* have now been demonstrated in relation to many, possibly all varieties of primary afferent fibre terminals. In this manner the flow of sensory information into the nervous system does not simply and directly reflect environmental changes; it is continually readjusted and modified at the first synapse depending upon local conditions in the grey matter. A particularly interesting and intensively investigated site at which presynaptic effects have been held to occur is in laminae II and III—the substantia gelatinosa (Wall 1964; Mendell and Wall 1964; Melzack and Wall 1965; Mendell 1966; Heimer and Wall 1968; Ralston 1974; Nathan 1976; Wall 1978). *One view* of the anatomy of this region has been described elsewhere (pp. 870, 887) and it *was* proposed as a mechanism whereby inflowing impulses from cutaneous (and other) afferents are subjected to a *tonic control mechanism* involving relative levels of depolarization and hyperpolarization of the primary afferent fibre terminals. The effect was thought to be mediated by the small and pyramidal cells of the substantia gelatinosa, but the precise synaptic mechanisms that exist are still the subject of much research (for earlier references consult Réthelyi and Szentágothai; but see also below). A most interesting and provocative *gate control theory* first proposed by Melzack and Wall (1965) concerning the possible mode of operation of the gelatinosal system in providing a 'gate' in relation to the inflow of impulses along nociceptive and other afferent pathways has promoted intense discussion. The *mechanisms initially* envisaged by the authors (as opposed to other fundamental elements of the theory) are summarized in 7.51.

Briefly, it *was* proposed that large-diameter afferents (e.g. from hairs and touch corpuscles) are excitatory to both small gelatinosa interneurons (SG) and to the larger neurons (T-cells) of the deeper lamina IV (from which, directly or indirectly, spinothalamic fibres arise). In contrast, small-diameter and non-myelinated afferents are excitatory to the T-cells but inhibitory to the SG cells, whilst the axons of the latter were presumed to exert presynaptic inhibition upon the terminals of all afferents which synapse with the T-cells. Within such a system, a low level of activity in the small-diameter afferents inhibits the SG cells, which are therefore prevented from inhibiting the T-cells, and thus the 'gate' to the lamina IV T-cells is open and will transmit intermittent small volleys of impulses from the large fibres. A prolonged high-frequency volley of impulses in the large-diameter afferents, however, will be transmitted to the lamina IV T-cells initially, but this soon ceases as activity in the SG cells closes the gate. Conversely, a persistent high level of activity in the small-calibre afferents will open the gate wide resulting in a massive bombardment of the lamina IV cells. The latter include some high threshold cells which are only activated by such an intense bombardment, the presumption being that onward transmission from such cells over the lateral spinothalamic tract will be appreciated as pain in supraspinal centres. In this concept, therefore, pain would result from the *imbalance* between varieties of inflowing impulses which occurs when there is a disproportionately large traffic along the small-diameter afferents. The latter, perhaps, should thus not be regarded as '*specific pain afferents*' but as a fibre system which continually monitors the *state of the tissues* innervated. Thus, in addition to *interaction* and *comparison* between the information flowing along different fibre types, other essential ingredients of the gate control theory (as initially stated) involve *presynaptic inhibition* of primary afferent terminals; furthermore, the overall 'sensitivity' of the gate may be varied by *descending control systems* from supraspinal sources.

Since the original publication of the theory many additional data have accumulated, and it has been progressively modified, modernized, and refined (Melzack 1973; Wall 1973, 1974, 1976). Nevertheless, Nathan (1976) was prompted to write a lengthy critical review of the theory, which the interested reader should undoubtedly consult. In his most recent publication at the time of writing, however, Wall (1978) has presented a *re-examination* and *re-statement* of the gate control theory of pain mechanisms. In summary he states: 'In 1965, we proposed that the transmission of information about injury from the periphery to the first central cells was under control. The setting of this control or gate was influenced by peripheral afferents, other than those which signalled injury. The gate was also influenced by impulses descending from the brain. Subsequent work has fully supported and enlarged this view. All the cells so far discovered which transmit information from nociceptors are inhibited by low threshold afferents and by descending controls. The mechanism by which this control is achieved remains completely unknown. Pre-synaptic inhibition as a phenomenon isolated from post-synaptic inhibition is in doubt. Whether the inhibitions and facilitations are pre-synaptic or post-synaptic or both is unknown. The role of the substantia gelatinosa in any function is unknown. That a gate control exists is no longer open to doubt but its functional role and its detailed mechanism remain open for speculation and for experiment.'

Other varieties of electrophysiological investigation have

7.51 The sensory 'gate' mechanism as *originally* proposed by Dr. R. Melzack and Prof. P. D. Wall for the *modus operandi* of the dorsal laminae of grey matter of the spinal cord. See text for a discussion of the effects of an imbalance in the sensory inflow along the large and small diameter afferent fibres. (From an illustration in *Science*, Vol. 150, with the permission of the authors and publishers. Copyright, 1965, American Association for the Advancement of Science.) Consult references for a critical review of the gate theory by Nathan (1976), and a comprehensive reappraisal of the evidence and modern re-statement of the theory by Wall (1978).

involved the exploration of the spinal grey matter with microelectrodes during the stimulation of muscle and cutaneous nerves (Eccles *et al.* 1954; Coombs *et al.* 1956) and during the 'natural' stimulation of peripheral receptors (Kolmodin 1957; Kolmodin and Skoglund 1960). The focal extracellular potentials evoked by such means correspond well with certain specific regions of the grey matter laminae and with the areas of termination of dorsal root afferent fibres determined by degeneration techniques. For further details the references quoted should be consulted.

UNIT RECORDING WITH INTRACELLULAR MICROELECTRODES

Physiological recordings made with microelectrodes inserted into individual cell somata deep within the spinal cord grey matter have, in recent years, provided much information, often of an unexpected nature, which has necessitated a radical reappraisal of many widely held views. Excellent examples of this experimental approach are a series of investigations of the activities of cells in spinal laminae IV–VI during natural forms of skin stimulation, passive limb movements, stimulation of cutaneous, muscle and visceral nerves in various combinations, and on occasion, simultaneous stimulation of various fibre tracts which descend from supraspinal sources (or after the removal of such influences).

Consult Wall (1967); Pomeranz *et al.* (1968); Wall (1970; 1978).

In the earlier experiments it was confirmed that a *functional lamination* exists which corresponds in large measure to that proposed on cytoarchitectonic grounds (p. 883). It was demonstrated that cells in all three laminae would respond to cutaneous stimulation, whereas movement only elicited a response in lamina VI. Cells in lamina IV possessed small receptive fields and responded as if many different types of specific cutaneous afferents *converged* upon an *individual cell* (e.g. it responded to hair movement, touch, skin cooling, etc.). Lamina V cells responded as if many cells of lamina IV converged upon each of them; they possessed much larger and more diffuse receptive fields. Response to movement was limited to cells in lamina VI, but many of the latter responded to both passive movement and cutaneous stimulation. Simultaneous stimulation of corticospinal fibres affected cells in all three laminae, sometimes facilitating and sometimes inhibiting their responses. It was also demonstrated that activity of certain brainstem centres inhibited cutaneous stimulation responses but enhanced responses to movement and could even *switch the 'modality'* of lamina VI cells from cutaneous to proprioceptive. In later investigations in which cutaneous, muscle, and visceral nerves were stimulated, the findings were expanded and refined. Particular emphasis was placed upon lamina V in which *fine myelinated afferents* from the *three* sources converged on *individual cells* and interacted in various ways. They possessed very large, non-discriminative receptive fields and it was proposed that in some way they signalled information concerning the general 'state' of the various tissues. These results will not be examined in detail here, but they are well summarized in a subsequent publication (Wall 1970) in which the characteristics of the spinal cord cells in laminae IV–VI are compared with those of the dorsal column nuclei (nucleus gracilis and nucleus cuneatus). The former are now considered to provide an important source of the crossed spinothalamic tract (Dilly *et al.* 1968) which is, as we have seen (p. 876), one of the principal ascending sensory pathways, whilst the latter receive some terminals of the fasciculi gracilis et cuneatus, the second major ascending sensory pathway. Their respective roles have long been a subject of controversy and a comparison emphasizes some important features of sensory physiology.

COMPARISON OF THE DORSAL COLUMN—MEDIAL LEMNISCUS AND THE SPINOTHALAMIC TRACT PATHWAYS

It is instructive to compare the size of the receptive fields, the degree of anatomical localization (somatotopical mapping), the maintenance of specificity of channels or the convergence and interaction among them, and the forms of control of transmission of impulses in the two systems.

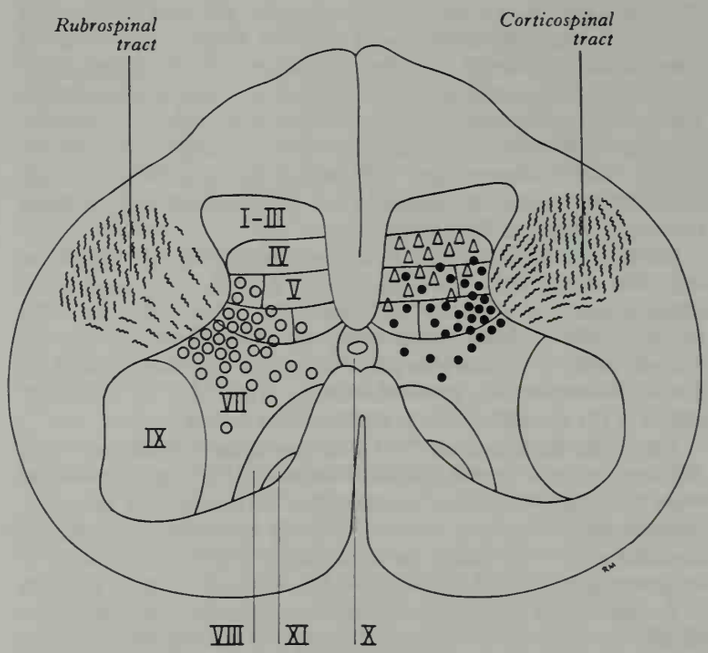
The cells of the dorsal column nuclei (Mountcastle 1968; Norton 1968) receive the synaptic terminals of the long, ascending, uncrossed, primary afferent fibres of the fasciculus gracilis and cuneatus (p. 881) which carry information concerning deformation of the skin, movement of hairs, joint movement, and rhythmical vibration of the tissues. In the cat, the fibres from hair receptors are superficial, whilst touch and vibration receptors are more deeply placed. The somatotopical localization of fibres in the dorsal white columns has already been described (p. 881) and further consideration of the structure and connexions of the dorsal column nuclei will be considered with the medulla oblongata (p. 881).

Unit recording with microelectrodes implanted in the cells of the dorsal column nuclei has shown that their *receptive fields* for touch (that is the skin area from which a response can be elicited) vary in size in different regions, but are generally small (and smallest in the digits). Some receptive fields have an *excitatory centre* and an *inhibitory surround*; thus a stimulus applied just outside the excitatory receptive area will inhibit the cell in question. The cells of the nuclei are spatially organized into an accurate somatotopic map of the periphery (in accord with the similar localization in the dorsal columns). *Specificity* in the cells is high, each responds to *only one type* of afferent fibre stimulation; thus a cell may respond to hair movement alone, or to joint movement, or to an applied sinusoidal vibration, but never to two of these. Indeed, a number of fibres converge upon a single cell but they are always of the same functional type.

The transmission of impulses from the dorsal columns to the medial lemniscus are subjected to a variety of control mechanisms (Jabbur and Towe 1961; Andersen *et al.* 1964). Concomitant activity in neighbouring dorsal column fibres may result in presynaptic inhibition by depolarization of the presynaptic terminals of one of them. Stimulation of the sensorimotor cortex also modulates the transmission of impulses by both pre- and post-synaptic inhibitory mechanisms, and sometimes by facilitation. These descending influences are mediated by the corticospinal tract. Modulation of transmission also follows reticular formation stimulation.

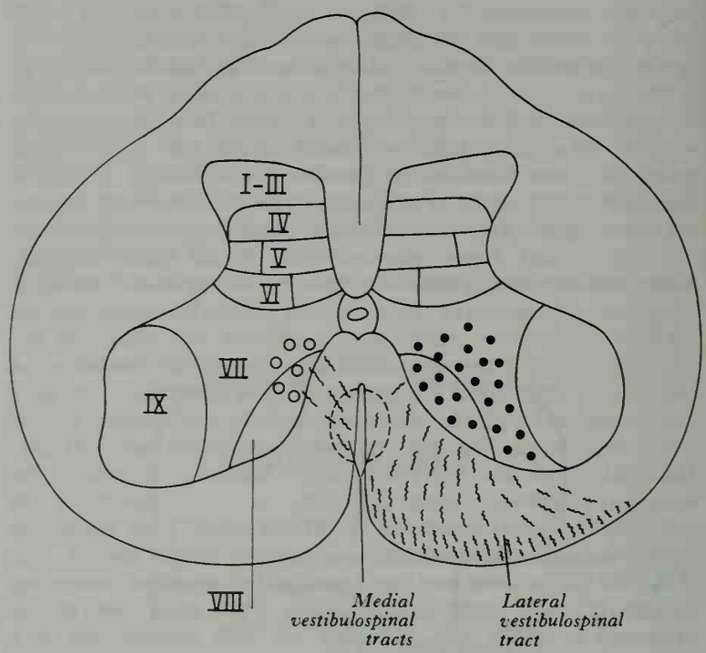
Clearly, the dorsal column nuclei are not simple 'relay nuclei' as was long supposed. They have been described as having the characteristics of 'a private and highly reliable telephone system in which afferent information is separated in channels which are discrete both for spatial origin and stimulus specificity of afferent fibres'. These features contrast strongly with those of the cells of origin of the spinothalamic tracts (see also p. 887).

The cells in laminae IV–VI of the spinal cord have very different receptive fields. Those of lamina IV have small fields and there is a high degree of somatotopic localization of the cells, whereas those of lamina V have extremely large diffuse fields, and respond to a wide range of stimulus strengths. *Specificity* of separate channels as it exists in the dorsal column nuclei is absent in the laminae of the cord. *Convergence of different functional types* of afferent fibre on to the *same cell* is the rule in the cord, the convergence varying with the lamina. Lamina IV cells receive large cutaneous afferents, lamina V cells receive fine afferents from skin, muscle, and splanchnic nerves in various combinations, whilst lamina VI cells receive large muscle and cutaneous afferents. The converging synaptic terminals from different sources result in an *interaction* between excitatory and inhibitory states, which summate to determine the output from the cell. The control of impulse transmission is modulated in a variety of ways. Firstly, the cutaneous afferents are possibly influenced by a tonic regulating mechanism in the substantia gelatinosa described previously. In addition, impulse transmission is greatly influenced by a variety of descending tracts from the sensorimotor cortex and brainstem centres (*vide supra*). The degree of control varies from simple changes in excitability of the cells in lamina IV to a complete reversal of modality in lamina VI.



The roles of the two major sensory pathways—dorsal columns and spinothalamic tract—have aroused considerable controversy. The classical view (Mountcastle 1968) holds that the dorsal column is the *essential discriminatory pathway* and that in its absence a mechanical stimulus is recognized as having occurred, but that it is impossible to specify it exactly as to location, intensity and shape. This view has been strongly challenged (Wall 1970), and it is pointed out that experimental animals with complete section of a dorsal column can in fact discriminate for weight, texture, two-point stimulation, vibration and position. It is proposed that environmental stimuli may be classified into two types: those which are 'passively impressed on an animal' and those that 'must be actively explored by motor movement or sequential analysis before they can be successfully discriminated'. Reception of the former is considered the role of the spinothalamic system, whilst that of the dorsal column system is to *initiate and programme an exploration* of a source of stimulation, and to carry the resultant flow of information. Further evidences in this field, perhaps derived from intracellular microelectrodes carried by freely moving animals—a technique currently being developed—will be awaited with great interest.

THE SPINAL TERMINATIONS OF DESCENDING TRACTS FROM SUPRASPINAL SOURCES

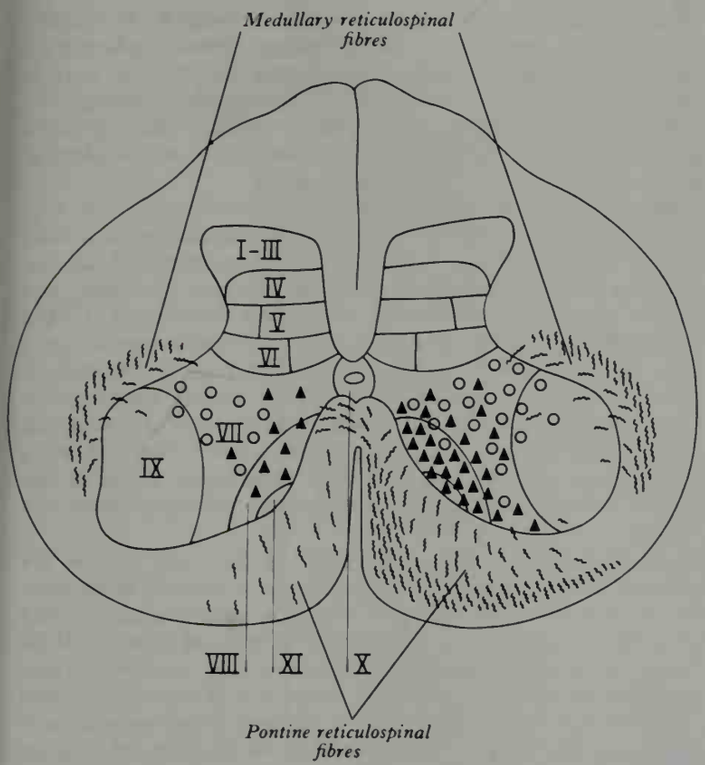


In recent years degeneration technique such as that of Nauta have added considerably to our knowledge of the sites of termination within the spinal cord grey matter of many of the principal

7.52A–C The spinal terminations of various descending tracts of the spinal cord determined experimentally in the cat, and referred to the laminar pattern of the grey matter which is described elsewhere in the present section. (Redrawn from *Neurological Anatomy* by A. Brodal, Oxford University Press, 1969, by courtesy of the author and publishers.)

The original papers and illustrations stemmed from the numerous publications by R. Nyberg-Hansen and his collaborators to whom we are grateful—consult bibliography under 'Spinal Terminations of Descending Tracts from Supraspinal Sources'.

A Terminations of corticospinal fibres from 'motor' areas of the cerebral cortex—black dots; corticospinal fibres from 'sensory' areas of cerebral cortex—white triangles; rubrospinal fibres—white dots.



B Terminations of vestibulospinal fibres; those from the lateral vestibulospinal tract—black dots; those from the medial vestibulospinal tract are shown on the opposite side of the cord as white dots.

descending fibre tract systems (Nyberg-Hansen 1964*a* and *b*, 1965, 1966 *a* and *b*, 1969; Nyberg-Hansen and Brodal 1963, 1964; Nyberg-Hansen and Mascitti 1964; Brodal 1969). The majority of these investigations, again, involve the spinal cord of the cat and occasionally primates other than man. The results, which may well embody general principles applying to many higher mammals, must not, however, be extrapolated in detail directly to the situation in the human cord. Some of the principal results are summarized in illustration 7.52A, B and C based upon the above references, in which the distributions of the terminals are related to the laminar architecture of the grey matter. The following salient points, some of which have already received brief mention with the human tracts, may be noted.

The corticospinal tract fibres in the cat terminate almost exclusively on interneurons in laminae IV–VII. Perhaps all such fibres terminate in this manner, but because of the very extensive ramifications of the dendrites of the multipolar motor neurons of lamina IX, some of which penetrate lamina VII, the presence of a few axodendritic contacts with motor neurons cannot be entirely excluded. Further experiments demonstrated that the corticospinal fibres which arise from 'sensory' cortical regions terminate chiefly in laminae IV and V, whereas those from 'motor' regions end in V–VII with the greatest concentration in the lateral part of lamina VI. Thus, although some overlap occurs, the two types of corticospinal fibre (from different cortical regions) are fairly distinct in their areas of termination. These findings are of particular interest in relation to the increasing volume of evidence concerning the corticospinal (pyramidal) tract as one of the principal supraspinal systems that *modulate the inflow of sensory information*. As we have seen, the latter may be mediated either by presynaptic inhibition of the terminals of the primary afferent fibres, or by postsynaptic inhibition or facilitation of the second (or subsequent) neurons in the afferent pathway. It should also be pointed out, however, that in contrast to the cat there is both anatomical (Hoff and Hoff 1934; Kupyers 1960; Liu and Chambers 1964), and physiological (Bernhard *et al.* 1953; Preston and Whitlock 1961; Landgren *et al.* 1962) evidence that in monkeys a small proportion of corticospinal fibres end monosynaptically on large *a* motor neurons. Much less is known with quantitative precision about the synaptic terminals in man; the majority undoubtedly end upon interneurons, but some evidence (Kupyers 1958) again indicates a small population of fibres ending directly on motor neurons.

Briefly, it may again be mentioned that physiological studies (Corazza *et al.* 1963) in the cat indicate that the corticospinal tract influences both α and γ motor neurons, and that in both cases the effect is mediated via interneurons. In general an *increased* flux of impulses along corticospinal axons has an excitatory effect on motor neurons which supply flexor musculature and an inhibitory one to those supplying extensor musculature. It must be stressed here and elsewhere, however, that the *converse* effects accompanying a *decreased* flux of impulses are equally important in functional terms.

The rubrospinal tract fibres in the cat arise from both the large and small celled parts of the contralateral red nucleus, which shows evidences of some degree of somatotopic organization. Degeneration studies after stereotactic lesions of the nucleus indicate that the tract descends throughout the cord to lumbosacral levels and that its terminals end upon interneurons in spinal cord laminae V–VII. Its zones of termination correspond rather closely with those of the corticospinal fibres which arise in 'motor' regions of the cerebral cortex. Again there are physiological evidences that increases in activity of the rubrospinal projection influences both α and γ motor neurons, via interneurons, facilitating flexor groups and inhibiting extensor ones. Since in some experimental animals a somatotopically organized *corticorubral projection* of fibres has been demonstrated from the sensorimotor cortex, some authors have stressed the presence of dual pathways from the cortex to the cord, one a *direct corticospinal projection*, the other an *indirect corticorubrospinal projection*. Both have similar terminations in the cord and many physiological attributes in common. Little precise knowledge is available, as we have seen, concerning the origin, localization, termination and functional significance of the rubrospinal system in man. Although often stated to be rudimentary and of little significance, clear evidence for such a view is lacking.

c Terminations of reticulospinal fibres; those originating in the medulla oblongata—white dots—are in general more dorsally placed than those originating in the pons—black triangles.

The vestibulospinal tracts, medial and lateral, have also been quite intensively investigated in experimental animals, but are much less well understood in man. As stated previously, the lateral vestibulospinal tract originates from both large and small cells of the *lateral vestibular nucleus* of the same side, descends in the anterolateral white column throughout the cord, its fibres terminating at successive levels largely in laminae VII and VIII, only a trivial number of terminals entering lamina IX. The medial vestibulospinal tract arises mainly from the medial vestibular nuclei of both sides. The fibres run in company at brainstem levels with other components of the medial longitudinal fasciculi and then descend, perhaps to mid-thoracic levels only, on both sides of the anterior median fissure of the cord. They, too, terminate in a more restricted zone which includes parts of laminae VII and VIII. Activation of the main lateral vestibulospinal tract results in excitation of extensor motor neurons and inhibition of flexor motor neurons. The excitation is a direct monosynaptic effect and it must be concluded that the terminals of the vestibulospinal fibres make synaptic contact with the extensive dendrites of some of the motor neurons that penetrate laminae VII and VIII. Gamma motor neurons are also considered to be facilitated whilst the inhibitory effect to the flexors is presumably mediated by inhibitory interneurons of the laminae in which the fibres terminate.

The reticulospinal tracts have been notoriously difficult to evaluate in the spinal cord of man and, again, much more precise information is available in the cat, from studies using the Nissl method for studying the acute retrograde responses in cell somata after spinal cord section, and also the Nauta technique for anterograde terminal degeneration after the placing of stereotactic lesions in the brainstem. Both pontine and medullary reticulospinal fibres from one side of the brainstem apparently pass to *both sides* of the cord, but the pontine fibres are much more densely concentrated on the ipsilateral side, whereas the medullary fibres also send a substantial population to the contralateral side. The spinal cord course of the two differs, the medullary fibres are claimed to pass in the lateral funiculi whilst the pontine fibres are concentrated ventromedially. Their zones of termination are summarized in 7.52c. (For further information concerning the pontine and medullary origins and the possible non-aminergic, noradrenergic, serotonergic, and enkephalin-containing nature of these reticulospinal fibres, consult pp. 847–853.) Briefly it may be mentioned that similar experiments indicate that the **tectospinal tract** from the contralateral superior colliculus and the **interstitiospinal tract**, which arises mainly in the ipsilateral interstitial nucleus of Cajal in the cranial midbrain, both terminate in spinal cord laminae VI–VIII. The latter and the reticular formation will be further discussed in subsequent sections.

SUMMARY OF SPINAL CORD ORGANIZATION

It has been proposed by Szentágothai (1967) that in broad outline it is convenient to consider the grey matter of the spinal cord as composed of a *central core* with paired *dorsal* and *ventral appendages*, each with some distinctive characteristics (7.53). (The unfamiliar terms core and appendage are retained in this summary since they do not correspond precisely with the dorsal and ventral grey columns of topographical neuroanatomy.)

The core, with our present methods of investigation, appears to present a diffuse, non-discriminative, reticular type of organization, within which there is both a great divergence and also convergence of information paths; the majority of its interneurons interconnect with many hundreds, perhaps thousands of other core interneurons distributed over a substantial length of the cord. In contrast the dorsal and ventral appendages have a greater degree of precise discriminative organization in terms of somatotopic mapping and various orders of functional localization. To give precise topographical limits to core and appendages is probably an intellectual abstraction and is certainly impossible at the present rudimentary state of our knowledge; indeed, the concept itself will undoubtedly need much revision (and perhaps lose much of its relevance) as knowledge and understanding increase. Roughly the central core is considered to encompass the interneurons of laminae VII and VIII (i.e. the intermediate zones of previous workers and the areas between the motor neuron columns). However, it may well be that many of the interneurons of the deeper laminae of the dorsal column and those within the motor cell columns should also be included under the concept of a reticular core. The ventral appendage corresponds to the cell columns of lamina IX whilst the dorsal appendage includes laminae I–VI.

The dorsal appendage is, as we have seen (pp. 870, 887), the principal receiving zone of the various exteroceptive, proprioceptive and interoceptive dorsal nerve root afferent fibres. The dorsally situated laminae (I–IV) are the main cutaneous afferent receiving areas, lamina V receives small-diameter afferents from skin, muscle and viscera, whilst lamina VI receives proprioceptive and some cutaneous afferents. It should be emphasized, however, that relatively few investigations have as yet been carried out; the functional boundaries are certainly not as clear-cut as the above description suggests, and undoubtedly a great variety of further functional 'types' of interneuron with many other grades and subtleties of interaction between them remain to be discovered. Further, it is inherent in the technique of intracellular microelectrode recording that because of their situation, size and shape, some cells can be investigated with relative ease, others with difficulty, and a large (and indeterminate) number are beyond our current technical reach; for these reasons a bias in our view of cord dynamics is inevitable.

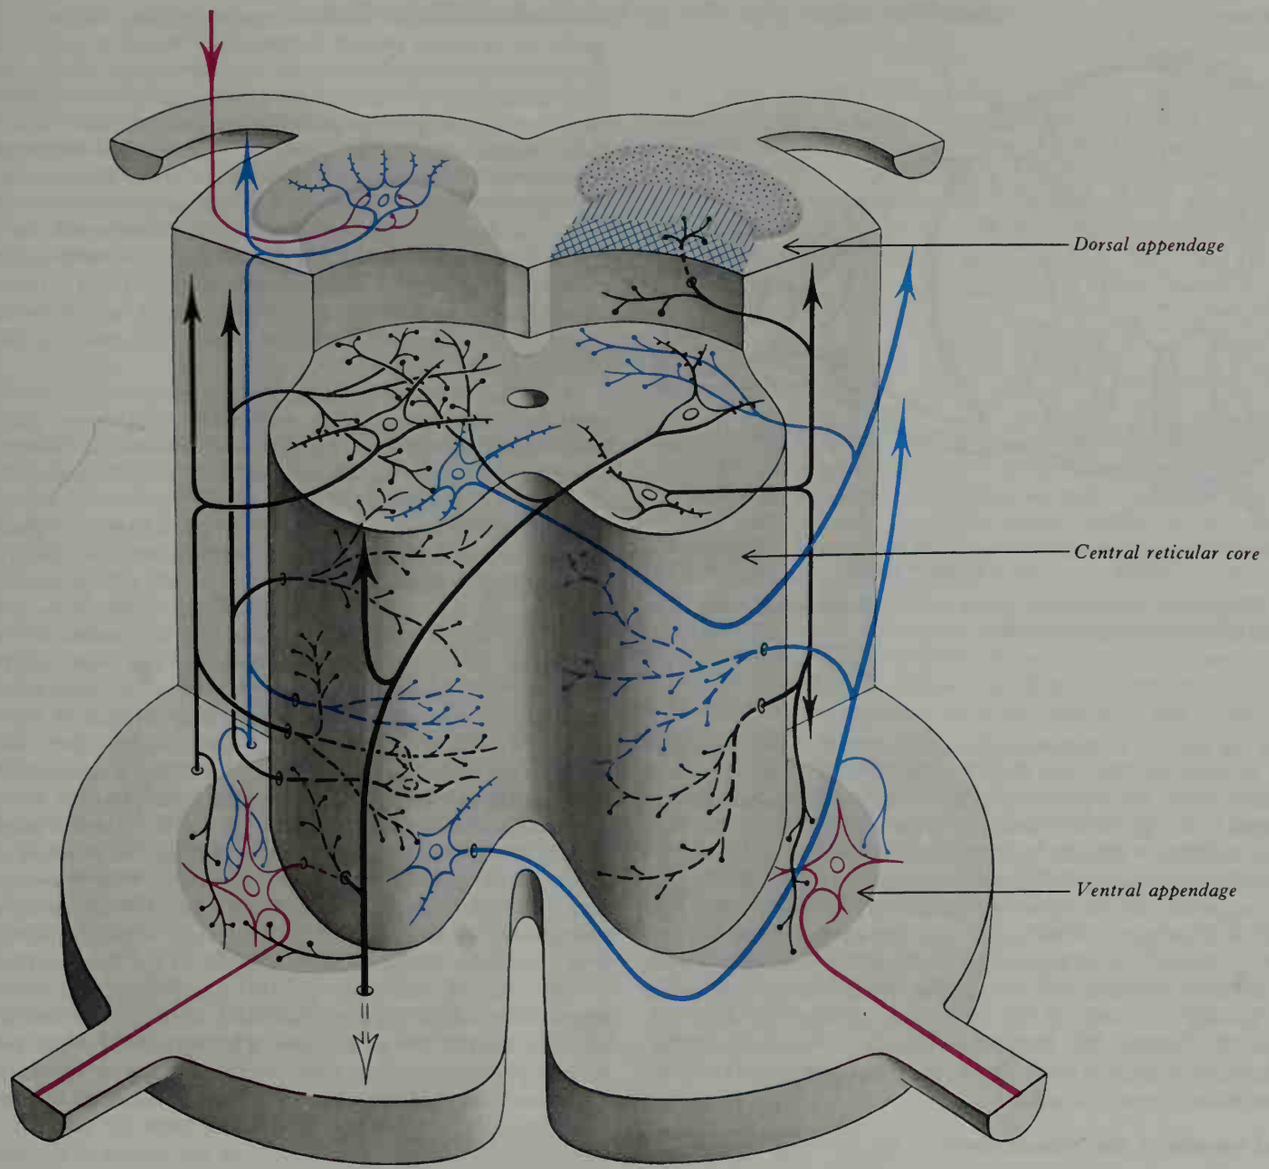
Nevertheless, it is becoming clear from the existing recordings that the dorsal appendage cells abstract information about the internal and external environment in many different forms. Cells and cell groups in different regions show great variety in their degree of somatotopic mapping, the size and response characteristics of their receptive fields, in their specificity or in the degree of convergence and interaction of different types of afferent channel upon a single cell. A brief comparison between the behaviour of the cells in the dorsal appendage of the cord with those in the dorsal column nuclei of the medulla oblongata has been given elsewhere (p. 891). Clearly, the simple view of spinal cord cells as providing merely relays in a series of invariant, discrete,

'unimodality' channels which transmit an elementary punctate view of the environment, either ventrally to motor neurons or cranially to brain centres, as they are often presented in neurological textbooks, must now be firmly rejected. A series of complex transformations of the patterns of inflowing information have already occurred within the dorsal appendage. The outflow along the axons of the dorsal appendage neurons passes to many destinations, either directly to motor neuron columns in the ventral appendage, indirectly via more ventrally situated laminae including the exceedingly complex arrangements of interneurons in the reticular core, on both sides of the cord and cranial and caudal to the level of the input in question. Cells with long axons in both the dorsal appendage and the reticular core contribute to the long ascending tracts, which reach a multiplicity of centres in the brainstem.

Further, transmission of impulses to and beyond the dorsal appendage cells may be modified in various ways by mutual interaction and the operation of controlling mechanisms. Mention has already been made (p. 890) of the facilitatory and inhibitory effects which may follow simultaneous activity in different categories of afferent fibre which converge on the same cell, and of the postulated tonic modulating system of the substantia gelatinosa, which affects the inflow of impulses from cutaneous afferents. In addition, much evidence is now accumulating which demonstrates that impulse transmission in all the laminae of the dorsal appendage (as in the remainder of the spinal cord grey matter) are strongly influenced by fibre systems which descend from supraspinal sources such as the sensorimotor cortex and the reticular formation of the brainstem; such effects may be mediated by either pre- or post-synaptic contacts and be either facilitatory or inhibitory depending upon the site and the circumstances. The biological significance of these mechanisms which control sensory input channels are still far from clear; they may be concerned with eliminating redundancy, reducing confusion by excessive bombardment of central networks, or be linked to 'states of readiness' of central mechanisms, or to the temporary 'preoccupation' of such centres with more immediately significant transformations. The subject is under intense and continuing analysis. It is increasingly clear, however, that the majority of fibre tract systems that descend from the brain and influence motor patterns of behaviour, do so by modifying the state and impulse transmission characteristics of interneurons in the deeply placed laminae of grey matter and much less frequently by influencing the motor neurons directly.

The reticular core interneurons form an exceedingly complex network in which each cell receives inputs from and transmits to large numbers of others (c.f. 'The Reticular Formation'—pp. 943–953). The core receives an input from the axonal terminals of some cells of the dorsal appendage, from proprioceptive dorsal root afferent fibres, and from some of the long descending tract systems. Because of the wealth of interneuronal connexions in this region, analysis has proved of the greatest difficulty, but the earlier view that it almost approaches a *random nerve network* in form is receding with the extensive application of the newer methods of analysis. The latter include the placing of minute stereotactic lesions within the core and observing subsequent degenerative phenomena, intracellular recording, elegant researches on thousands of specimens using the Golgi technique (for an extensive review of this field consult the collection of essays in Brazier 1969), and the newer techniques of mapping of somata or axonal terminals according to their content of putative neurotransmitters (*see* p. 950). One type of organization that has emerged concerns the quantitative analysis of connectivity or 'transmitting power' of different types of interneuron and some of the descending tract systems. Details cannot be given here, but briefly some axonal terminals pursue an extremely long course through the grey matter giving off perhaps only two or three synaptic end bulbs to each of the many hundreds of interneurons encountered in transit. Others concentrate large numbers of terminals on one or a small group of neurons. Thus, diffuse or '*non-discriminative*' connexions have been contrasted with '*discriminative*' ones. Further, it has been shown that contrary to earlier opinion many proprioceptive afferents have terminals in the core that are strictly 'segmentally' localized to narrow *transverse* 'sheets' of grey matter (in contrast to the dorsal appendage cutaneous afferents which terminate in extensive narrow *longitudinal* sheets). It is largely through such complex interneuronal aggregates that inflowing sensory information interacts with that descending from higher centres to set in train the endless variety of locomotor responses; and although our understanding of them is still in its infancy, the continued application of modern powerful methods offers a considerable prospect of further success in this region.

The ventral appendage as described elsewhere (pp. 869, 873, 883) consists of a columnar organization of the cell somata of α and γ motor neurons and again neighbouring interneurons. Attention was also directed to the physiological evidence for 'tonic' and 'phasic' types of α cell related to different varieties of striated muscle fibre, and to the existence of different types of γ cell whereby the 'static' and 'dynamic' responses of the muscle spindles are under independent central control mechanisms. Unfortunately, the detailed synaptology of these different cell types is uncertain. Further, it was shown that whilst a considerable degree of somatotopic localization exists in the ventral columns, its detailed arrangement and significance also remain to be determined.



The principal synaptic connexions of the *motor neurons* are derived from: (1) direct monosynaptic terminals from proprioceptive dorsal root afferents within the same or neighbouring spinal cord segments; (2) terminals from collateral branches of the axons of dorsal appendage interneurons; (3) terminals from interneurons of the reticular core which are of high density and 'discriminative' when derived from the same spinal segment, and diffuse or 'non-discriminative' when derived from neighbouring segments; (4) a few direct monosynaptic terminals from the vestibulospinal and (in various primates including man) the corticospinal tracts, although in the main these tracts end on interneurons.

How these various channels which converge on the motor neurons interact to produce integrated motor behaviour is still far from clear. However, a few generalizations can be made. The principal descending pathways can be grouped: those wherein impulse volleys are excitatory to flexor musculature and inhibitory to extensors (the corticospinal, rubrospinal and medullary reticulospinal tracts) and those which have the converse effect (the vestibulospinal and pontine reticulospinal pathways). However, this simple view of the broad dualistic action of certain descending tracts does little justice to the large volume of detailed investigation that has been reported on the complex modifications of reflex activities by descending systems; but, as yet, it has proved difficult to fit these into an overall behavioural picture.

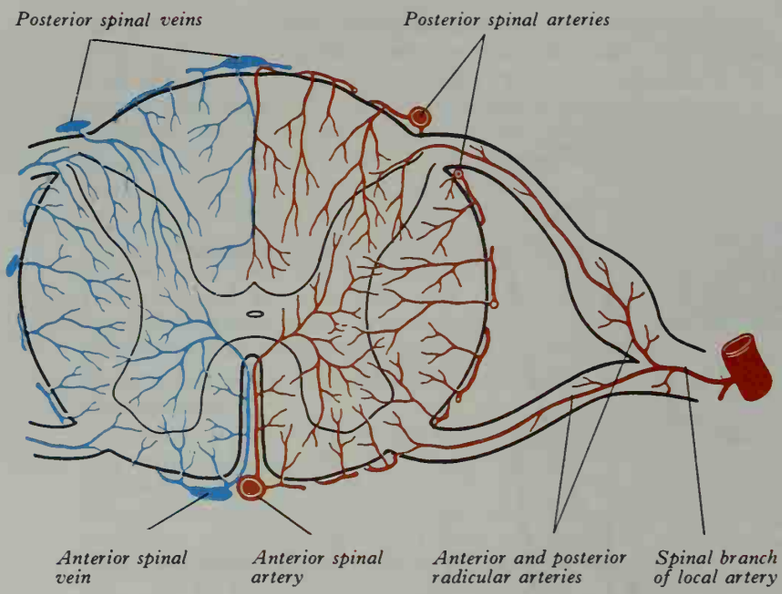
Secondly, there are two distinct pathways by which a muscle may be thrown into a state of contraction (or relaxation); the first or α *pathway* involves an immediate and direct change in the excitatory level of the α motor neurons innervating the motor units. It is considered that such a mechanism operates only infrequently, and that is when a sudden forceful response is appropriate. In the majority of instances a γ *pathway* is operative in which the sequence appears to be—activity in local interneurons, followed by activity (or inhibition) of the γ efferents to the muscle spindles, which in turn via the local muscle servo-loop mechanism (p. 859) causes an appropriate change in the tonic and phasic α motor neurons. The detailed mechanism whereby this so-called α-γ *linkage* is maintained or broken under different conditions is still under investigation (Granit 1970). It should also be noted, however, that some recent researches have indicated that during voluntary actions, initiating activity in the α system may be more frequent than was previously recognized (*see* p. 860).

Applied Anatomy. In injury to the spinal cord the segmental level of the interference may be determined with some precision from clinical data and the application of accurate anatomical knowledge, where available.

Complete division of the spinal cord above the fourth cervical segment causes death by respiratory failure resulting from paralysis of the phrenic and intercostal nerves. Lesions between C_5 and T_1 produce paralysis in all four limbs (quadriplegia); the degree of paralysis in the upper limb varies with the site of the

7.53 A highly simplified stereodiagram illustrating the concept of the spinal cord as consisting of a central 'reticular core' of grey matter, with related dorsal and ventral 'appendages' of grey matter. Many structural features are omitted, and only a few examples, relevant to the concept, are included. A dorsal column neuron, and others, more ventrally placed, which give rise to descending, long ascending, and local collateral branches, are shown in blue. Varieties of interneuron are in black. Two motor neurons are shown in red; also in red is a single example of a fibre descending from a supraspinal source. See text for a more detailed description; see also 7.47A and B for the origin and termination of some tracts, and 7.49 for one view of the fine structure of the substantia gelatinosa. (Redrawn from J. Szentágothai in: *Recent Development of Neurobiology in Hungary*, I. L. Lissák (ed.). By courtesy of the author and publishers, Akadémiai Kiadó, Budapest, 1967.)

lesions. At the fifth segment the upper limb paralysis will be complete; at the sixth the arms adopt a position of abduction and lateral rotation, with the elbows flexed and the forearms supinated due to the unopposed activity of the deltoids, spinati, rhomboids, bicipites and brachiales, which are supplied by the fifth cervical nerve. In cervical lesions at progressively lower levels the innervation of correspondingly more muscles of the upper limb is retained. Lesions of the first thoracic segment result in paralysis of the small muscles of the hand together with interference with sympathetic outflow, resulting in contraction of the pupil, recession of the eyeball, narrowing of the palpebral fissure and absence of sweating on the face and neck (Horner's syndrome). Sensation will be retained in areas deriving their innervation from segments above the site of the lesions. In particular, cutaneous sensation will be retained in the neck and chest down to the second intercostal space, because this area is innervated by the supraclavicular nerves (C_3 and C_4).



In the thoracic region, division of the spinal cord results in paralysis of the trunk below the segmental level of the lesion and of both lower limbs (paraplegia).

The first sacral neural segment is opposite the junction of the thoracic and lumbar vertebrae and injury, which commonly occurs here, results in paralysis of the urinary bladder and rectum and of the muscles supplied by the sacral segments. Cutaneous sensibility is lost in the 'saddle' area in the perineum and buttocks, back of the thigh, leg and sole of the foot. The lumbar nerve roots which pass distally to join the cauda equina at this level may be divided and then the result is complete paralysis of both lower limbs. Lesions below the first lumbar vertebra may divide or damage the nerves of the cauda equina, but severe nerve damage is uncommon and is usually confined to the nerve root at the level of the bony injury.

Neurological symptoms may also arise from interference with the blood supply of the spinal cord, particularly in the lower thoracic and upper lumbar regions.

The Vertebral Levels of Spinal Cord Segments

Of clinical importance is the position of the spinal segments relative to the vertebrae. A useful approximation is: in the cervical region the tip of the spine of a particular vertebra corresponds to the level of the succeeding cord segment (i.e., the sixth cervical spine is opposite the seventh cord segment); in the upper thoracic

7.54 Diagram of the intrinsic blood vessels of the spinal cord. The position of the veins is quite variable.

region the apex of a vertebral spine corresponds to two segments lower in number (i.e., the fourth spine is level with the sixth segment); in the lower thoracic region there is a difference of three segments (i.e., the tenth thoracic spine is level with the first lumbar segment). The eleventh thoracic spine overlies the third lumbar segment and the twelfth thoracic spine is opposite the first sacral segment. In the newborn child, on the other hand, the spinal cord extends to the upper border of the third lumbar vertebra. Barson (1970) examined the terminal level in 258 pre- and postnatal subjects, and stated that the perinatal level is the third lumbar vertebra, rising somewhat during the first two months of postnatal life. Individual variation was considerable: first to fourth lumbar at birth, first to third in a number of children (3 months to 15 years of age).

Blood vessels of the Spinal Cord

Blood reaches the spinal cord along the spinal branches of the vertebral, deep cervical, intercostal and lumbar arteries which, with the anterior and posterior spinal arteries, contribute to the formation of longitudinal anastomotic channels along the cord (*see* pp. 695, 710, and Gillilan 1972). These spinal branches give rise to anterior and posterior radicular arteries which approach the spinal cord along the ventral and dorsal nerve roots. Most of the anterior radicular arteries are small and terminate within the ventral nerve roots or in the plexus in the pia around the cord. The posterior radicular arteries supply the dorsal root ganglia; according to Somogyi *et al.* (1973) these ganglionic ramules enter at both poles of each ganglion, forming distinctive patterns of distribution around ganglion cells and amongst nerve fibres. The same authors have described the arterial supply of spinal roots (Undi *et al.* 1973). A small but variable number of radicular arteries (usually four to nine), mainly situated in the lower cervical, lower thoracic and upper lumbar regions, are larger than the remainder and in addition reach the anterior median sulcus of the spinal cord, where they divide into slender ascending and large descending branches. These branches anastomose with one another and with the anterior spinal arteries above to form a single, or in places paired, longitudinal vessel of uneven calibre along the anterior median sulcus. Frequently one of these anterior radicular arteries is considerably larger than the remainder and is often termed the *arteria radicularis magna* (of Adamkiewicz). Its exact position varies, but it arises from one of the intersegmental branches of the descending aorta in the lower thoracic or upper lumbar vertebral levels. In two-thirds of cases it arises on the left-hand side. Reaching the spinal cord, this vessel sends one branch to join the anterior spinal artery below and another to anastomose with the division of the posterior spinal artery lying in front of the dorsal roots. The arteria radicularis magna may sometimes be responsible for most of the blood supply of as much as the lower two-thirds of the spinal cord.

From the anterior spinal artery central branches pass into the anterior median fissure. Here each one passes either to the right or left to supply the anterior grey column, base of the posterior grey column, including the dorsal nucleus, and the adjacent white matter (7.54).

Each posterior spinal artery gives rise to a pair of longitudinally running channels which anastomose frequently, one lying in front of, the other behind the attachment of the dorsal roots. These longitudinal channels are reinforced at intervals by posterior radicular arteries, which are variable both in number and size but are more numerous than the anterior radicular arteries. In addition the vessel in front of the dorsal nerve roots receives an anastomotic ramus from the descending branch of the arteria radicularis magna. Lazorthes *et al.* (1971) have largely confirmed the above description, but they emphasize the uneven calibre and interruptions in the longitudinal spinal arteries which do not form completely continuous channels. At the level of the conus they communicate by anastomotic loops. They also point out the potential importance of anastomoses other than those between pial, or peripheral spinal arterial branches, indicating a posterior spinal series of anastomoses between rami of the dorsal divisions of the segmental arteries in the vicinity of the spinous processes.

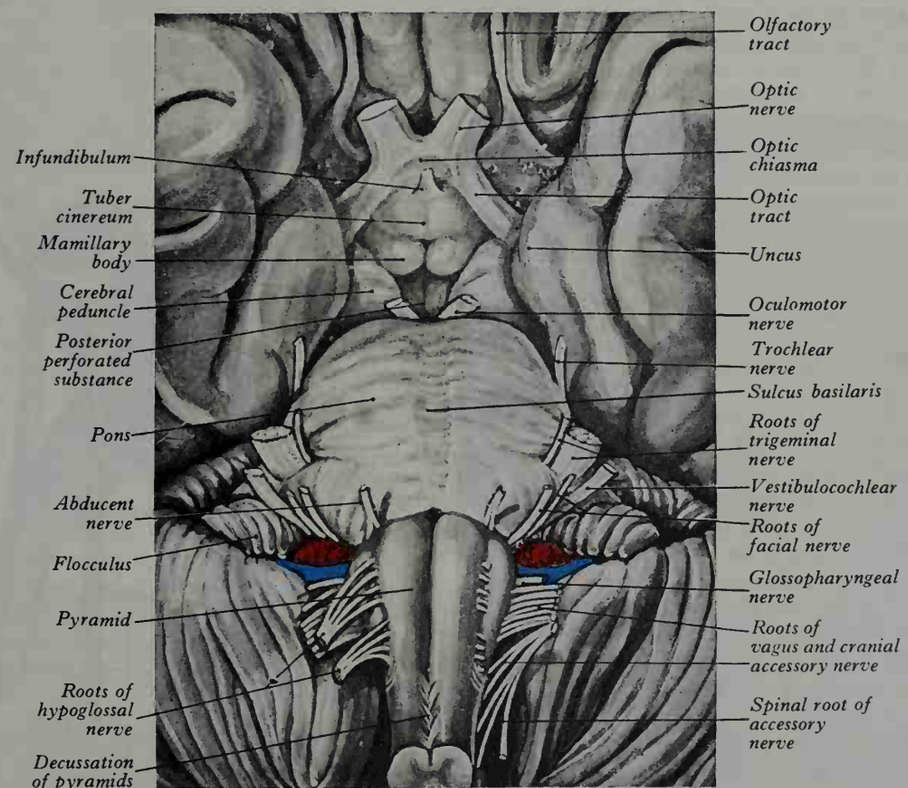
The central branches of the anterior spinal artery are responsible for the supply of as much as two-thirds of the cross-sectional area of the spinal cord. The remainder of the posterior grey columns, posterior white columns and the peripheral parts of the lateral and anterior white columns are supplied by numerous small radially directed vessels derived from the posterior spinal arteries and from the vessels forming the plexus in the pia mater (Torr 1957; Gillilan 1958). In a detailed microangiographic investigation of the human spinal cord at cervical levels (Turnbull *et al.* 1966) there were from 1 to 6 anterior, and 0 to 8 posterior radicular spinal arteries. Each centimetre of the anterior spinal artery gave rise to 5 to 8 central branches. No anastomoses were observed within the cord itself. Overlapping of the territories of the central spinal arteries was confirmed, and similar overlapping in the longitudinal direction was emphasized.

The veins of the spinal cord drain into six tortuous, often plexiform and longitudinal channels, one along the anterior median fissure and a second along the posterior median sulcus and the others, often incomplete, situated on each side, one pair just behind and the other in front of the line of attachment of the ventral and dorsal nerve roots. These six vessels communicate freely with one another and above with the veins of the cerebellum and the cranial venous sinuses. The veins accompanying the anterior spinal artery receive sizable venules from the central grey matter, while much of the blood draining the periphery of the spinal cord enters the veins of the pia mater. Further details of these veins are found on p. 756.

THE RHOMBENCEPHALON OR HINDBRAIN

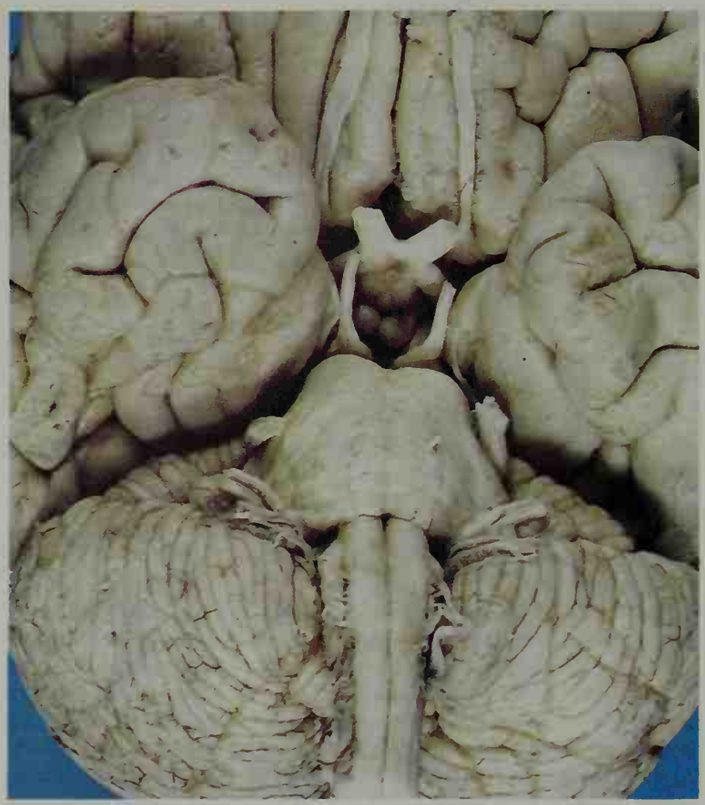
The rhombencephalon comprises the medulla oblongata, pons and cerebellum; its cavity is the fourth ventricle. The medulla oblongata and pons are traversed by fibre tracts which interconnect these and other parts of the central nervous system and contain, amongst others, collections of nerve cells which constitute the nuclei of several of the cranial nerves. The following cranial nerves have their superficial origins from the pons and medulla oblongata: trigeminal, abducent, facial, vestibulocochlear, glossopharyngeal, vagus, cranial roots of the accessory, and hypoglossal. Scattered among the nuclei and tracts is the *reticular formation* (p. 943) which consists of intermingled grey and white matter and also includes nuclei of nerve cells concerned with the control of the heart, the respiratory apparatus and the alimentary tract.

THE MEDULLA OBLONGATA



The medulla oblongata extends from the lower margin of the pons to a transverse plane passing above the first pair of cervical nerves; this plane corresponds with the upper border of the atlas behind, and the middle of the dens of the axis in front; at this level the medulla oblongata is continuous with the spinal cord. However, it must be emphasized that the plane of junction is arbitrary; the internal structure of the spinal cord changes *gradually* to that of the medulla oblongata. The anterior surface of the medulla oblongata is separated from the basilar part of the occipital bone and the upper part of the dens by the membranes of the brain and the occipito-axial ligaments. Posteriorly it is received into the notch between the hemispheres of the cerebellum, and the upper portion of this surface forms the lower part of the floor of the fourth ventricle.

The medulla oblongata is somewhat piriform in shape (7.55, 56), its broad extremity being directed upwards to merge with the pons, while its narrow lower end is continuous with the spinal cord. It measures about 3 cm longitudinally, 2 cm transversely at its widest part, and 1·25 cm anteroposteriorly. The central canal of the spinal cord is prolonged into its lower half, and then expands as the cavity of the fourth ventricle; the medulla oblongata may therefore be divided into a lower, *closed part* containing the central canal, and an upper, *open part* corresponding with the lower half of the fourth ventricle. Its anterior and posterior surfaces are marked by median fissures.



The anterior median fissure contains a shallow fold of pia mater, and extends along the entire length of the medulla oblongata; below, it is continuous with the anterior median fissure of the spinal cord; above, it ends at the lower border of the pons in a small triangular expansion termed the *foramen caecum*. Its lower part is interrupted by bundles of fibres which cross obliquely from one side to the other, the *decussation of the pyramids*. Some fibres, the *anterior external arcuate fibres*, emerge from the fissure above this decussation and curve laterally over the surface of the medulla oblongata.

The posterior median sulcus is a narrow groove which exists only in the closed part of the medulla oblongata; it is continuous below with the posterior median sulcus of the spinal cord, but becomes rapidly shallower at cranial levels, and ends about the middle of the medulla oblongata, where the central canal expands into the cavity of the fourth ventricle.

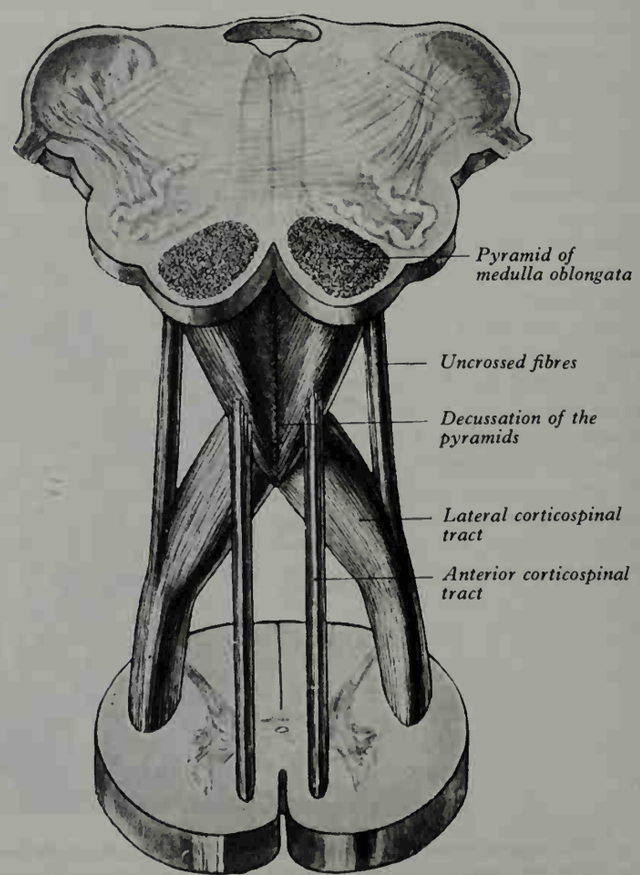
Many of the cranial nerves emerge from or enter the substance of the medulla oblongata, and they appear at the surface in line with the roots of spinal nerves. The fibres of the hypoglossal nerve correspond in position with ventral spinal roots and emerge in linear series from a furrow termed the *anterolateral sulcus*.

7.55 The ventral aspect of the brainstem and the interpeduncular fossa. The wall of the lateral recess of the fourth ventricle is shown in blue, and the choroid plexus, which protrudes through the foramen of the lateral recess into the subarachnoid space, is coloured crimson. Note that the lateral recess covers the medial part of the flocculus and is itself partially obscured by a rootlet of the glossopharyngeal nerve.

7.56 The ventral aspect of the brainstem, interpeduncular fossa and adjacent parts of the cerebellar and cerebral hemispheres. For identification of the various structures, compare with 7.55. (Dissection by Dr. E. L. Rees, Department of Anatomy, Guy's Hospital Medical School.)

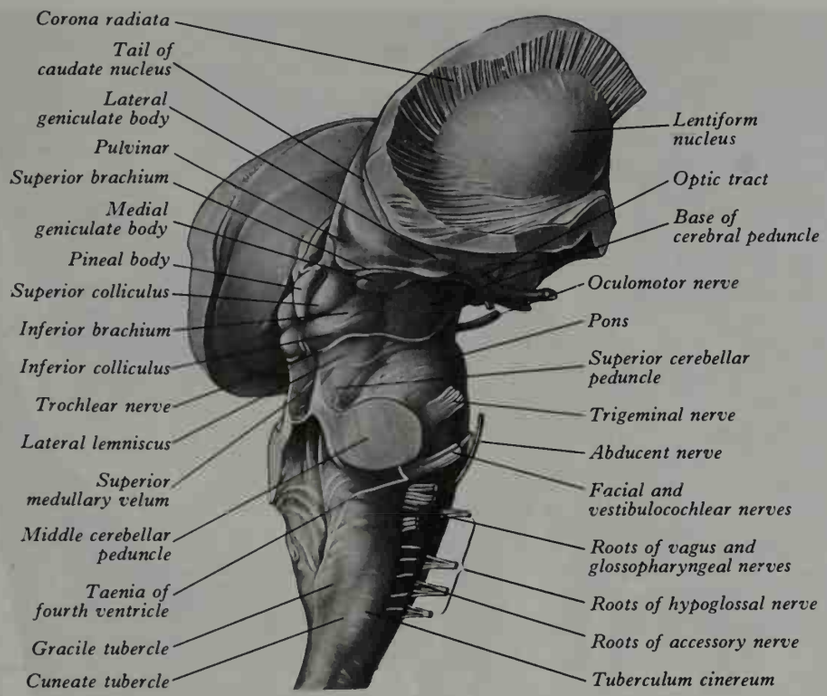
Similarly, the accessory, vagus, and glossopharyngeal nerves are in line with dorsal spinal roots (p. 867) and enter or leave through the bottom of a sulcus named the *posterolateral sulcus*. Advantage is taken of this arrangement to subdivide each half of the medulla oblongata into anterior, middle and posterior regions. Although these three regions *appear* to be directly continuous with the corresponding funiculi of the spinal cord, they do not contain precisely the same nerve fibres, since some of the fasciculi of the spinal cord end or begin in the medulla oblongata, while others alter their course in passing through it.

The anterior region of the medulla oblongata (7.55, 56) lies between the anterior median fissure and the anterolateral sulcus, forming an elongated surface elevation which is named, somewhat inappropriately, the *pyramid*. Its upper end is slightly constricted and between it and the pons the fibres of the abducent nerve emerge; below, it tapers into the anterior funiculus of the spinal cord, with which it is superficially continuous.



The two pyramids contain descending fibres which pass from the cerebral cortex to the spinal cord. When traced downwards, approximately 70–90 per cent of these fibres leave the pyramids in successive bundles, and decussate in the anterior median fissure, forming what is termed the *decussation of the pyramids*. Having crossed the median plane, they pass down in the posterior part of the lateral funiculus of the spinal cord as the lateral corticospinal tract. The remaining fibres—i.e. those in the lateral part of the pyramid—do not cross the median plane; some descend as the anterior corticospinal tract (7.57) into the anterior funiculus of the same side of the spinal cord while others incline backwards and laterally to join the lateral corticospinal tract of the same side (p. 877). The corticospinal tracts display a clear segregation of their descending fibres upon a topographical basis at almost all levels; and in the medullary pyramids this arrangement is similar to that which exists at cranial levels, the most lateral fibres being concerned with the innervation of the legs, the most medial with the arms and neck. How far the same pattern is carried on into the ventral corticospinal tracts or through the decussating corticospinal fibres is not fully clarified, but a similar somatotopic sorting of fibres is usually described in the lateral corticospinal tracts as they extend into the spinal cord.

The lateral region of the medulla oblongata (7.58) is limited in front by the anterolateral sulcus and the roots of the hypoglossal nerve, and behind by the posterolateral sulcus and the roots of the accessory, vagus and glossopharyngeal nerves. Its upper part consists of a prominent oval mass which is named the *olive*, while its lower part is of the same width as the lateral funiculus of the spinal cord, and appears on the surface to be a direct continuation of it. Only a portion of the lateral funiculus of the spinal cord is continued upwards into this region, because the lateral corticospinal tract is derived mainly from the contralateral pyramid, and most of the fibres of the posterior spinocerebellar tract leave the funiculus to enter the inferior cerebellar peduncle in the posterior region of the medulla. The lateral intersegmental tract and the anterior spinocerebellar tract are continued upwards in the lateral region of the medulla oblongata.



The olive is a smooth, oval elevation between the anterolateral and posterolateral sulci and lateral to the pyramid. It is caused by underlying groups of nerve cells forming the *inferior olivary nuclei* (p. 904). It is lateral to the pyramid, separated by the anterolateral sulcus and the fibres of the hypoglossal nerve. It is about 1·25 cm long, and dorsolateral to its cranial end there is a slight depression at the lower border of the pons in which the roots of the facial nerve appear. The anterior external arcuate fibres emerge from the anterior median fissure, and wind backwards across the pyramid and the olive to enter the inferior cerebellar peduncle (7.67).

The posterior region of the medulla oblongata (7.58A, B; 59) lies behind the posterolateral sulcus and the roots of the accessory, vagus and glossopharyngeal nerves, and, like the lateral region, is divisible into caudal and cranial levels.

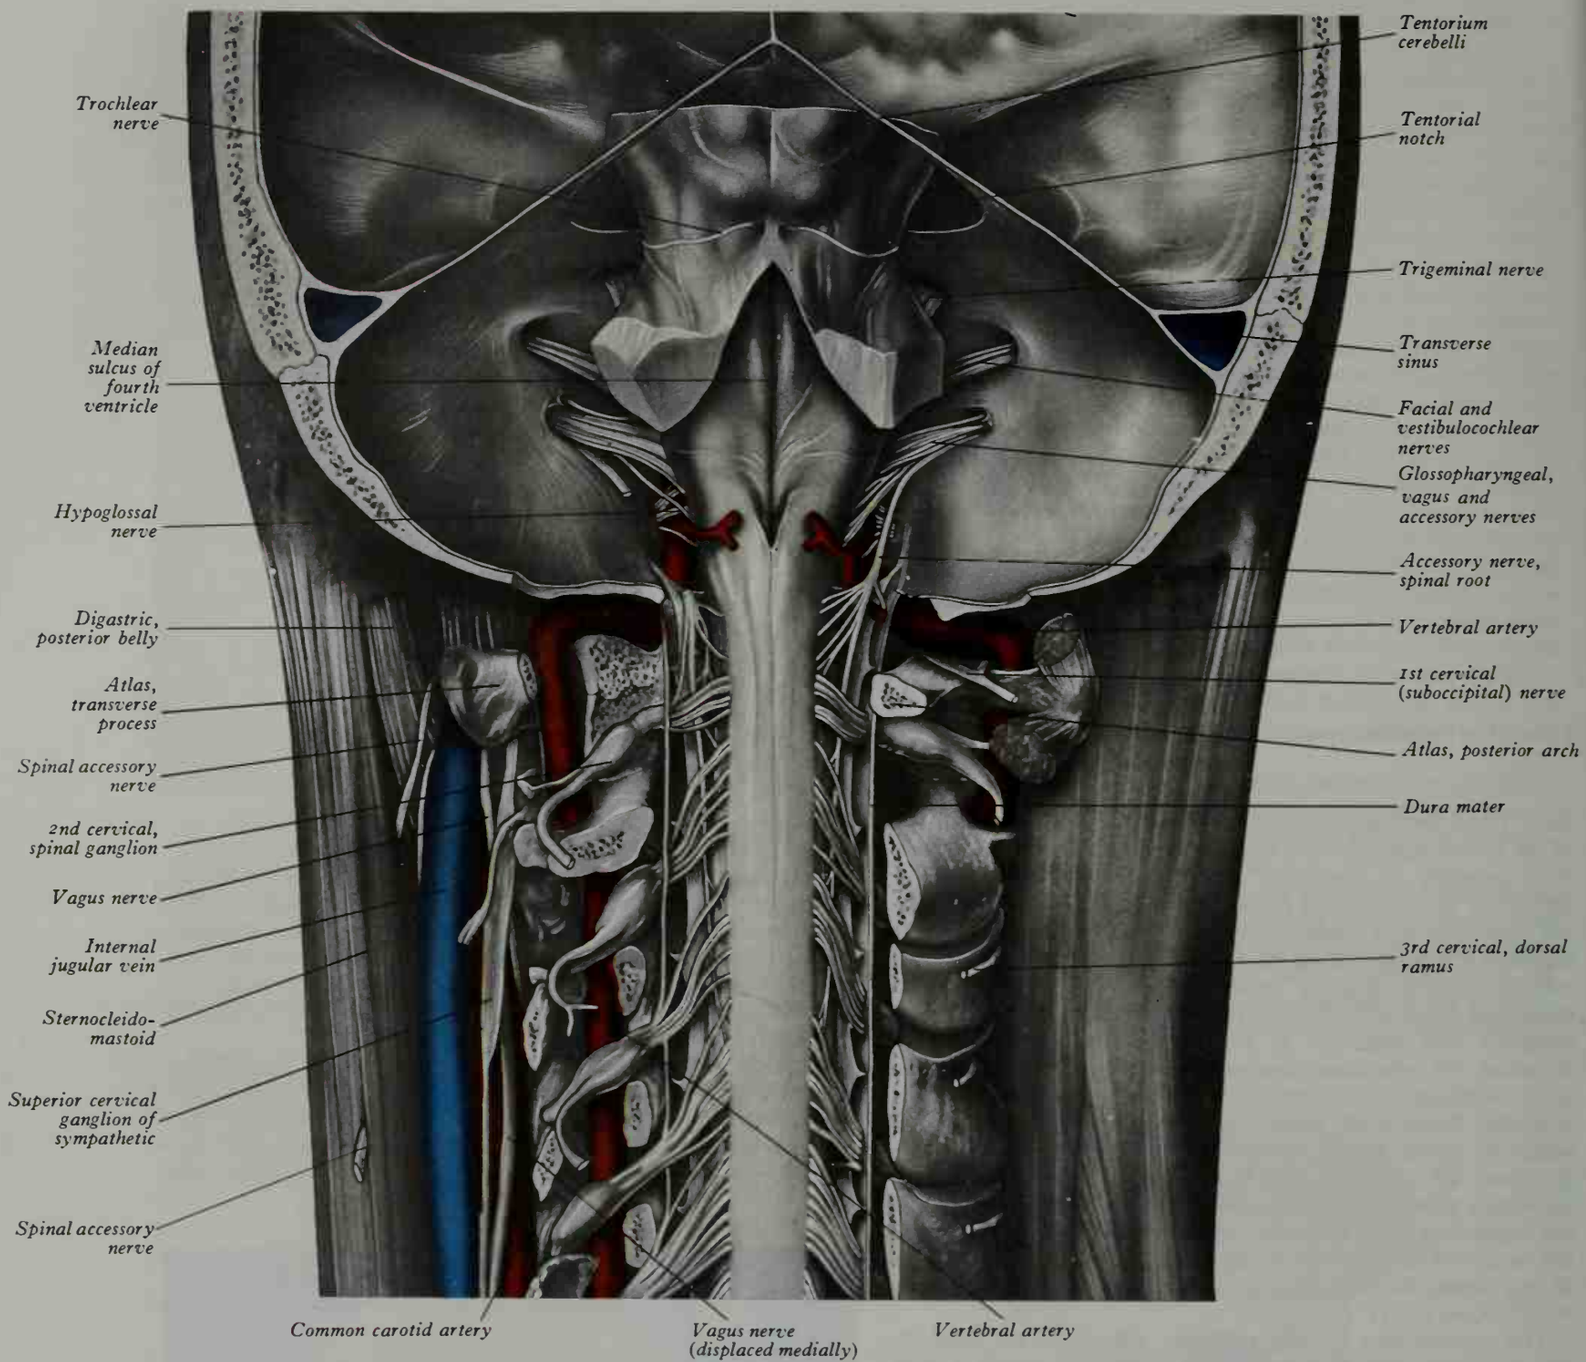
The *caudal part*, limited behind by the posterior median sulcus, consists of the upward continuation of the *fasciculus gracilis* and the *fasciculus cuneatus* of the spinal cord. The fasciculus gracilis flanks the posterior median sulcus, and is separated from the fasciculus cuneatus by the cranial continuation of the postero-intermediate sulcus and septum of the cervical spinal cord (p.

7.57 Schematic dissection to show the decussation of the pyramids.

7.58A The brainstem, posterolateral aspect.

865). These two fasciculi are at first vertical; but at the caudal end of the fourth ventricle they diverge from the median plane, and each presents an elongated swelling. The swelling on the fasciculus gracilis is the *gracile tubercle*, and is produced by the upper end of a subjacent nucleus of grey matter termed the **nucleus gracilis**; that on the fasciculus cuneatus is termed the *cuneate tubercle*, and is caused similarly by the **nucleus cuneatus**. Most of the fibres of these two fasciculi end by forming synapses with the cells in their respective nuclei. A third elevation, the *tuberculum cinereum*, can sometimes be recognized in the caudal part of the posterior region of the medulla (7.58). It is located between the fasciculus cuneatus and the roots of the accessory nerve, and is narrow below but wider above. It is produced by a nucleus which is continuous below with the substantia gelatinosa, and in which the fibres of the spinal tract of the trigeminal nerve end; these fibres separate the nucleus from the surface of the medulla oblongata (p. 911). For further details of this region, including the obex and the taeniae of the fourth ventricle, *see* p. 932.

The *cranial part* of the posterior region of the medulla oblongata is occupied by the *inferior cerebellar peduncle*, a thick rounded ridge situated between the lower part of the fourth ventricle and the roots of the glossopharyngeal and vagus nerves. The two inferior cerebellar peduncles incline away from the dorsolateral aspect of the medulla oblongata towards the cerebellum. As they ascend, they diverge from each other, and form the lower parts of the lateral boundaries of the fourth ventricle; higher up, they are directed backwards, each passing into the corresponding cerebellar hemisphere. Near their entrance into the cerebellum they are crossed by several strands of fibres, the *striae medullares*, which run to the median sulcus of the floor, or anterior wall, of the fourth ventricle (7.88, 90). The inferior cerebellar peduncle is not the upward continuation of the fasciculus gracilis and fasciculus cuneatus, although it appears to be so, for the fibres of these fasciculi end in the gracile, cuneate and accessory cuneate nuclei. The composition of the inferior cerebellar peduncle is described on p. 916.



INTERNAL STRUCTURE OF THE MEDULLA OBLONGATA

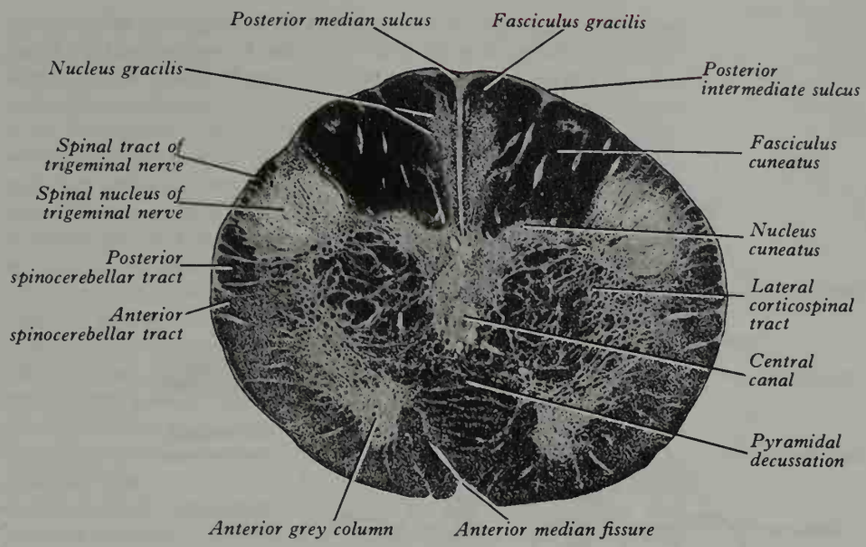
The internal structure of the medulla oblongata, like that of other parts of the brainstem, has been studied chiefly in transverse sections by a combination of histological and experimental methods, three-dimensional reconstructions also being largely based upon serial transverse sections. It is hence customary and convenient to reconstruct such regions in description by reference to appearances in sample transverse sections at a variety of levels. In the account which follows, both of the medulla and other brainstem levels, this method will be employed, the medulla being considered at four successive levels, the first being the most caudal. The disposition of the principal brainstem nuclei is shown in profile in illustrations 7.62 and 7.64, which should be consulted frequently when reading the subsequent sections.

(1) **A transverse section through the caudal end of the medulla oblongata** shows details very similar to those at the cranial end of the spinal cord, as would be expected (7.60). The posterior, lateral and anterior funiculi can be identified, and they contain the same nerve tracts. The grey matter shows two very

7.58B The right lateral aspect of the brainstem, lentiform nucleus and corona radiata. For identifications compare with 7.58A. (Dissection by Dr. E. L. Rees, Dept. of Anatomy, Guy's Hospital Medical School.)

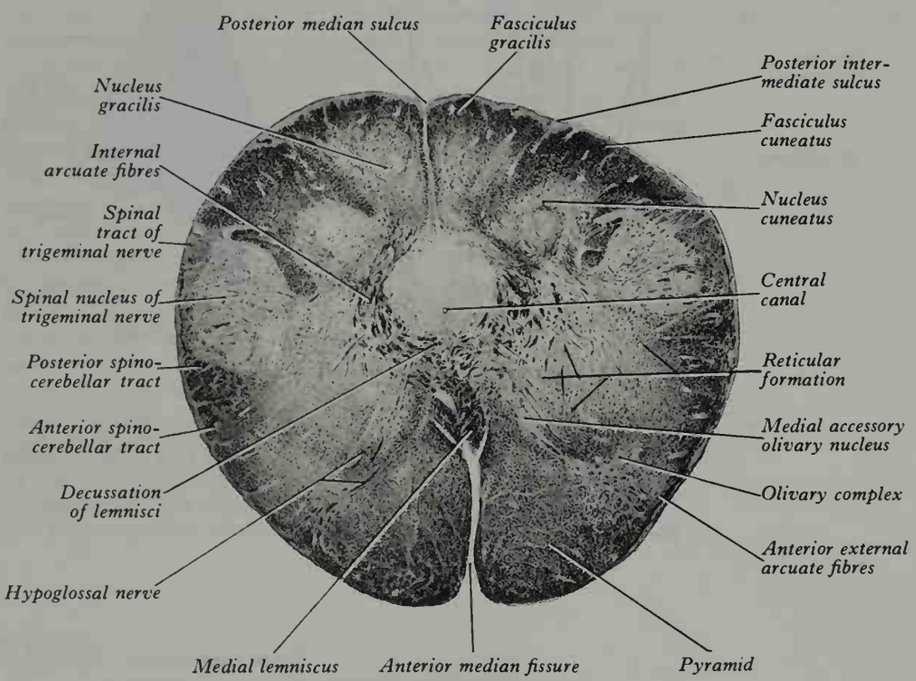
7.59 Dissection exposing the brainstem and upper five cervical spinal segments after removal of large portions of the occipital and parietal bones and the cerebellum together with the roof of the fourth ventricle. On the left the foramina transversaria of the atlas and the third, fourth and fifth cervical vertebrae have been opened to expose the vertebral artery. On the right the posterior arch of the atlas and the laminae of the succeeding cervical vertebrae have been removed.

striking alterations. The anterior grey column is separated from the central grey matter by the decussating corticospinal fibres, which are coursing backwards and laterally to reach the lateral funiculus of the opposite side. In the upper part of the medulla oblongata the corticospinal fibres occupy the pyramid in its ventromedial portion, but in the lower part the majority of the corticospinal fibres cross the median plane, inclining backwards, as they do so (7.57), and decussating anterior to the central grey matter. The decussation takes place in an orderly manner with the fibres which terminate in the cervical segments of the spinal cord decussating first. This *decussation of the pyramids* is the most striking feature in sections of the medulla oblongata at this level. The actual proportion of the fibres which take part is subject to variation, but, as a rule, at least three-quarters do so and continue down the spinal cord in the lateral funiculus as the lateral corticospinal tract. Of the remaining fibres some retain their ventromedial position and descend in the anterior funiculus of the spinal cord as the anterior corticospinal tract; others descend with the crossed fibres in the lateral funiculus of the same side (7.57). As a result of this decussation the anterior intersegmental tract of the spinal cord is displaced nearer to the central grey matter, which also takes up a more dorsal position so that the central canal inclines backwards as it ascends. The continuity between the anterior grey column and the central grey matter, maintained throughout the whole length of the spinal cord, is severed. The detached anterior grey column rapidly diminishes in size as it ascends; it is subdivided into the *supraspinal nucleus*, the source of efferent fibres of the first cervical nerve, and the *spinal nucleus of the accessory nerve*, which lies dorsolaterally and gives origin to the upper fibres of the spinal part of that nerve. The supraspinal nucleus is continuous above with that of the hypoglossal nerve. The nucleus of the spinal part of the accessory nerve is continued into the upper five segments of the spinal cord where it lies in the dorsolateral part of the anterior grey column. Above it merges with the nucleus ambiguus (p. 905).



The outline of the posterior column of grey matter can still be

made out, but it, too, has undergone some modification. A narrow, strip-like portion of grey matter appears in the middle of the fasciculis gracilis, continuous ventrally with the base of the posterior horn. This is the inferior end of the *nucleus gracilis*, which extends upwards as far as the caudal limit of the fourth ventricle and forms an elevation on the posterior surface of the medulla oblongata, already described as the gracile tubercle (p. 899). A second cuneiform projection from the base of the posterior horn, beginning at a slightly higher level, invades the ventral part of the fasciculus cuneatus, and constitutes the *nucleus cuneatus*.



The *substantia gelatinosa* is a prominent feature in the direct upward continuation of the apex of the posterior grey column of the spinal cord. Here this apex is continuous with the lower end of the *nucleus of the spinal tract of the trigeminal nerve*, and the fibres of the tract itself are interposed between the nucleus and the surface of the medulla oblongata (7.60). It is considered in detail on pp. 911, 1086.

(2) **A transverse section just rostral to the decussation of the pyramids** shows an accentuation of the differences already noted and the appearance of certain new elements (7.61).

The *nucleus gracilis* has increased in breadth and the fibres of its corresponding fasciculus are grouped together on its dorsal, medial and lateral surfaces; the *nucleus cuneatus* has undergone a similar change. At first both retain their continuity with the central grey matter, but this is lost at higher levels. The fibres of the fasciculus gracilis and cuneatus have ascended uncrossed through the spinal cord, and the majority terminate in their respective nuclei at different levels by forming synapses with their contained nerve cells. New fibres arise in the nuclei and constitute further neurons on the pathway of tactile and proprioceptive sensibilities. These *internal arcuate fibres* emerge from the ventral aspects of the nuclei and, curving forwards and laterally at first round the central grey matter, they bend medially to reach the median plane, where they decussate with the corresponding fibres of the opposite side (7.61). Thereafter, they turn upwards and ascend on the opposite side close to the median raphe, constituting the *medial lemniscus*. The *decussation of the lemnisci* occurs in the area dorsal to the pyramids and in front of the central grey matter, which is in this way displaced still more dorsally towards the dorsal surface of the medulla oblongata. As the internal arcuate fibres sweep forwards they intervene between the spinal tract of the trigeminal nerve and the central grey matter. From the foregoing remarks it might appear that the gracile and cuneate nuclei are simply relay stations on a main sensory pathway widely regarded as the major route for impulses concerned with the more discriminative aspects of tactile and locomotor sensibility. During the last decade abundant anatomical and physiological evidence has led to a reappraisal of these views. Anatomically, the neuronal population of these nuclei has long been considered somewhat uniform, despite the early definition of many cell types within them by Cajal (1900). Although many of the neurons are multipolar, they vary much in size and are by no means uniformly distributed. Taber (1961) and Kuypers and Tuerk (1964) have described a variety of neurons in the nuclei and Biedenbach (1972) has defined two zones, of contrasting cytoarchitecture. In all species examined, including monkeys, the rostral region of each nucleus is *reticular* in nature, consisting of small and large multipolar neurons with long dendrites, and large but rounded neurons with short and profusely branching dendrites; this third type of neuron predominates in the caudal part of each nucleus, in which the neurons are *clustered* in various formations. These two zones differ in their connexions. Both receive dorsal root fibres, which terminate at all levels of the gracile and cuneate nuclei; but the caudal zone receives a denser input than the rostral (reticular) zone. Dorsal funicular fibres which arise from neurons in the spinal grey substance terminate only in the reticular zone. In all these connexions there is variable somatotopical distribution of terminals on the basis of spinal roots, which follows that in the dorsal funiculi; but considerable and variable degrees of overlap have been observed (*see* for example, Millar and Basbaum 1975). In monkeys, the hind leg and tail are represented medially in the nuclei, the trunk ventrally, and the digits dorsally. There is also

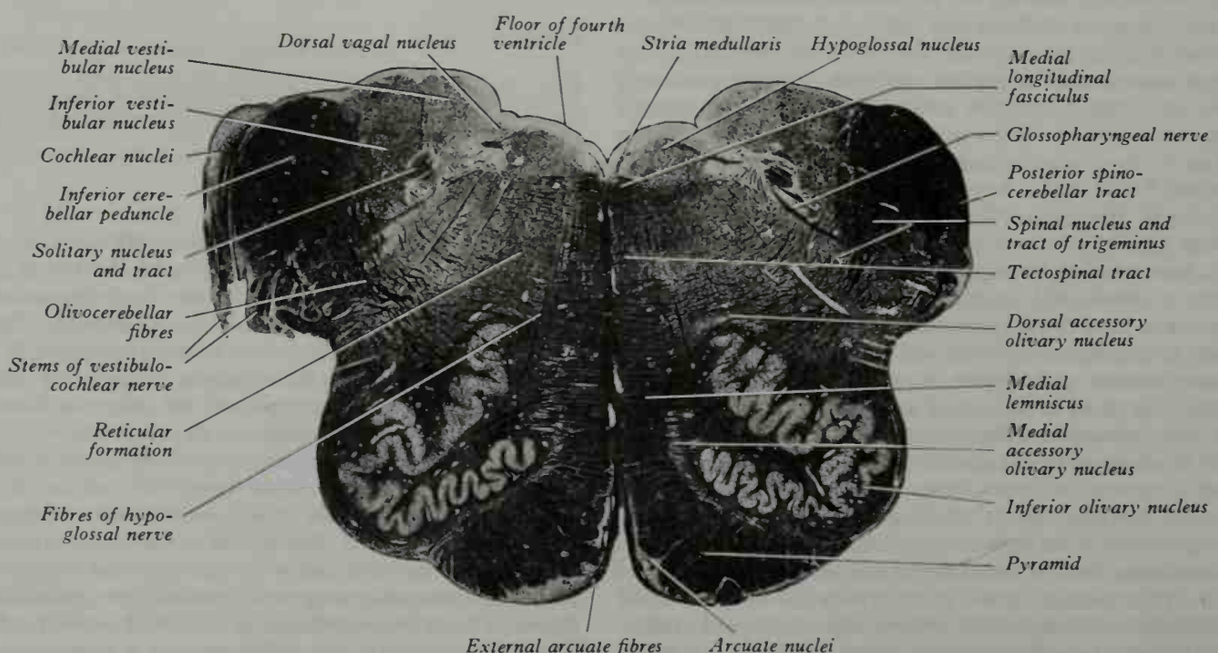
modality specificity; the caudal zone responds to low threshold cutaneous stimuli, while the neurons of the reticular (rostral) region respond to inputs from fibres subserving cutaneous and proprioceptive stimuli from joints and muscles. Both nuclei contain intrinsic cells or interneurons (Andersen *et al.* 1964; Rustioni and Sotelo 1974), and many of these are inhibitory in their effects. However, primary spinal afferents form synapses with the large rounded multipolar neurons which constitute the major source of efferent projection from the nuclei, thus forming a simple relay between spinal cord and higher levels. The descending afferents from the somatosensory cortex (p. 958), which reach the nuclei through the corticospinal tracts appear to be restricted in termination to the reticular zones; they may inhibit or enhance activity at the nuclear level, which is clearly a region of complex modulation of incoming sensory information. The same reticular zones also receive a projection from the reticular formation proper (Špaček and Lieberman 1974). It appears probable, for example, that a 'feed-back' mechanism

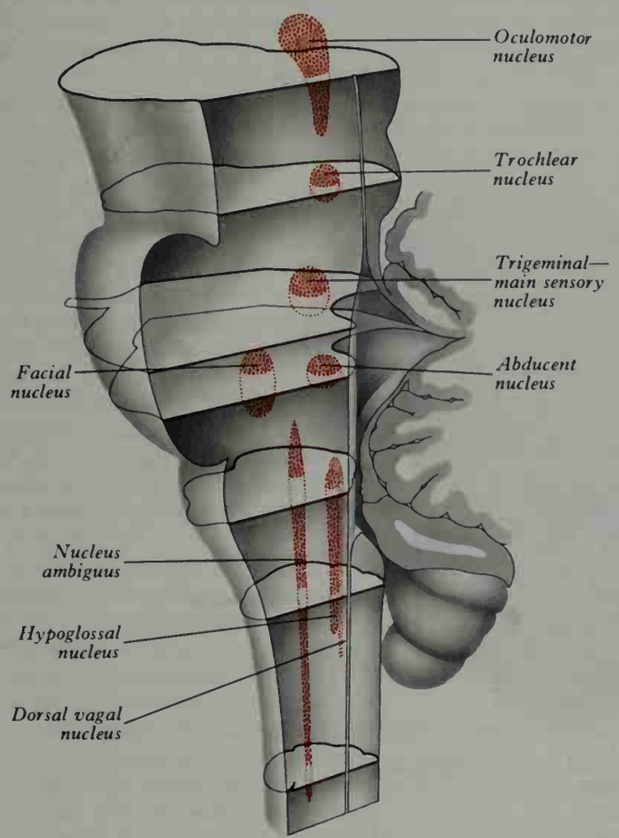
7.62 *Surface projection* of some cranial nerve nuclei on the dorsal aspect of the brainstem. Motor nuclei in red; sensory in blue. The vestibular nuclei are indicated in the main diagram by interrupted lines and are shown in detail in the small diagram. The olfactory and optic centres are not shown.



from the gracile and cuneate nuclei to the spinal cord also exists. By antidromic stimulation (Dart 1971), retrograde horseradish peroxidase studies (Kuypers and Maisky 1975), and anterograde autoradiographic transport techniques (Burton and Loewy 1977), it has been shown in cats and monkeys that cells in these nuclei project to various regions of the ipsilateral dorsal appendage of the spinal grey matter. These descending fibres are presumably those involved in the depression of dorsal column neuronal activity which follows stimulation of the column itself (Hillman and Wall 1969).

The *accessory cuneate nucleus* lies dorsolateral to the cuneate nucleus. It contains large cells similar to those of the thoracic nucleus of the spinal cord and gives origin to the *posterior external arcuate fibres* (p. 916); these enter the cerebellum through the ipsilateral inferior cerebellar peduncle. The accessory cuneate nucleus receives its afferents from the lateral fibres in the fasciculus cuneatus which are derived from the cervical segments. It provides a pathway, the *cuneocerebellar tract*, for proprioceptive impulses from the upper limb, destined for the cerebellum, which enter the spinal cord above the upper limit of the thoracic nucleus. A group of neurons, currently known as *'nucleus Z'*, was first identified in the cat by Brodal and Pompeiano (1957) between the rostral pole of the nucleus gracilis and the termination of the inferior vestibular nucleus and it is said to be present in the human medulla (Webster 1977). Its principal input appears to be from the dorsal spinocerebellar tract (Rustioni 1973), and it may constitute a separated part of the reticular zone of the gracile nucleus, which it resembles in cytoarchitecture. It is considered to be concerned in proprioception from the ipsilateral hind limb (Landgren and Silfvenius 1971).

The *nucleus of the spinal tract of the trigeminal nerve* (7.62) is at this level separated from the central grey matter by the internal arcuate fibres. It is separated from the lateral surface of the medulla oblongata only by the spinal tract of the trigeminal nerve, the fibres of which terminate in the nucleus, and by some of the fibres of the posterior spinocerebellar tract, which is beginning to incline dorsally to enter the inferior cerebellar peduncle (p. 916).



Two additional collections of grey matter occur at this level. One is dorsal to the lateral part of the pyramid, while the other is placed to its medial side and not far from the median plane. These are parts of the *medial accessory olivary nucleus* and will be considered together with the inferior olivary nucleus (p. 904).

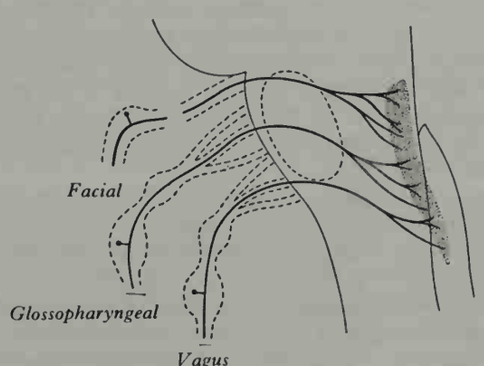
The central grey matter, now occupying a position near the dorsal surface of the medulla oblongata, contains three important nuclei. A prominent group of large motor nerve cells, interspersed

7.63 Transverse section through the medulla oblongata at mid-olivary level. Weigert Pal preparation. Magnification *c.* ×4·5.

with myelinated fibres, is situated in the ventromedial part of the central grey matter. This is the *nucleus of the hypoglossal nerve*. It extends upwards into the open part of the medulla oblongata, where it lies under the medial part of the trigonum hypoglossi in the floor of the fourth ventricle. Immediately adjacent to the hypoglossal nucleus are several other smaller groups of nerve cells collectively spoken of as the '*perihypoglossal complex*' or '*perihypoglossal grey*'. Neither term has more than topographical significance, for none of them is known to be in any way connected with the hypoglossal nerve or its nucleus. Included in the complex

7.64 Diagram of motor nuclei of the cranial nerves. The sectional planes shown correspond to those depicted elsewhere in the text.

are the nucleus intercalatus (of Staderini), the 'sublingual' nucleus (of Roller), the nucleus prepositus hypoglossi, and the nucleus paramedianus dorsalis (reticularis), all of which contain cells suggestive in their characteristics of reticular connexions, which have been definitely ascribed to the paramedian nucleus (Brodal 1957). Gustatory and visceral afferent connexions have been attributed to the intercalated nucleus, but there is more convincing evidence that the perihypoglossal nuclei in general project to the cerebellum, at least in the cat (Torvik and Brodal 1954) and the monkey (Mehler *et al.* 1960). A topographical representation of lingual musculature has been described in the hypoglossal nucleus (p. 1083).



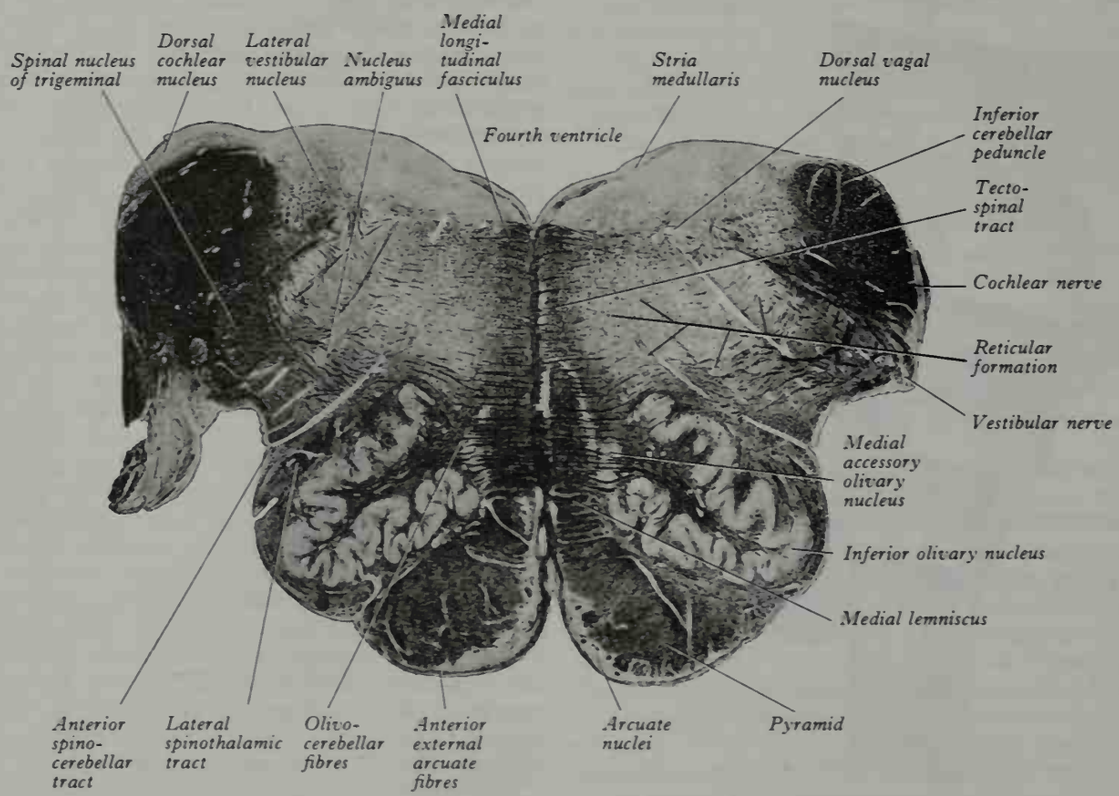
Dorsolateral to the hypoglossal nucleus, there is a second group of cells, the *dorsal nucleus of the vagus*. It is a mixed nucleus, containing cells of at least two types. The larger cells give rise to the fine fibres which innervate non-striated muscle; the smaller spindle-shaped cells may possibly be concerned with visceral afferent impulses. On the other hand many authorities believe that all the vagal visceral afferent fibres terminate in the nucleus of the tractus solitarius (*vide infra*). At a higher level the dorsal vagal nucleus is situated lateral to the hypoglossal nucleus in the floor of the fourth ventricle and corresponds in position to the trigonum vagi.

A third group of cells lies dorsolateral to the dorsal nucleus of the vagus at this level. It is the *nucleus of the tractus solitarius* (7.65), and it is intimately related to a group of descending fibres which constitute the *tractus solitarius* itself. At the caudal end of the medulla oblongata these two nuclei fuse dorsal to the central canal. As the nucleus of the tractus solitarius is traced upwards it comes to lie more deeply in the medulla oblongata, on the ventrolateral aspect of the dorsal nucleus of the vagus, with which it is practically coextensive. The tractus solitarius receives afferent fibres from the facial, glossopharyngeal and vagus nerves, and they enter the nucleus in that order from above downwards, conveying to it gustatory sensibility from the mucous membrane of the tongue and palate (facial, glossopharyngeal and vagus), and, according to many authorities, visceral sensibility from the pharynx (glossopharyngeal and vagus) and from the oesophagus and the abdominal part of the alimentary canal (vagus). In this rostrocaudal representation there is some degree of overlap (Schwartz *et al.* 1951; Kerr 1962). The nerve cells of the solitary nucleus are smaller than those of the dorsal vagal nucleus. It is presumed that their axons project to the thalamus and perhaps thence to the cerebral cortex, though experimental attempts to establish this in the cat have failed (Morest 1967). The same study demonstrated connexions with the dorsal vagal nucleus and nucleus ambiguus. There is evidence that the solitary nucleus projects to the upper levels of the spinal cord through a solitariospinal tract (p. 876) both in man (Collier and Buzzard 1903), and the cat (Torvik 1957). The nucleus is considered to receive fibres from the spinal cord, cerebral cortex and cerebellum (Angaut and Brodal 1967). Nerve cells aggregated in a position ventrolateral to the nucleus of the solitary tract have sometimes been termed the *nucleus parasolitarius* (Crosby *et al.* 1962).

Numerous scattered islets of grey matter occur in the centre of the ventrolateral portion of the medulla oblongata. They occupy an area which is freely intersected by nerve fibres running in all directions and which is therefore termed the *reticular formation*. It is present at all levels of the medulla oblongata and extends upwards into the tegmentum of the pons and midbrain. There is no clear demarcation between the reticular formations in these various regions and they are considered collectively on p. 943.

The white matter has undergone an important rearrangement above the corticospinal decussation. The *pyramids* contain corticospinal and corticonuclear fibres, the latter being distributed to the many nuclei of the cranial nerves. They form two large bundles in the ventral part of the section, on each side of the anterior median fissure. Dorsally they are related to the accessory olivary nuclei and the decussation of the lemnisci.

The fibres of the *medial lemniscus* (p. 901), after emerging from the lemniscal decussation, turn upwards on each side in the form of a flattened tract, closely applied to the median raphe. In this



7.65 Diagram of afferent fibres of the facial, glossopharyngeal and vagus nerves, conveying gustatory impulses to the nucleus of the tractus solitarius.

position they ascend to the pons, increasing in number as additional fibres join them from the upper levels of the decussation. Ventrally they are related to the pyramidal fibres, and dorsally to the medial longitudinal fasciculus and tectospinal tract. In the decussation the fibres undergo a rearrangement whereby those derived from the gracile nucleus come to lie ventral to those derived from the cuneate nucleus; at a higher level where

the disposition of the medial lemniscus in the brainstem becomes altered (p. 938), the gracile fibres are lateral and the cuneate fibres medial. The fibres of the medial lemnisci at this level have been shown to display in the monkey (Ferraro and Barrera 1936) and chimpanzee (Walker 1937) a laminar somatotopic arrangement on a segmental basis.

The *medial longitudinal fasciculus* forms a small compact tract of nerve fibres, situated close to the median plane and ventral to the hypoglossal nucleus. Below, it is continuous with the anterior intersegmental tract of the spinal cord, but at this medullary level it is displaced dorsally by the decussations of the pyramids and medially, intersecting the fibres of the medial lemniscus (7.63, 66). They cross the median plane and sweep dorsal to or traverse the olivary nucleus of the opposite side, intersecting the lateral spinothalamic tract, rubrospinal tract and nucleus of the spinal tract of the trigeminal nerve to enter the inferior cerebellar peduncle, by which they are conveyed to the cerebellum. Afferent connexions to the nucleus can be divided into ascending and descending fibres. The ascending fibres, mainly crossed, reach the nucleus from all levels of the spinal cord travelling in one or, possibly, two *spino-olivary tracts*. Some ascending connexions also reach the inferior olivary complex via the dorsal white

7.66 Transverse section through the superior half of the medulla oblongata. Weigert Pal preparation. Magnification *c.* × 4·5.

lemnisci. It is continued upwards through the pons and the midbrain in the same position relative to the central grey matter and the median plane, and therefore is closely related throughout its course with the somatic efferent column of the grey matter. The constituent fibres of the tract run relatively short courses within it, for they are derived from a variety of sources, which are detailed on p. 939.

The spinocerebellar, spinotectal, vestibulospinal, rubrospinal and lateral spinothalamic (spinal lemniscal) tracts are all in the anterolateral area, limited dorsally by the nucleus of the spinal trigeminal tract and ventrally by the pyramid.

(3) **A transverse section at the level of the caudal limit of the fourth ventricle** (7.63), shows a number of new elements, together with most of those already described at a lower level. The total amount of grey matter shows a distinct increase owing to the presence of the large olivary nucleus, the arcuate nucleus and nuclei associated with two divisions of the vestibulocochlear, the glossopharyngeal, vagus and accessory nerves.

The *inferior olivary nucleus* is a large hollow mass of grey matter, with irregularly crenated walls and a longitudinal hilum placed on its medial side. It is surrounded by a capsule of myelinated fibres forming the *amiculum of the olive*. Situated dorsolateral to the pyramid, the nucleus corresponds to the surface elevation of the olive, but extends upwards almost to the pons. The olivary nucleus consists of small cells, a large number of their axons forming the *olivocerebellar tract*. These axons emerge from the hilum or through the adjacent wall and run

columns (Hand and Liu 1966). The descending fibres arise from the cortex of the cerebrum, thalamus, basal nuclei, red nucleus and central grey matter of the midbrain (Walberg 1960). Some of these are said to travel in a bundle called the *central tegmental fasciculus* (Jansen and Brodal 1950).

The *medial accessory olivary nucleus* is a curved lamina of grey matter which is found at this level. The concavity of the curve is directed laterally and the nucleus is interposed between the medial lemniscus and the pyramid, on the one hand, and the medial and ventral aspects of the inferior olivary nucleus on the other.

The *dorsal accessory olivary nucleus* is a second lamina of grey matter, placed dorsal to the medial part of the inferior olivary nucleus.

Both the inferior and the accessory olivary nuclei are intimately associated with the cerebellum. Phylogenetically, the accessory olivary nuclei are older than the inferior nucleus, and they send their fibres to the paleocerebellum (p. 916). The inferior olivary nucleus occurs only in mammals and, in the course of evolution, it has enlarged in a caudal direction. In all their connexions, whether with higher levels in the cerebral hemispheres, the spinal cord, or the cerebellum, the olivary nuclei show a marked and often highly specific organization upon a somatotopic basis. This is particularly so in the case of cerebellar connexions, which are considered in detail later (pp. 916, 918, 924).

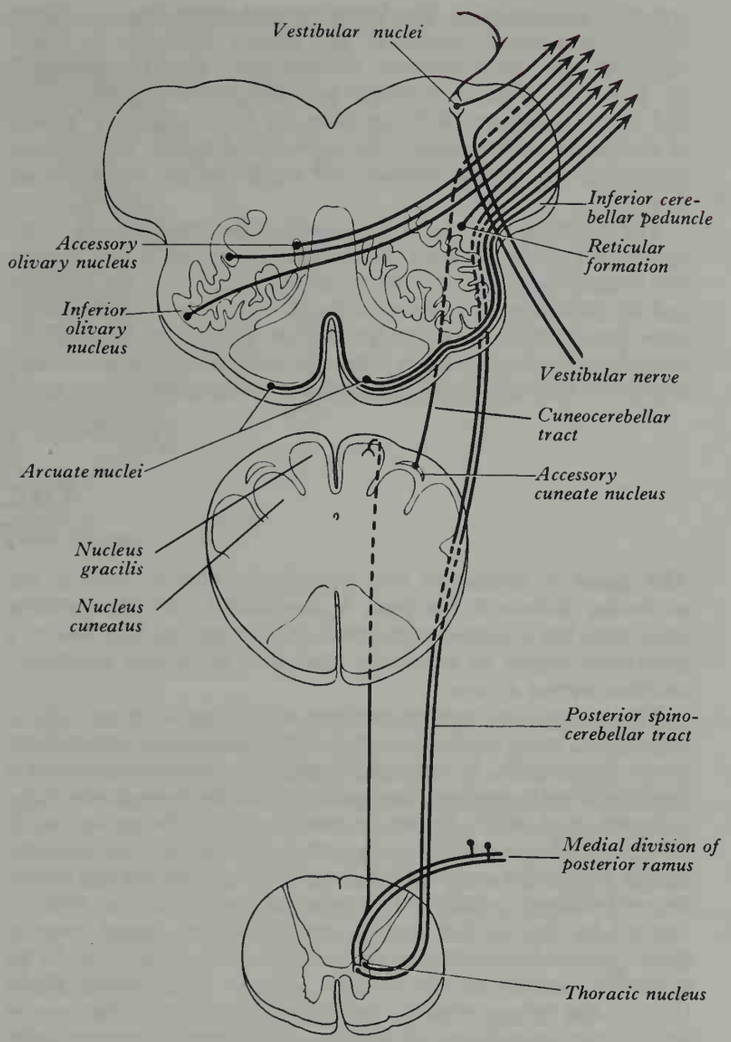
The *arcuate nuclei* form curved, interrupted bands of grey matter which are closely applied to the anterior and medial aspects

of the pyramids; they appear to be caudally displaced nuclei pontis (Rasmussen and Peyton 1946). They give origin to the anterior external arcuate fibres.

The central grey matter, which, at this level, is spread out over the floor of the ventricle, contains the *hypoglossal nucleus* and the *dorsal nucleus of the vagus*, the *nucleus of the tractus solitarius* lying ventrolateral to the last-named; lateral to these, and on the medial side of the inferior cerebellar peduncle, the lower part of the *inferior and medial nuclei of the vestibular nerve* may be recognized (p. 908). Between the hypoglossal nucleus and the dorsal nucleus of the vagus is the *nucleus intercalatus* (p. 903).

A small isolated group of large motor nerve cells, termed the *nucleus ambiguus*, is placed deeply in the reticular formation. It extends upwards as far as the upper limit of the dorsal nucleus of the vagus. The fibres which emerge from its upper end join the glossopharyngeal nerve, and those which emerge at a lower level join the fila of the vagus and cranial part of the accessory nerves. Inferiorly it is continuous with the spinal nucleus of the accessory nerve (p. 900). It consists of large motor neurons, the fibres of which are distributed to striated muscle of branchial origin (p. 1074). These first pass dorsally and medially for a short distance and then curve laterally to join the emerging fila of the cranial portion of the accessory, the vagus and glossopharyngeal nerves. Histologically, the nucleus ambiguus can be divided into several groups of cells in man, as in other mammals; experimentally some degree of representation of the muscles innervated has been established (Lawn 1966, and p. 1076). At the rostral extremity of the nucleus ambiguus, between this and the facial nucleus, is a small group of cells named the *retrofacial nucleus*. Though thus apparently in line with special visceral efferent nuclei, it is reputed to be a source of general visceral efferent fibres of the vagus nerve (*see* p. 1076).

The nucleus gracilis and the nucleus cuneatus, now diminishing in size and irregular in outline, occupy the dorsolateral portion of the section, and ventral to them the *nucleus of the spinal tract of the trigeminal nerve* can be recognized without difficulty.



The *cochlear nuclei* may be observed on the surface of the inferior cerebellar peduncle (pp. 909, 910).

The white matter of the medulla oblongata shows little change at this level apart from the development of the inferior cerebellar peduncle on the lateral side of the fourth ventricle. The pyramid, the medial lemniscus, the tectospinal tract and the medial longitudinal bundle occupy the same relative positions as they did at a lower level. The fibres of the olivocerebellar tract, sweeping across the median plane and turning dorsally to join the inferior cerebellar peduncle, have already been described in connexion with the olivary nucleus (p. 902). The *anterior external arcuate fibres* have their cells of origin in the arcuate nuclei of both sides and, emerging from the anterior median fissure, they run laterally, backwards and upwards over the surface of the pyramid, the olive and the spinal tract of the trigeminal nerve. Reaching the posterior spinocerebellar tract, they ascend with it to enter the inferior cerebellar peduncle (7.67).

The emerging fila of the hypoglossal nerve leave the ventral aspect of its nucleus and run forwards through the reticular formation. Passing lateral to the medial lemniscus and medial to, or sometimes through the wall of, the olivary nucleus, they curve laterally to emerge from the anterolateral sulcus. A relatively small lesion in the ventral part of the medulla oblongata at this level may therefore involve both the corticospinal tract and the hypoglossal nerve, causing a characteristic crossed paralysis. The muscles of the tongue are paralysed on the same side as the lesion, but it is the limbs of the opposite side of the body that are affected, for the lesion is situated above the level of the pyramidal decussation.

More dorsally, the reticular formation is traversed by the fibres of the vagus, travelling from their origin in the dorsal nucleus, the nucleus ambiguus and the nucleus of the tractus solitarius to the posterolateral sulcus, where they emerge.

The *spinal lemniscus* (p. 880), lies dorsal to the olivary nucleus and separated from the surface of the medulla oblongata by the anterior spinocerebellar and the spinotectal tracts. There is evidence from surgical procedures in man, and experiments in other animals, that the fibres are arranged somatotopically; those

7.67 Diagram to show some of the afferent components of the inferior cerebellar peduncle; the efferent components have been omitted. See text for further details.

conveying impulses from the lower limb are superficial, those from the upper limb deep and those from the trunk intermediate. As it ascends through the upper part of the medulla oblongata, the spinal lemniscus is closely related to the nucleus ambiguus, and a small lesion in the ventral part of the reticular formation may cause paralysis of the vocal fold and of the soft palate of the same side, but a loss of sensibility to pain and temperature on the opposite side of the body.

(4) **A transverse section of the most rostral part of the medulla oblongata** shows little change. The dorsal surface of the medulla oblongata here is relatively flat as compared with the preceding level and may show a few fibres of the stria medullaris just under this surface (p. 910). The inferior olivary nucleus occupies the same relative position, but the accessory olivary nuclei are broken up and diminishing (7.66).

The medial nucleus of the vestibular nerve has widened and lies on the lateral and dorsal sides of the dorsal vagal nucleus, which is now depressed below the floor of the rhomboid fossa. The inferior nucleus of the vestibular nerve intervenes between the medial nucleus and the inferior cerebellar peduncle. At the pontomedullary junction the *lateral vestibular nucleus* replaces the inferior nucleus and the lower parts of the cochlear nuclei are usually seen. (*See* p. 908 for details of the vestibular nuclei.)

The nucleus of the tractus solitarius, the nucleus of the spinal tract of the trigeminal nerve and the nucleus ambiguus show little alteration in position.

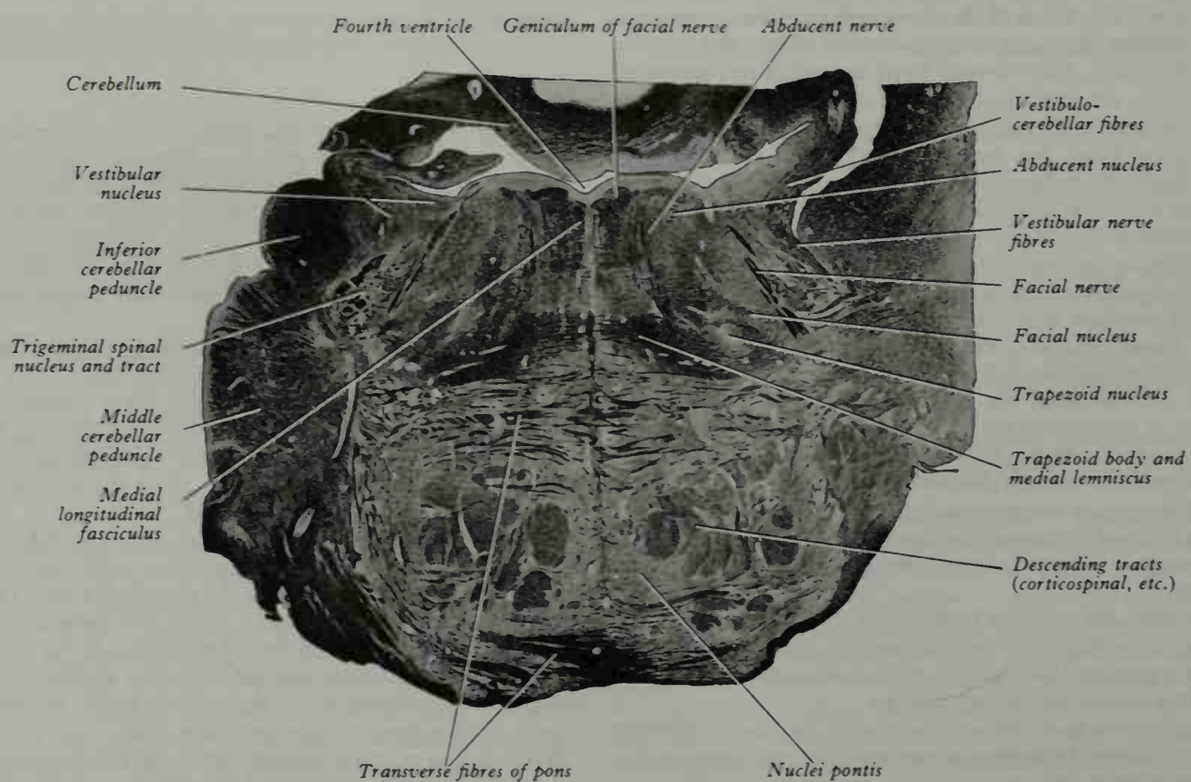
The arrangement of the white substance at this level shows no

conspicuous alteration. The lateral spinothalamic tract, or spinal lemniscus, ascends dorsal to the olivary nucleus, its fibres retaining the somatotopical arrangement already described (p. 880). The *inferior cerebellar peduncle* has increased in size and forms a well-marked elevation on the dorsolateral aspect of the medulla oblongata. The extensive array of fibres, from many sources, which compose the peduncle are described on p. 916.

The disposition of the *medial lemniscus* becomes altered in the upper part of the medulla oblongata. Its ventral region widens and becomes insinuated between the dorsal aspect of the pyramid and the narrowing cranial end of the olivary nucleus (7.71). At the same time its dorsal part recedes from the tectospinal tract and the medial longitudinal bundle. This alteration is continued so that, as it enters the pons, the medial lemniscus is extended in a coronal plane (7.70) in the ventral part of the tegmentum (p. 911). The medial lemniscus comprises the projection fibres on the pathway for proprioceptive and tactile sensibility. It is believed that, in its course through the medulla oblongata, it is joined by the fibres of the anterior spinothalamic tract (p. 876). On entry into the pons, therefore, the medial lemniscus contains many of the proprioceptive, tactile and pressure fibres from the lower limb, the trunk and the upper limb of the *opposite* side and there are good grounds for believing that the lower limb fibres are placed most laterally and adjoin those from the upper limb, while those from the neck lie most medially.

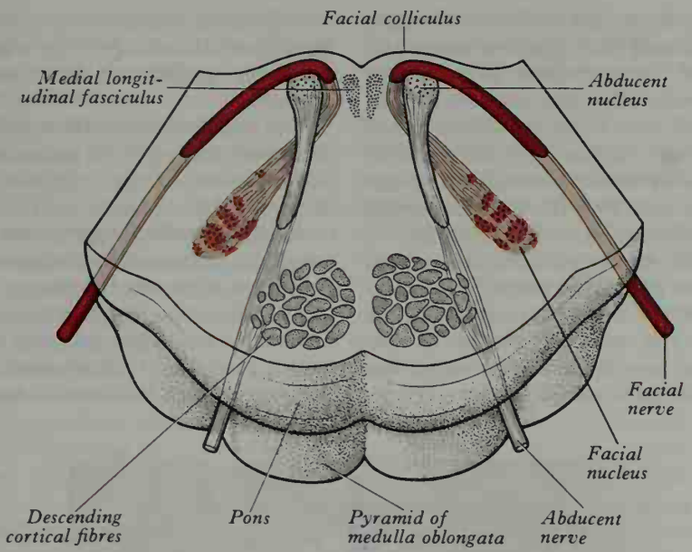
The medullary reticular formation: in the preceding pages no attempt has been made to describe the reticular 'columns', 'nuclei' and their subdivisions, classification and connectivity. These matters are reviewed in some detail on pp. 943–953.

THE PONS



The pons is ventral to the cerebellum. Rostral to it is the midbrain. Inferiorly the pons is continuous with the medulla oblongata, but is demarcated from it in front and on each side by a transverse furrow in which the abducent, facial and vestibulocochlear nerves appear.

The *ventral* or *anterior surface* of the pons (7.55, 56) is prominent, being markedly convex from side to side, less so from above downwards. It consists of transverse fibres arched like a bridge across the median plane, and converging on each side into a compact mass which forms the middle cerebellar peduncle. It adjoins the dorsum sellae of the sphenoid bone and the adjacent basilar part of the occipital bone, and is limited above and below by well-defined borders. The anterior surface of the pons is marked by the shallow median *sulcus basilaris*, which usually lodges the basilar artery; this sulcus is bounded on each side by an eminence caused by the descent of the corticospinal fibres through the substance of the pons. Lateral to these eminences, a little above the mid level of the pons, the trigeminal nerves make their exit, each consisting of a smaller, superomedial, motor root, and a larger, inferolateral, sensory root; lines immediately lateral to the superficial origins of the trigeminal nerves, may be taken as arbitrary boundaries between the ventral surface of the pons and the middle cerebellar peduncles.



The *dorsal* or *posterior surface* of the pons is hidden by the cerebellum. It contributes to the upper half of the rhomboid fossa, with which it is described (p. 933).

Transverse sections through the pons show that it is divided into a dorsal region or *tegmentum* and a *ventral (basilar) part*. The tegmentum is the direct upward continuation of the medulla oblongata, excluding the pyramids. The ventral part contains bundles of longitudinal fibres, some of which are continued into the pyramids of the medulla oblongata, numbers of transverse fibres and scattered collections of grey matter which constitute the *nuclei pontis*. (It should be noted that the term 'pons' is commonly used in two senses: firstly, to denote the externally visible protuberance of the ventral part of the region and, secondly, to designate both this and the tegmental part, i.e. the whole of the brainstem between medulla oblongata and mesencephalon.)

In mammals a correlation exists between the degree of

development of the cerebral hemispheres, ventral part of the pons and cerebellum (neocerebellum, p. 914). The ventral part of the pons is not present in submammalian forms; it is present in marsupials and higher mammals and possibly in the monotremes. As the mammalian scale is ascended, the ventral part increases in size *pari passu* with cerebrum and cerebellum.

INTERNAL STRUCTURE OF THE PONS

The ventral part of the pons presents a similar arrangement of its grey and white matter at all levels. The longitudinal bundles (7.71) comprise corticopontine, corticonuclear and corticospinal fibres, which are continued downwards from the crus cerebri (p. 935). As they enter the upper limit of the ventral part of the pons, they form a compact collection of fibres, but they rapidly become dispersed into numerous smaller bundles, separated from one another by the *nuclei pontis* and the transverse fibres of the pons. The *corticospinal fibres* descend through the whole length of the pons and enter the pyramids of the medulla oblongata, where they converge into compact tracts (p. 898). They are accompanied by *corticonuclear fibres*, some of which pass to the various contralateral nuclei of the cranial nerves in the pons; the remainder continue into the medulla oblongata to end in a similar manner. Clinically there is evidence that the facial nucleus and certain other nuclei (p. 910) also receive ipsilateral corticonuclear fibres. The *corticopontine fibres*, which are derived from the cerebral cortex of the frontal, temporal, parietal and occipital lobes, terminate at different levels in the nuclei pontis (7.68). The axons of the cells of the nuclei pontis form the *transverse fibres of the pons* (pontocerebellar fibres), and constitute the middle cerebellar

peduncle. The frontopontine fibres terminate in the nuclei pontis above the level of the emerging roots of the trigeminal nerve and are relayed to the opposite half of the cerebellum as the upper transverse fibres of the pons. A few of the pontocerebellar fibres do not cross the midline; they all end as mossy fibres of the cerebellar cortex (p. 924). Some degree of somatotopic organization is carried through this system of connexions. Axons from the tectum of the midbrain may also relay in the nuclei pontis (Pearce 1960), as may in addition some from spinal levels.

The *nuclei pontis* comprise all the masses of nerve cells which are scattered throughout the ventral part of the pons. They are of various sizes and shapes. As already indicated, they constitute cell stations on the pathway from the cerebral cortex to the cerebellum. The cells of the nuclei pontis are derivatives of the rhombic lip which migrate ventrally and cranially.

The *medial nucleus* of the vestibular nerve is continued upwards for a short distance into the tegmentum of the pons. The *lateral vestibular nucleus* lies between it and the inferior cerebellar peduncle.

The vestibular nuclei lie subjacent to the vestibular area in the rhomboid fossa (p. 933) and comprise the medial, lateral, inferior and superior. They receive fibres from the vestibular division of the vestibulocochlear nerve and send their axons to the cerebellum, medial longitudinal fasciculus, spinal cord and lateral lemniscus. The *medial vestibular nucleus* extends from the medulla oblongata at the level of the upper end of the olive into the lower part of the pons. As it ascends it broadens, so that the dorsal nucleus of the vagus becomes depressed below the floor of the fourth ventricle. It is crossed by the striae medullares, which separate it from the floor of the fourth ventricle. Caudally it is

7.71 Ventral aspect of a dissection of the pons, the medulla oblongata and the right cerebellar hemisphere. In the pons and medulla, the dissection is deeper on the left (right side of figure). Note the spiralling of the medial lemniscus and compare with 7.103.

All the cells which migrate in this direction do not succeed in reaching the ventral part of the pons. Some of them remain, forming an oblique ridge across the dorsolateral aspect of the inferior cerebellar peduncle, and constitute the *nucleus of the circumolivary bundle* (corpus pontobulbare). It has been held that the fibres, to which this discrete part of the nuclei pontis gives origin, run vertically upwards on the surface between the emerging seventh nerve on the medial side, and its sensory root and the eighth nerve on the lateral side (but for an alternative view *see* p. 910). The afferent fibres to the nucleus have been claimed to traverse the whole length of the pons with the corticospinal fibres and leave them only in the medulla oblongata. They course obliquely backwards and upwards over the surface of the olive, to reach their destination, forming part of the *fasciculus circumolivaris pyramidis* (7.77).

The dorsal, tegmental part of the pons varies in its internal details at different levels, especially in regard to its cytoarchitecture. These differences can be adequately illustrated for general purposes by sections at two representative levels, one cranial, one caudal.

A transverse section through the caudal part of the tegmentum passing through the facial colliculus (7.68), contains the motor nuclei of the abducent and facial nerves, the nuclei of the vestibular and cochlear divisions of the eighth nerve, and certain isolated collections of grey matter which will be described below.

continuous with the nucleus intercalatus. The *inferior vestibular nucleus* lies between the medial nucleus and the inferior cerebellar peduncle. It extends from the level of the cranial limit of the nucleus gracilis to the pontomedullary junction. It is interspersed by bundles of fibres from the descending part of the vestibular nerve and from the vestibulospinal tract. The *lateral vestibular nucleus* lies immediately cranial to the inferior nucleus and extends upwards almost to the level of the nucleus of the abducent nerve. It is composed of large multipolar cells. The cells of this nucleus give origin to the fibres of the vestibulospinal tract. The *superior vestibular nucleus* is small and lies above the medial and lateral nuclei.

The *fibres of the vestibular part of the vestibulocochlear nerve* can be seen entering the medulla oblongata between the inferior cerebellar peduncle and the spinal tract of the trigeminal nerve and are directed towards the vestibular area. After entering the brainstem, they separate into ascending and descending bundles and branches. The descending fibres terminate in the medial, lateral and inferior vestibular nuclei. They descend on the medial side of the inferior cerebellar peduncle and intermingle with the cells of the inferior nucleus. The ascending fibres pass either into the superior and medial nuclei and a few to the cerebellum. The fibres to the cerebellum pass superficially through the inferior cerebellar peduncle (in the *juxtarestiform body*) to terminate in the nucleus fastigii, the flocculonodular lobe and the uvula (p. 913). The vestibular nuclei not only project extensively to the

cerebellum (p. 916), but also receive axons from parts of the cerebellar cortex and the fastigial nuclei (p. 917). Their projections to the spinal cord, through the vestibulospinal tract, have already been described (p. 875). Vestibular connexions also reach the cord through the medial longitudinal fasciculus (p. 885). Efferent axons are also projected to higher levels in the cerebrum, probably mediating a bilateral cortical representation, but evidence for this is scanty. The vestibular complex sends fibres in addition to the pontine reticular nuclei (p. 946) and via the medial longitudinal fasciculus to the motor nuclei of the ocular muscles.

A number of minor groups of neurons in the vicinity of the named vestibular nuclei have been identified in experimental animals; only one of these, the *interstitial nucleus* of the vestibular nerve, is known to receive axons from it. The *nucleus parasolitarius* (p. 903) may be associated with the vestibular complex on the basis of afferent connexions from the fastigial nucleus of the cerebellum (p. 926). The total number of nerve cells in the vestibular nuclei much exceeds the complement of afferent fibres in the vestibular part of the eighth cranial nerve, and this is linked with the observation that vestibular afferents reach only limited regions of the vestibular nuclei, many of whose cells may be interneurons, many also being the sources of the varied projections mentioned above. There is considerable evidence of spatial representation of the vestibular apparatus in the nuclei (p. 1073). For an appraisal of the large volume of experimental research in connection with the vestibular pathway *see* Rasmussen and Windle (1960); Brodal *et al.* (1962).

The *fibres of the cochlear division of the vestibulocochlear nerve* partially encircle the lateral surface of the inferior cerebellar peduncle to terminate in the *dorsal* and *ventral cochlear nuclei*, which project slightly from the surface of the peduncle. The *dorsal cochlear nucleus*, which forms the auditory tubercle (p. 934), is on the posterior aspect of the peduncle and is continuous medially with the vestibular area in the rhomboid fossa. The *ventral cochlear nucleus* is on the anterolateral side of the peduncle in the interval between the cochlear and vestibular fibres of the vestibulocochlear nerve. The two parts of the vestibulocochlear nerve and the cochlear nuclei are usually seen in sections at the pontomedullary junction.

The ventral cochlear nucleus is highly complex in its cytoarchitecture, consisting of many cell types, variously described as giant, large and small spherical, multipolar, granular, and so on, the variants being on the whole grouped in separate regions of the nucleus (Cajal 1909; Lorente de Nó 1933). (*See* also p. 1074.) Degeneration experiments demonstrate a marked degree of topographical order in the termination of cochlear nerve fibres in the nucleus, in that different parts of the spiral organ of the cochlea and differing frequencies of stimulation appear to be related to specific cells serially arrayed in the ventrocaudal part of the ventral nucleus (Schuknecht 1960; Whitfield 1960). All the cochlear nerve fibres enter the nucleus, bifurcating as they do so into ascending branches, which terminate in the ventral nucleus, and descending branches traversing it to reach the dorsal cochlear nucleus (*vide infra*). The total number of cochlear nerve fibres has been estimated at about 25,000 in man, and since the ventral nucleus alone contains at least three times as many nerve cells as this in the cat, whose cochlear fibres are about half the human complement, it is clear that the cells in the cochlear nuclei greatly outnumber the fibres in the nerve. (Ferraro and Minckler 1977 have assessed the fibre count of the lateral lemniscus at a much higher value. *See* p. 1074.) Thus, a mere fraction of the cochlear nerve cells receive terminals from the nerve, though it is said that each fibre forms connexions with several cells (Lewy and Kobrak 1936). These terminals are limited to the ventral and caudal region of the ventral cochlear nucleus, some of whose neurons are probably local interneurons, the remainder being the sources of axons leaving the nucleus, as described below.

The dorsal cochlear nucleus is topographically almost continuous with the ventral nucleus, the two being separated by a thin stratum of nerve fibres. The dorsal nucleus also shows a complex organization, based upon a laminar pattern and containing a considerable spectrum of nerve cell types, including giant cells and other types like those in the ventral nucleus and also a fusiform or pyramidal type peculiar to it. Again, the terminals in the dorsal nucleus appear to be limited in their distribution, being derived, of course, from the descending branches of the cochlear nerve mentioned above (Osen 1969).

While details of the types of cells in the cochlear nuclei which project from them are not yet available, such axons are probably derived from several types, since a large proportion of the total number of cells have efferent axons, a few only being confined to the nuclei. These efferents all end at pontine levels in the superior olivary, trapezoid, and lateral lemniscal nuclei (*vide infra*), and they leave the cochlear nuclei by at least three routes. (1) The most ventral contingent of efferent fibres are also the most numerous, forming by their decussation the *trapezoid body* at the level of the pontomedullary junction (7.70). These axons ascend slightly as they approach the midline to decussate, but a minor number do not cross; they form connexions in the ipsilateral superior olivary nuclei. Those which decussate relay in the contralateral nuclei, and in both cases the next order of axons ascend in the corresponding *lateral lemniscus*. A few of the decussating fibres pass through the contralateral superior olive into the lateral lemniscus, where they relay in the lemniscal nuclei. (2) Some of the axons derived from ventral cochlear nucleus cells pass dorsally superficial to the descending spinal fibres of the trigeminal nerve and to the cerebellar fibres in the inferior peduncle, together with axons of the dorsal cochlear nucleus, which form the third group. These ventral cochlear fibres, which are smaller in calibre than those forming the trapezoid decussation, swerve ventromedially to cross the midline ventral to the medial longitudinal fasciculus as the *intermediate acoustic striae* (of Held 1893); their further progress is uncertain, but they probably pass rostrally within the opposite lateral lemniscus. (3) The most dorsal group of cochlear projection fibres, derived from the dorsal cochlear nucleus, turn medially around the dorsal aspect of the inferior cerebellar peduncle and continue towards the midline as the *dorsal acoustic striae* (of Monakow 1905). They are not to be confused with the striae medullares of the fourth ventricle (p. 910), to which they are ventral and thus more deeply situated. As the dorsal acoustic striae incline ventromedially they approach and cross the midline to reach and ascend in the opposite lateral lemniscus, in the nuclei of which they probably relay.

The *superior olivary complex of nuclei* is located laterally in the reticular formation at the level of the pontomedullary junction. Medial to the complex are the trapezoid nucleus and body, inferior to it the much larger inferior olivary group of nuclei (p. 904). The superior olive consists of a number of named nuclei and other small groups of nerve cells (Irving and Harrison 1967). The *lateral superior olivary nucleus* (the S-shaped segment of the feline olivary complex) is relatively small in primates, including man. Medial to it is the *medial (accessory) superior olivary nucleus* (the para-olivary nucleus of Minckler), which is large in man. Medial again to this is the nucleus of the trapezoid body (*vide infra*). Dorsally situated in the complex is a *retro-olivary group* of nerve cells, reputed to be the origin of the efferent cochlear fibres described below. Interconnexions between the individual nuclei of the superior olivary complex have been described. Unit recording from the lateral nucleus in the cat (Warr 1966) has established the existence of a tonotopical mode of organization, adjoining groups of nerve cells being related to ipsilateral cochlear fibres concerned with different but related acoustic frequencies. The medial superior olivary nucleus receives impulses from both cochlear spiral organs, and physiological evidence suggests that it forms part of a pathway concerned in auditory localization. Together with the trapezoid nuclei, the superior olivary groups are the main relay stations of the ventral and largest projection of the cochlear nuclei. Their complex connexions, as demonstrated in experimental animals, are not yet well authenticated in the human brainstem. Neuronal counts of certain of these nuclei have been recorded (for man) by Ferraro and Minckler (1977).

The *trapezoid nucleus* is sometimes described as consisting of two parts—a ventral component of cells scattered among the fascicles of the trapezoid body and a more compact dorsal nucleus located medial to the superior olivary complex. Although usually regarded as relay stations on the auditory pathway, the trapezoid nuclei in man remain in this regard an uncertain issue. Some of the axons of the trapezoid nuclei may enter the medial

longitudinal fasciculus, ascending therein to terminate in the trigeminal and facial nuclei and also those of the motor nerves of the extraocular muscles. Such connexions could mediate reflexes involving the muscles in the middle ear (stapedius and tensor tympani) and the eye muscles.

The *nucleus of the lateral lemniscus* consists of small aggregations of nerve cells dispersed among the fibres of this fasciculus. Lateral and medial groups have been described. They receive bilateral afferent axons from both cochlear nuclei, and their efferents pass cranially into the midbrain through the lateral lemniscus; their further connexions will be considered later (pp. 941, 976). Total neuronal counts for these nuclei were of the order of 18,000–24,000 in human brainstems (Ferraro and Minckler 1977).

Efferent cochlear nerve fibres travel centrifugally in the cochlear nerves to innervate the spiral organ (Held 1893; Rasmussen 1967). Though comparatively few in number (about 500 in the cat), experiment suggests that they play an important part in hearing, perhaps being involved in both inhibitory and excitatory reflexes through the cochlear nuclei (Allanson and Whitfield 1955). Lateral inhibition has also been demonstrated by the unit recording technique applied at the trapezoid level of the auditory pathway. The efferent cochlear fibres appear to be derived from retro-olivary cells in the superior olivary complex, fibres from each side proceeding to both cochleae—hence the term 'olivocochlear' fibres. Borg (1973) has confirmed a projection to the cochlea from neurons not only dorsal but also ventral to the superior olivary nucleus, in the rabbit; he has also described a descending connexion from the inferior colliculus to the olivary complex (confirming a much older finding by Münzer and Wiener 1902). Since there is some evidence of a descending projection from the medial geniculate body to the inferior colliculus, a complete efferent corticocochlear pathway appears to be established (p. 976).

The *striae medullares of the fourth ventricle*, as already stated above, are *not* formed of nerve fibres involved in the auditory pathway. There is considerable evidence on the contrary that they are part of an *aberrant cerebropontocerebellar* connexion, in which the arcuate nuclei (p. 905) pontobulbar body (p. 908), and the external arcuate fibres (p. 905) are all concerned. Some confusion exists among the accounts of various authorities, especially regarding the role of the pontobulbar body. The following description merely presents the consensus of these views, some of which appear to be more reliably established than others. Embryological evidence (p. 164) suggests that some of the nerve cells which migrate ventrally towards the pons from the rhombic lip to form the nuclei pontis largely fail to do so and remain near the fourth ventricle as the pontobulbar body or nucleus. Others migrate further and are scattered superficially over the ventral aspect of much of the extent of the medullary pyramids as the arcuate nuclei, a sizable congregation of them occurring immediately caudal to the pons. Both groups of cells are considered to receive corticobulbar projections, those to the arcuate nuclei descending in the pyramids with the corticospinal fibres. Axons from the arcuate nuclei of both sides pass dorsally round the side of the medulla, cranial, superficial and caudal to the inferior olive as a thin stratum, fascicles of which are usually visible on the surface. All these fibres pass into the inferior cerebellar peduncle, being known collectively as *external arcuate fibres*. Some external arcuate fibres (so-called) follow an *internal* course passing dorsally from the arcuate nuclei through the substance of the medulla close to the median raphe. Reaching the floor of the fourth ventricle, these fibres decussate and turn laterally subjacent to the ependymal lining of the ventricle, entering the cerebellum by the inferior peduncle. In this latter part of their course these fibres form the striae medullares; from their connexions they are also known as the *arcuatocerebellar tract*. There is some evidence that this ends in the flocculus (Szentágothai 1955). Some of these fibres are said to end in the pontobulbar nucleus, but this may be a confusion with projection fibres of the nucleus. Some of the latter may travel ventrally forming part of a compact bundle, the *circumolivary fasciculus*, which skirts the caudal pole of the inferior olive, usually appearing as a surface feature of this part of the medulla. The fasciculus and the pontobulbar nucleus have been found absent in aplasia of the pons, an interesting confirmation of their affiliation with the pontocerebellar projection (Baumgarten 1959). The efferent circumolivary fibres which pass ventrally join the arcuatocerebellar tract, with which they reach the striae medullares and enter the contralateral inferior cerebellar peduncle. However, as pointed out previously (p. 908), afferent fibres to the pontobulbar nucleus have also been considered to run in the circumolivary fasciculus, and the precise contribution of efferent and afferent fibres to the fasciculus cannot yet be regarded as settled.

The nucleus of the abducent nerve is in the central grey matter a short distance from the median plane, and in line with the nuclei of the third and fourth cranial nerves, above, and the hypoglossal nerve, below, thus forming a somatic motor column (p. 164). It is close to the medial longitudinal fasciculus, which is placed to its ventromedial side. In this way fibres from the vestibular and cochlear nuclei and the nuclei of other cranial nerves, especially the oculomotor, communicate with the abducent, which also bears an intimate relation to the emerging fibres of the facial nerve (*vide infra*). The outgoing fibres of the sixth nerve pass ventrally downwards through the reticular formation, intersecting the trapezoid body and the medial lemniscus and traversing the basilar part of the pons to emerge at its lower border. (See also p. 1069.)

The facial nucleus lies in the ventrolateral part of the reticular formation of the pons, immediately behind the dorsal nucleus of the trapezoid body. Dorsal to it, and somewhat to its lateral side, is the spinal tract of the trigeminal nerve and its associated nucleus. The facial nucleus receives fibres from the corticonuclear tract of the opposite side, a smaller number from that of the same side (p. 1070), and also fibres from the ipsilateral rubroreticular tract. Its large motor cells give origin to the fibres of the facial nerve. These fibres do not pass directly from their origin to the surface of the brainstem, but pursue a very remarkable course. At first they incline dorsally and medially towards the rhomboid fossa, passing below the abducent nucleus (7.69). They then course upwards on the medial side of this nucleus, coming into close relationship with the medial longitudinal fasciculus, through which the facial nerve may be brought into communication with the other cranial nerves. Finally, the fibres of the facial curve forwards and laterally around the upper pole of the abducent nucleus forming the *genu of the facial nerve* and pass forwards, laterally and downwards through the reticular formation. In the last part of their course to the surface they pass between their own nucleus medially and the nucleus of the spinal tract of the trigeminal nerve lateral to them.

The unusual behaviour of the emerging fibres of the facial nerve provided apparent evidence in favour of the theory of neurobiotaxis (p. 164). In the 10 mm human embryo the facial nucleus lies in the floor of the fourth ventricle, occupying the position of the branchial (special visceral) efferent column, and at this stage it is placed at a level rostral to the abducent nucleus. As growth proceeds, the facial nucleus migrates relative to surrounding structures at first caudally, dorsal to the sixth nucleus, and then ventrally to reach its adult position. As it migrates the axons to which its cells give rise elongate, and their subsequent course maps out the pathway along which the facial nucleus has travelled.

It must be remembered that the facial nucleus not only receives fibres from the corticonuclear tracts for volitional control, but (in addition to many other sources) it also receives afferents from its own sensory root (through the nucleus of the tractus solitarius) and from the nucleus of the spinal tract of the trigeminal nerve. These latter sources of stimulation complete local reflex loops, in every way similar to the segmental reflex loops in the spinal cord. It was considered that to retain its proximity to the nucleus of the tractus solitarius and to the nucleus of the spinal tract of the trigeminal nerve the facial nucleus migrated 'neurobiotactically' from its original position in the basal lamina.

The nucleus of the facial nerve is divided into several parts. The cells which give rise to the axons innervating the muscles in the scalp and upper part of the face are placed towards the dorsal part of the nucleus and are believed to receive corticonuclear fibres from both sides (Papez 1927; Buskirk 1945). The subgroups of

neurons which form the nucleus may represent discrete motor pools (p. 1070).

The salivatory nucleus is near to the rostral end of the dorsal nucleus of the vagus, just above the junction of the medulla oblongata and pons (Lewis and Shute 1959). It is in close relation to the caudal end of the nucleus of the facial nerve. It is customary to divide it into *superior and inferior salivatory nuclei* which send their secretomotor fibres to the salivary and, perhaps, the lacrimal glands through the facial and glossopharyngeal nerves respectively (pp. 1070, 1074).

The nucleus of the spinal tract of the trigeminal nerve is continued up through the lower part of the pons, the fibres of the tract still being closely applied to the lateral aspect of the nucleus. It is placed ventral to the lateral vestibular nucleus and is intersected by the fibres of the vestibular nerve destined for that nucleus. The inferior cerebellar peduncle lies to its lateral side below, but inclines dorsally as it ascends to the cerebellum, and the spinal tract of the trigeminal nerve and its nucleus are subsequently related laterally to the middle cerebellar peduncle. Above, the nucleus becomes continuous with the superior sensory nucleus of the trigeminal. The spinal 'tract' is unfortunately named, for it does not consist of fibres originating in the central nervous system but of the descending axons of the trigeminal nerve derived from nerve cells in the trigeminal ganglion. From these fibres collaterals and terminals enter the spinal nucleus, which is continuous at its caudal end with the substantia gelatinosa of the dorsal grey column in the spinal cord (p. 1060). Rostrally it merges with the main sensory nucleus of the nerve. It is mainly concerned with the mediation of pain and thermal sensibilities in the trigeminal area. There is a well-established topographic organization within the nucleus. (For further details *see* p. 1060.)

In addition to tracts already studied at a lower level the white matter of the lower part of the tegmental region of the pons contains the trapezoid body, the lateral lemniscus and the emerging fibres of the sixth and seventh cranial nerves, which are new elements not present in the upper part of the medulla oblongata.

The *medial lemniscus* occupies the ventral part of the tegmentum. Its outline, on transverse section, is a flattened oval, extending laterally from the median and paramedian raphe (7.68). The vertically running fibres of the medial lemniscus are intersected by the horizontal fibres of the trapezoid body. Laterally they are related to the *lateral spinothalamic tract* and to the *trigeminal lemniscus*. The fibres of the latter are derived from the cells of the nucleus of the spinal tract of the trigeminal nerve of the opposite side, and convey painful and thermal impressions from the skin of the face, the mucous membranes of the conjunctiva, tongue, mouth, nose, etc. The lemnisci are now arranged as a transverse band composed, from the medial to the lateral side, of the medial and trigeminal lemnisci, lateral spinothalamic tract and lateral lemniscus.

The *trapezoid body* is formed by fibres derived from the cochlear nuclei (mainly the ventral) and from the nuclei of the corpus trapezoideum. They run transversely and rostrally in the ventral part of the tegmentum, and, having intersected or passed ventral to the vertical fibres of the medial lemniscus, they cross the median raphe, decussating with the corresponding fibres of the opposite side. Before they reach the emerging fibres of the facial nerve the fibres of the trapezoid body turn upwards to contribute to the *lateral lemniscus*, as the *ascending* part of the auditory pathway.

The course of the outgoing fibres from the nuclei of the abducent and facial cranial nerves has already been examined.

The *medial longitudinal fasciculus* is sited close to the midline, immediately ventral to the floor of the fourth ventricle. It is closely related to the nucleus of the abducent nerve and to the emerging fibres of the facial nerve, as they ascend on the medial side of that nucleus. The proximity of the fasciculus suggests that it may receive fibres from and transmit fibres to both structures (p. 939). As it lies in the lower part of the pons, the medial longitudinal fasciculus receives fibres from the vestibular nuclei and possibly from the dorsal nucleus of the trapezoid body (p. 909), through the peduncle of that nucleus. These contributions from the eighth nerve form the greater part of the fasciculus (p. 939) which is the main 'intersegmental' tract in the brainstem, particularly concerned with interactions between the nuclei innervating the ocular muscles, and between these and the vestibular system.

A transverse section at a rostral level in the tegmentum of the pons contains new elements in connexion with the trigeminal nerve (7.70), but otherwise shows no very notable alteration.

The motor nucleus of the trigeminal nerve lies in the reticular formation of the pons, deep to the lateral part of the floor of the fourth ventricle in line with the fibres of the trigeminal nerve traversing the ventral part of the pons (7.70).

The principal (superior) sensory nucleus of the trigeminal nerve lies on the lateral side of the motor nucleus, intervening between it and the middle cerebellar peduncle, and is continuous below with the nucleus of the spinal tract. The second neuron fibres from the principal sensory nucleus cross the median plane and ascend with the medial lemniscus to the thalamus (p. 1060).

The *nucleus of the lateral lemniscus* is a small collection of cells placed on the medial aspect of the tract in the cranial part of the pons. It receives synaptic terminals from some fibres of the lateral lemniscus; some of its efferent fibres enter the medial longitudinal fasciculus, whilst others return to the lemniscus. It is to be associated, as a relay station, with the nucleus of the trapezoid body.

The white matter of the tegmentum at this level is marked by the absence of the trapezoid body, which is now replaced by the lateral lemnisci, and the invasion of its dorsolateral part by the superior cerebellar peduncles.

The *medial lemniscus* (7.71) occupies a position in the ventral part of the tegmentum, but it has moved laterally a short distance from the median raphe. Here it is joined medially by the projection fibres from the principal sensory nucleus of the trigeminal nerve, which convey proprioceptive, tactile and pressure impulses from the receptive area covered by it. More laterally it is related dorsally to the trigeminal lemniscus and lateral spinothalamic tract, conveying pain and thermal impulses, and to the lateral lemniscus and its nucleus. As the lateral lemniscus ascends, it passes dorsally and lies close to the surface. It will be seen subsequently to send its fibres into the inferior colliculus and the medial geniculate body. The *medial longitudinal fasciculus* retains its paramedian position.

The *superior cerebellar peduncle* is a large collection of fibres many of which take origin in the dentate nucleus of the cerebellum (p. 926), and pass upwards and forwards to enter the lateral part of the roof of the fourth ventricle. As it ascends in this position it inclines forwards and medially and enters the dorsolateral part of the tegmentum. The *anterior spinocerebellar tract* is intimately associated with the foregoing. It has already been traced up through the medulla oblongata, where it lies dorsal to the olivary nucleus and separated from the surface only by the anterior external arcuate fibres. In the lower part of the pons it inclines dorsally between the sensory nucleus of the trigeminal nerve and the middle cerebellar peduncle until it reaches the lateral aspect of the superior peduncle. Its fibres then descend dorsally in a curve to enter the cerebellum.

The *reticular formation* is continued through all levels of the pons and its named nuclei, columns, and aggregates of aminergic neurons, and what is known of their connectivity is summarized on pp. 946–947.

THE CEREBELLUM

The cerebellum, the largest part of the hindbrain, lies behind the pons and medulla oblongata, and its median portion is separated from these structures by the cavity of the fourth ventricle. It lies in the posterior cranial fossa and is covered by the tentorium cerebelli (p. 986). It is somewhat ovoid in form, but constricted in its median part, and flattened from above downwards, its greatest diameter being from side to side. Its average weight in the male is about 150 grams. In the adult the proportion between the cerebellum and cerebrum is about 1 to 8, in the infant about 1 to 20.

GENERAL FORM OF THE CEREBELLUM

The cerebellum consists of two *cerebellar hemispheres* joined by a narrow median strip, the *vermis*. On the *superior surface*, however, there is no deep grooving in the paramedian planes, so that the surface of the superior vermis, which is raised into a slight median ridge, is directly continuous with the hemisphere on each side (7.72). Anteriorly the *superior vermis* projects beyond the free margin of the tentorium cerebelli, and from there it slopes downwards and backwards, related above to the straight sinus. The upper surface of each hemisphere is in contact with the tentorium cerebelli, and slopes downwards and laterally from the superior surface of the vermis. It is bounded, in front, by an anterolateral margin, which corresponds to the attachment of the tentorium cerebelli to the superior border of the petrous part of the temporal bone, and behind, by a curved posterior margin, which abuts against the transverse sinus as it lies in the attached margin of the tentorium cerebelli.

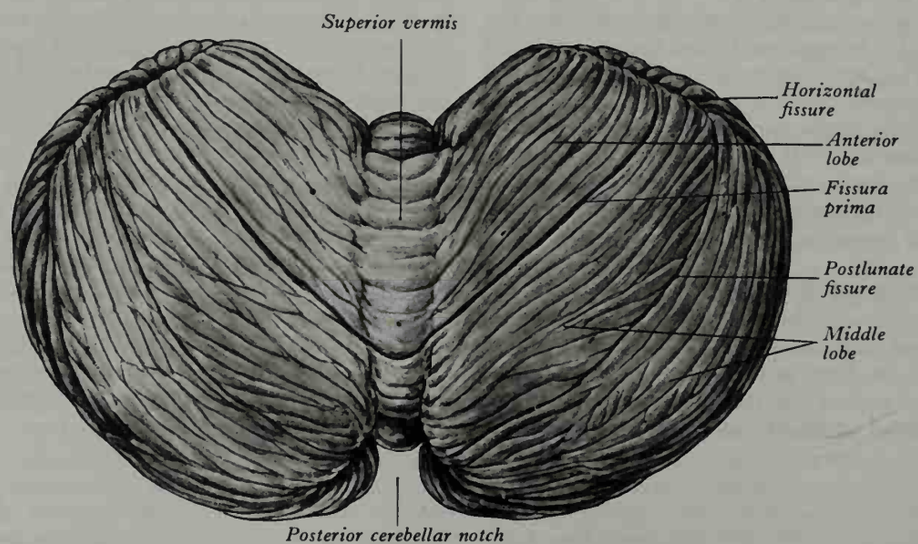
On the *inferior surface* the cerebellar hemispheres are separated from each other by a deep hollow, which is termed the *vallecula* (7.75). The inferior surface of the hemisphere is irregularly convex and lies in contact with the posterior surface of the petrous part of the temporal bone, the sigmoid sinus, the mastoid part of the temporal bone and the lower part of the squamous portion of the occipital bone. The *inferior vermis* projects into the floor of the vallecula and is limited on each side by the *sulcus valleculae*.

Anteriorly the cerebellum presents a wide, shallow *anterior cerebellar notch*, adapted to the pons and the upper part of the medulla oblongata, but these portions of the brainstem are separated from it by the fourth ventricle. In the floor of the anterior cerebellar notch the penduncles pass into the white centre of the cerebellum.

Posteriorly the hemispheres are separated from each other by the posterior cerebellar notch, which is a deep and narrow interval containing the falx cerebelli of the dura mater.

SURFACE TOPOGRAPHY OF THE CEREBELLUM

The surface of the cerebellum is everywhere marked by closely set transverse but somewhat curved fissures which give it a laminated appearance and separate its constituent *folia*. Some of the fissures are deeper than others and divide the organ into several *lobules*. The most conspicuous of these fissures is the *horizontal fissure*. This extends around the lateral and posterior borders of each cerebellar hemisphere from the middle cerebellar peduncle in front to the posterior cerebellar notch behind; it marks the junction of the superior and inferior surfaces of the cerebellum.



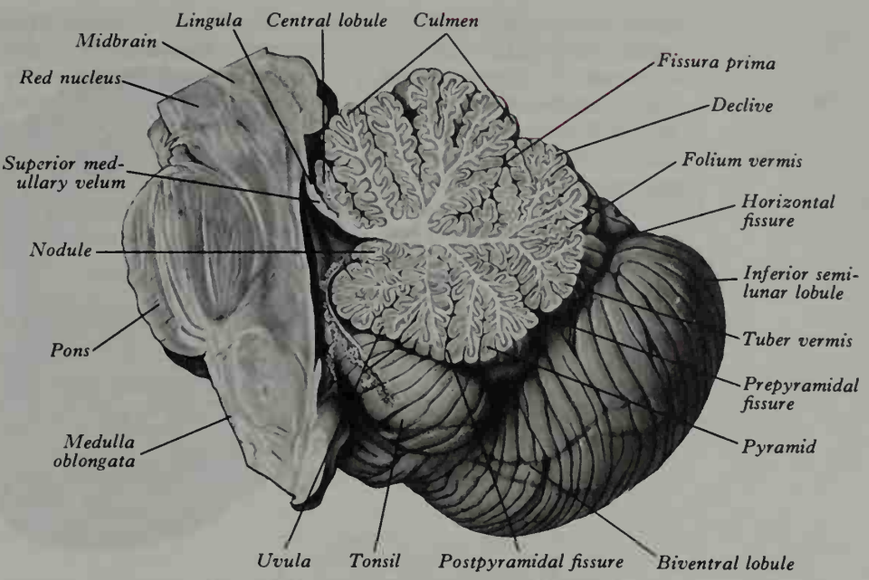
Superior surface (7.72, 85). The most conspicuous fissure of the superior surface is the *fissura prima*. This is somewhat V-shaped with its apex directed dorsally, and cutting into the superior surface of the vermis at the junction of its anterior two-thirds with the posterior third. The lines of the fissure are directed anterolaterally around the superior surfaces of the cerebellar hemispheres to meet the horizontal fissures close to their anterior ends.

The superior surface of the vermis is divided by short, deep fissures into the *lingula*, *central lobule*, *culmen*, *declive* and *folium vermis* in that anteroposterior order. Each of these divisions, excepting the lingula, is continuous laterally with the adjoining lobule of the cerebellar hemispheres (7.73, 85). The fissura prima indents the superior surface of the vermis between the culmen and declive.

The lingula consists of a single lamella which presents four or five poorly marked folia on its surface; its white matter is directly continuous with that of the superior medullary velum. The lingula is separated from the central lobule by the *postlingual fissure*. The central lobule is continuous laterally with the *alae of the central lobule*. These are limited behind by the *postcentral fissure*. Between this fissure and the fissura prima lies the culmen medially and laterally the *quadrangular lobule*.

The superior surface of the cerebellar hemispheres and vermis behind the fissura prima is divided by the curved *postlunate fissure* into an anterior portion which consists of the declive with its lateral extensions, the *lobuli simplices* and a posterior portion, the *folium vermis* with the adjoining parts of the cerebellar hemisphere termed the *superior semilunar lobules* which are limited behind by the horizontal fissures.

Inferior surface (7.75, 85). This includes the inferior surface of the vermis and the inferior aspect of each cerebellar hemisphere. The inferior vermis is divided into four smaller portions named from behind forwards the *tuber vermis*, *pyramid*, *uvula* and *nodule*. The tuber vermis is continuous laterally with



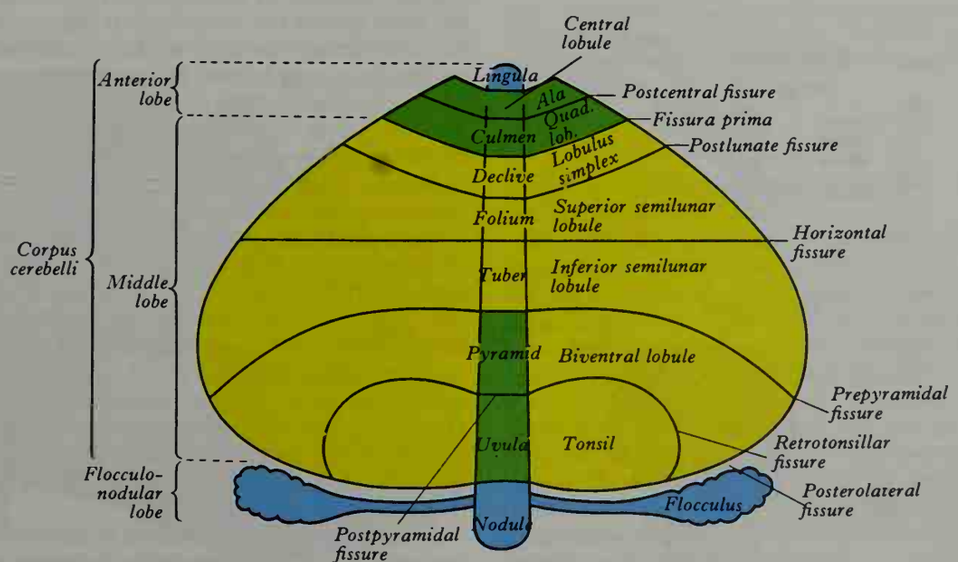
7.72 Superior aspect of the cerebellum to show major fissures and lobes. Compare with 7.74.

the *inferior semilunar lobules*. These parts are bounded, behind, by the horizontal fissure and, in front, by the *prepyramidal fissure*. The *pyramid* is separated from the *uvula* by the *postpyramidal fissure* or *fissura secunda* and is continuous laterally with the *biventral lobule* on the inferior surface of each hemisphere. In front of the uvula and separated from it by the median portion of the *posterolateral sulcus* is the nodule (7.73, 75).

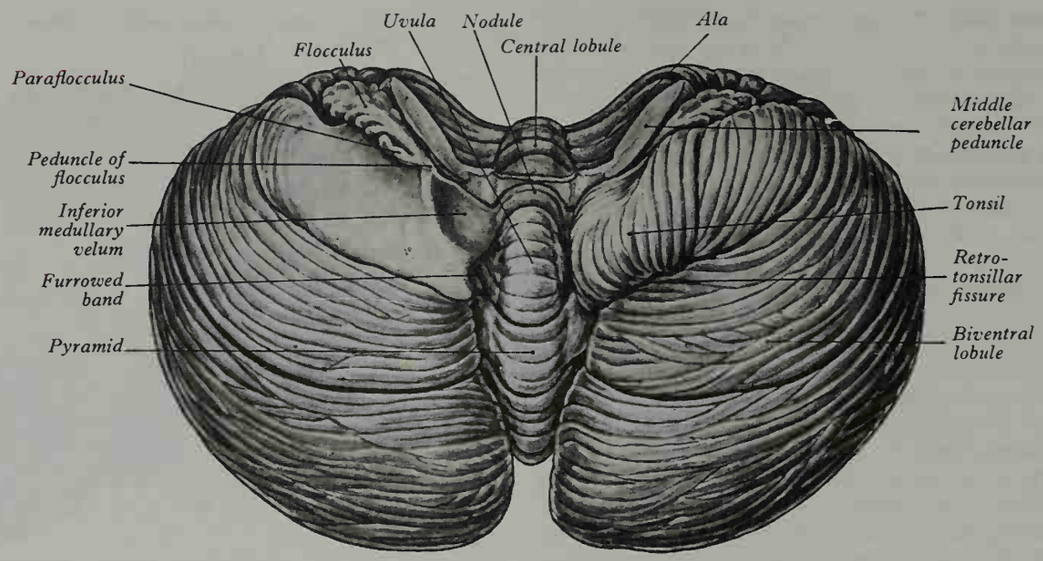
On the inferior aspect of the cerebellar hemisphere, anterior to the biventral lobule, is a deep fissure, the *retrotonsillar*, which passes laterally from the sulcus valleculae opposite the fissura secunda and then curves forwards to gain the anterior part of the inferior surface of the hemisphere. Together with the anterior part of the sulcus valleculae it bounds a circumscribed portion of the cerebellum, termed the *tonsil*, which is connected to the uvula across the floor of the sulcus valleculae by a strip of cortex, termed the *furrowed band* (7.75). Superiorly the tonsil lies in intimate relation with the inferior surface of the inferior medullary velum.

The *nodule* is the most anterior part of the inferior surface of the vermis. Behind, it is separated from the uvula by the posterolateral fissure, and on each side it is connected to the flocculus and the white core of the hemisphere by the inferior medullary velum. Its anterosuperior aspect is directed towards the fourth ventricle. Anteriorly it is covered with grey matter and crossed by two or three shallow fissures. In this situation it is separated from the ventricular cavity by a double layer of pia mater and its associated choroid plexus, and the ventricular ependyma (7.89). Posteriorly the grey matter is deficient, and the white matter is on the surface covered only with a layer of neuroglia and the ependyma (7.89). The lateral aspect of the nodule is free anteriorly and is covered with grey matter; posteriorly, it presents a narrow strip, where its white core would be exposed, were it not directly continuous with the nervous layer of the inferior medullary velum.

The *flocculus* is a small, partially detached portion of the cerebellum which lies immediately below the vestibulocochlear nerve as it enters the brainstem, and is crossed anteriorly by the fila of the glossopharyngeal and vagus nerves as they pass laterally to reach the jugular foramen. It is somewhat oval in outline, with a crenated margin, and from its medial end a narrow band of white fibres emerges, which constitutes the *peduncle* of the flocculus; it is covered anteriorly by the lateral recess of the fourth ventricle and the part of the choroid plexus which projects from the aperture of the recess (7.55). The peduncle contains both afferent and efferent fibres. At the lateral angle of the floor of the fourth ventricle it divides into dorsal and ventral parts. Through the dorsal part the flocculus establishes connexions with the nodule and the uvula. The ventral part passes medially and turns upwards close to the lateral border of the pontine part of the floor of the ventricle. Many of these fibres are afferent and are derived from the vestibular nuclei and also, according to some authorities, from the medial accessory olivary nucleus, but others are efferent to the vestibular nuclei and some appear to ascend to a higher level.



7.73 Median sagittal section of the cerebellum and brainstem.



THE LOBES OF THE CEREBELLUM

The cerebellum can be divided into two fundamental parts termed the flocculonodular lobe and the corpus cerebelli, the latter comprising an anterior and middle lobe (7.74, 85A). These subdivisions possess functional as well as morphological and embryological significance. The *flocculonodular lobe* consists of both flocculi, their peduncles and the nodule. The *corpus cerebelli* comprises the remainder of the cerebellum and is separated from the flocculonodular lobe by the *posterolateral fissure*, which is the first to appear on the cerebellum both in phylogeny and ontogeny. The corpus cerebelli is subdivided by the *fissura prima* into anterior and middle lobes. The *anterior lobe* lies in front of the fissure and comprises the lingula, central lobule, culmen, alae of the central lobules and quadrangular lobules. The remainder of the corpus cerebelli is termed the *middle lobe* and comprises the declive, folium vermis, tuber vermis, pyramid, uvula, lobuli simplices, biventral lobules, semilunar lobules and tonsils.

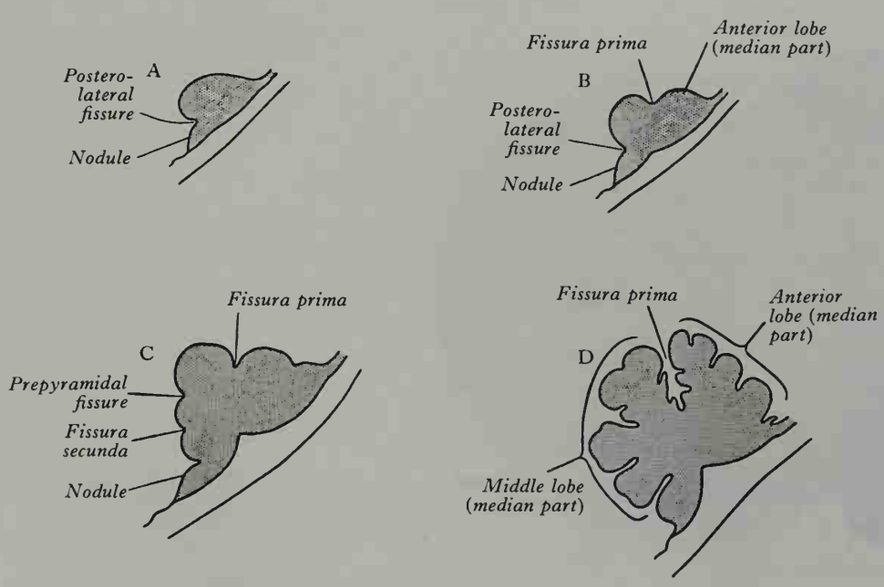
Certain sectors of the cerebellum are phylogenetically older than the rest. The flocculonodular lobe, which is predominantly

7.74 Diagram to show the morphological and functional subdivisions of the cerebellum. *Blue*: archicerebellum. *Green*: paleocerebellum. *Yellow*: neocerebellum. See also illustration 7.85 for further details.

7.75 Inferior aspect of the cerebellum. The tonsil and the adjoining part of the biventral lobule of the right side have been removed.

vestibular in its connexions, together with the lingula, which receives spinocerebellar in addition to vestibular connexions, constitute the oldest part of the cerebellum, the *archicerebellum*. The anterior lobe, excluding the lingula, but together with the pyramid and uvula of the middle lobe, is phylogenetically the next part to appear and is predominantly *spinocerebellar* in its afferent connexions, constituting the *paleocerebellum*. At this stage in phylogeny, this newly acquired lobe separates the archicerebellum into two parts, the lingula in front and the flocculonodular lobe behind. With the evolution of the neopallium in the mammal, there is a further expansion of the cerebellum with the addition of the middle lobe, excepting the pyramid and uvula. This addition constitutes the *neocerebellum* and is predominantly *corticopontocerebellar* in its afferent connexions. Like the paleocerebellum, the neocerebellum intervenes between the anterior and flocculonodular lobes (7.74, 85A).

The superior medullary velum is a thin lamina of white substance, which stretches between the superior cerebellar peduncles (brachia conjunctiva), and with them forms the roof of the cranial part of the fourth ventricle; its deep surface is covered with the ventricular ependyma. The velum is narrow anterosuperiorly, where it extends into the interval between the inferior colliculi, and broader postero-inferiorly, where it is continuous with the white substance of the superior part of the vermis. The folia of the lingula are prolonged on to the dorsal surface of its lower half, and a median ridge, termed the *frenulum veli*, descends upon its superior part from between the inferior colliculi. The trochlear nerves emerge at the sides of the frenulum (7.87).



The inferior medullary vela are two thin, somewhat crescentic, sheets placed one on each side of the nodule. Each consists of a thin layer of white matter and neuroglia, surfaced over internally by the ventricular ependyma, and externally by the pia mater. Its internal surface forms the lower wall of the lateral dorsal recess of the fourth ventricle (p. 932); its external surface is related to the superior aspect of the tonsil. Its convex peripheral margin is continuous with the white core of the cerebellum and with the sides of the pyramid, uvula and nodule; its anterior (sometimes inferior) border is free (7.87) and from it the ventricular ependyma is prolonged downwards in close apposition with the pia mater to form the thin part of the roof of the ventricle and to reach the taeniae. At its anterolateral corner the velum is continuous with the dorsal part of the peduncle of the flocculus, from which most, if not all, of its nerve fibres are derived (7.75).

GROSS DEVELOPMENT OF THE CEREBELLUM

For the initiation of cerebellar development *see* p. 165. Early in the third month the cerebellum is represented by a mass which stretches across the roof of the cranial part of the hindbrain vesicle, becoming bilobar like an hour-glass. Its narrow median part is destined to form the vermis, and its enlarged extremities develop into the hemispheres. As growth proceeds a number of transverse grooves appear on the dorsal aspect of the cerebellar rudiment, and give rise to the numerous fissures which characterize the surface of the cerebellum (7.75, 76).

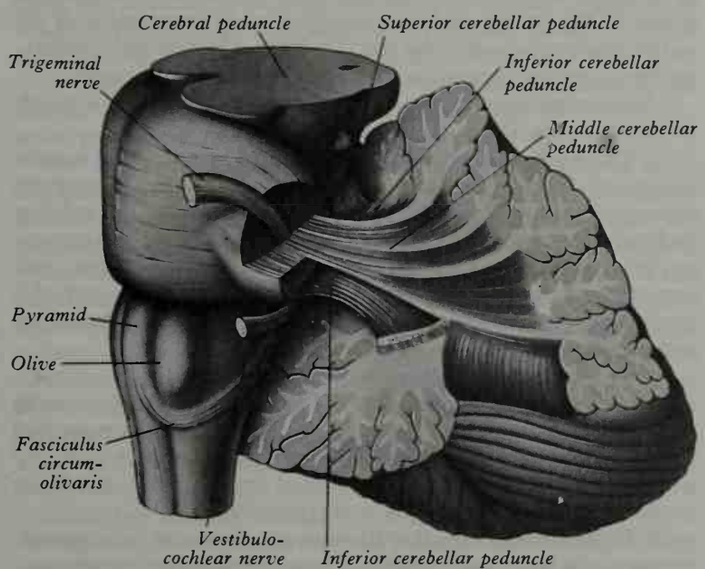
The lateral parts of the *posterolateral fissure* appear before any of the others and demarcate the most caudal region from the rest of the cerebellar rudiment, by which the flocculi can be identified. The right and left parts of this fissure extend medially and meet in the median plane, where they demarcate the nodule. The flocculonodular lobes can now be recognized and constitute the most caudal part of the cerebellum at this stage; but, owing to the growth of the adjoining areas, they come to occupy the anterior part of the inferior surface in the adult. They are formed in close proximity to the line of attachment of the epithelial roof, i.e. to the rhombic lip (p. 164).

At the end of the third month a transverse furrow appears on the cranial slope of the cerebellar rudiment, and deepens to form the *fissura prima*, which cuts into the vermis and both hemispheres, separating off the most cranial region of the rudiment to form the anterior lobe.

7.76 Median sagittal sections through the developing cerebellum at four successive stages.

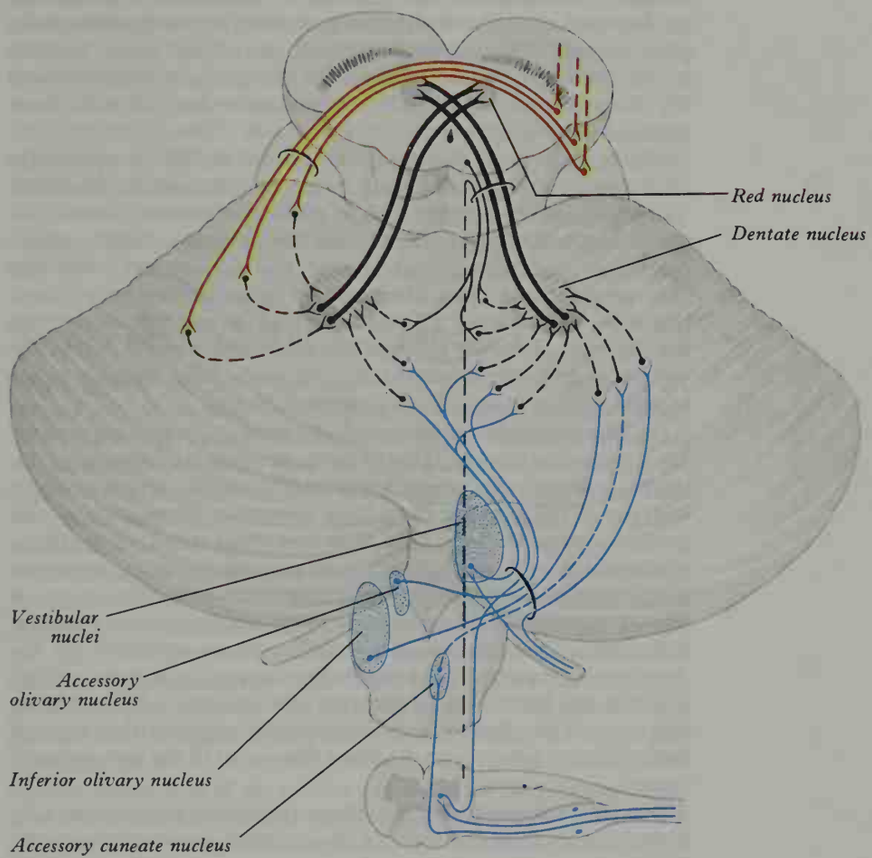
About the same time two short transverse grooves appear on the inferior surface of the vermis behind the postnodular fissure. The first of these is the *fissura secunda*, which demarcates the uvula, and the second is the *prepyramidal fissure*, which demarcates the pyramid (7.76). The whole cerebellum grows in a dorsal direction, and the caudal, or inferior, aspects of the hemispheres undergo much greater enlargement than the inferior surface of the vermis, which therefore becomes buried at the bottom of a deep hollow—the *vallecula*. While these changes are taking place numerous additional fissures develop, but they have little morphological significance. The most extensive of them forms the *horizontal fissure*.

In many mammals a portion of the hemisphere immediately cranial to the flocculus becomes demarcated, and in some it forms a very prominent part of the cerebellum. Owing to its relation to the flocculus, it is termed the *paraflocculus*, but the relationship is purely topographical, and, in contradistinction to the flocculus, the paraflocculus derives its afferent connexions mainly, if not entirely, from the cerebral cortex. It is uncertain whether any homologue of the paraflocculus exists in the human cerebellum, or whether it is represented by some small patches of grey matter which are found not infrequently on the inferior surface of the middle cerebellar peduncle. (For a résumé of *cellular neurogenesis* of the cerebellum consult pp. 166, 167.)



INTERNAL STRUCTURE OF THE CEREBELLUM

The cerebellum exhibits a profound difference in structure from the spinal cord, the medulla oblongata and the pons, for the grey and white matter of which it is comprised are arranged in the opposite manner. The grey matter or cortex covers the whole surface of the cerebellum, folding into all the various fissures which cross its surface. Certain aggregations of grey matter are found in its interior, but that does not in any way alter the prominence of the peripheral distribution of the grey matter and the central arrangement of the white matter. In this way the cerebellum resembles the cerebrum, and it is this modification of the disposition of the grey matter which has rendered possible the enormous degree of expansion which these two parts of the nervous system have undergone during the process of evolution.



The White Matter of the Cerebellum

The white matter forms a central core, which is much thicker in the lateral parts than it is in the median area, where it forms a flattened strip connecting the enlarged lateral portions with each other. From its surfaces a series of nearly parallel plates or laminae project towards the surface, and these give off secondary laminae, usually more or less at right angles to the primary laminae. In turn the secondary laminae may give off still shorter laminae, all of which are covered with grey matter. When a section is made through the cerebellum parallel with the median plane it divides the primary laminae at right angles, and the cut surface presents a characteristic branched appearance which is termed the *arbor vitae* (7.73).

The white matter consists of (1) fibrae propriae, (2) projection fibres, and (3) the myelinated axons of the Purkinje cells (*vide infra*), (4) 'climbing' afferent fibres (*vide infra*), and (5) 'mossy' afferent fibres (*vide infra*).

7.77 Dissection of the left cerebellar hemisphere and its peduncles (by the late Dr. E. B. Jamieson, University of Edinburgh).

7.78 A simplified diagram of the connexions of the cerebellum showing some components of the peduncles—inferior (blue), middle (magenta) and superior (black). The important cerebellothalamic fibres and other efferent systems, have been omitted.

The fibrae propriae or intrinsic fibres, as their name suggests, do not leave the cerebellum, but interconnect different regions of the organ. The *association fibres* connect adjacent or more distant folia of the cerebellar cortex, including those of the vermis. They do not cross the midline and the majority are relatively short bundles. Their detailed anatomy has not been extensively investigated (but see also p. 922). Numerous *commissural fibres* interconnect the two hemispheres; many are grouped into an *anterosuperior commissure*. A *postero-inferior commissure* also exists and crosses the midline near the fastigial nuclei (*vide infra*). In addition to interhemispheric cortical connexions, and running with them, are *decussating* spinocerebellar and cerebellovestibular fibres.

The projection fibres connect the cerebellum with other parts of the brain and spinal cord. They are grouped together into three large bundles or *peduncles* (7.77) on each side and these issue

from the anterior cerebellar notch. The superior peduncles connect the cerebellum to the midbrain, the middle peduncles to the pons, and the inferior peduncles to the medulla oblongata. Some of these connexions are shown in a highly simplified manner in 7.78.

THE INFERIOR CEREBELLAR PEDUNCLE

The inferior cerebellar peduncle is a thick bundle of white fibres, both entering and leaving the cerebellum from many sources and to many destinations. As described elsewhere (p. 899) it is formed on the dorsolateral aspect of the superior half of the medulla oblongata. The two peduncles diverge as they continue to ascend, but upon reaching the anterior cerebellar notch, each bends sharply posteromedially to enter into its respective hemisphere. As it bends and curves backwards it is insinuated between the middle peduncle on its lateral aspect and the superior peduncle medially. Some authorities consider it convenient to divide the inferior peduncle, for descriptive purposes, into a small medially placed strand, the *juxtarestiform body*, and a large lateral bundle, the *restiform body*. The relation of the oblique *pontobulbar body* to the dorsolateral aspect of the peduncle has already been mentioned (p. 908).

The tracts entering the cerebellum through the inferior peduncle stem from a variety of sources in the spinal cord and medulla. They include the olivocerebellar, parolivocerebellar, vestibulocerebellar, reticulocerebellar, posterior spinocerebellar, cuneocerebellar and trigeminocerebellar tracts, together with the anterior external arcuate fibres and other arcuatocerebellar fibres (the striae medullares). The tracts *leaving* the cerebellum through the inferior peduncle include the cerebello-olivary, cerebellovestibular and cerebelloreticular pathways, with minor bundles of cerebellospinal and cerebellonuclear fibres.

(1) **The posterior spinocerebellar tract**, as we have seen (p. 879), originates from cells in the thoracic nucleus of the same side, shows a somatotopic lamination of its fibres, and conveys a variety of types of information from both cutaneous exteroceptors and proprioceptors from the hind limb and lower trunk. Some fibres are 'modality-specific' whilst others carry information converging from more than one source; the transmission along both types of fibre may be modified by activity in descending tracts from the brainstem. The dorsal spinocerebellar fibres terminate in the 'hind-limb' regions of the cerebellar cortex (*vide infra*) which includes the vermis of the anterior lobe (central lobule, culmen and some of the declive) together with the neighbouring parts of their adjacent lobules, whilst other fibres end in the pyramid and uvula.

(2) **The cuneocerebellar tract** (posterior external arcuate fibres) passes from the cells of the external (accessory) cuneate nucleus to gain the anterior and posterior regions of the vermis of the same side. This tract and its nucleus of origin are somatotopically organized, and are functionally similar to the posterior spinocerebellar tract, but in relation to the fore-limb and upper trunk. The anterior and posterior areas of the cerebellar cortex which receive spinal afferents, and the localization of afferent terminals within these areas, are illustrated in 7.85A, B.

(3) **The olivocerebellar tract** is composed of the axons of neurons in the inferior olivary nucleus, whilst (4) **the parolivocerebellar tracts** originate from the dorsal and medial accessory olivary nuclei. It had long been suspected that a close correspondence existed between points on the surface of the inferior olive and ones on the cortex of the contralateral cerebellar hemisphere. Subsequently, studies of human cases with degenerative disease, and both physiological and anatomical experimentation in animals, have confirmed this. Further, it has been shown that a remarkably precise point-to-point interconnexion exists between all points of the olivary complex of nuclei and the opposite hemisphere. Broadly, a dorsoventral and a mediolateral correspondence exists with the inferior olive projecting to the larger and more lateral parts of the hemisphere, whilst the accessory olives project to the vermian and paravermian regions. Illustration 7.85E is a simplified summary of these findings based largely on clinical cases (for further details *see* Jansen and Brodal 1954; Brodal 1969). Whilst the olivocerebellar fibres largely cross the midline, some authorities have described a few fascicles which terminate ipsilaterally. The olivocerebellar fibres end in the cortex as *climbing fibres* which have, in recent years, been recognized as of great functional significance—they are discussed further below. In association with this it should be emphasized that afferents converge upon the olivary nuclei both from the spinal cord, the cerebral cortex and other subcortical centres. The spino-olivary tracts already described (p. 881) convey cutaneous and proprioceptive afferents to the accessory olivary nuclei, which in turn project largely on to the 'spinal regions' of the contralateral cerebellar hemisphere completing a *spino-olivocerebellar* system. Cortico-olivary fibres descend largely from motor regions of the cerebral cortex and terminate in localized areas of the inferior and accessory olivary nuclei (Sousa-Pinto and Brodal 1969) completing a *cortico-olivocerebellar pathway*. Additionally, other subcortical nuclei, including the corpus striatum, red nucleus and brainstem reticular formation, all project on to restricted regions of the olivary complex and may thus differentially affect cerebellar cortical activity.

Not all olivocerebellar fibres, however, terminate as climbing fibres in the cortex—some end in the contralateral fastigial, emboliform, globose and dentate intracerebellar nuclei, and the projections are to some degree somatotopically organized. These various nuclei will be further discussed below.

(5) **The reticulocerebellar tract** arises mainly from both large and small cells of the *lateral reticular nucleus* of the medulla (*nucleus of the lateral funiculus—see* p. 946), but other *perihypoglossal* and *paramedian* reticular nuclei also contribute—p. 903. Parts of the latter, in particular neuron group A2, the *nucleus commissuralis* part of the perihypoglossal group are noradrenergic (p. 949) and almost certainly contribute such fibres via the inferior peduncle to both the intracerebellar nuclei and cortex. The reticulocerebellar fibres end in the 'spinal' regions of the cerebellar vermis mentioned above.

It should be noted at this point that various indirect channels to the cerebellum thus exist through the intermediary of the medullary reticular nuclei, because of the convergence on them of spinoreticular, vestibuloreticular and corticoreticular pathways which are described elsewhere in this section.

(6) **The vestibulocerebellar tract** is in the main composed of primary afferent (root) fibres of the vestibulocochlear nerve, but some secondary fibres stem from cells of the medial and inferior vestibular nuclei. The fibres terminate ipsilaterally in the cortex of the archicerebellum, principally in the flocculus and nodule, but a small number are considered to end also in the uvula and lingula. Other vestibulocerebellar fibres are distributed to the fastigial nuclei of both sides. It is held (Stein and Carpenter 1967) that the primary vestibulocerebellar fibres are mainly those with sensory endings in the ampullae of the semicircular ducts. In contrast, the nuclei of origin of the secondary fibres are the sites of termination of the rather small spinovestibular tract (p. 877). The vestibulocerebellar fibres occupy part of the juxtarestiform body (*vide supra*).

The remaining pathways which enter the cerebellum through its inferior peduncle are less well understood.

(7) **The anterior external arcuate fibres** arise from arcuate nuclei of both sides and, together with some superficial reticulocerebellar fibres, course over the surface of the inferior peduncle to enter the cerebellum. As stated above, the arcuate nuclei are possibly homologous with the pontine nuclei, and accordingly, the anterior external arcuate fibres form part of a *cortico-arcuatocerebellar* pathway, but the cerebellar termination and significance of the latter is unclear.

(8) **The striae medullares**, encountered previously (p. 910), are also thought to originate in the arcuate nuclei; they partially decussate and pass to the flocculus. They are sometimes termed the *arcuatofloccular tract* (fibres of Piccolomini) and are probably to be grouped with the anterior external arcuate fibres, and those derived from the pontobulbar body (p. 908).

(9) **Trigeminocerebellar fibres** both crossed and uncrossed, are known to enter the cerebellum from the superior sensory and descending (spinal) nuclei of the trigeminal nerve. Their distribution, and the status of other nucleocerebellar tracts which

have been described are uncertain in the human cerebellum.

The tracts leaving the cerebellum in the inferior peduncle include:

(10) **Cerebello-olivary fibres**, as yet of uncertain origin, which leave in the inferior peduncle to terminate on cells of the inferior olivary nucleus.

(11) **Cerebellovestibular fibres**, which issue from the ipsilateral flocculus, nodule, and fastigial nucleus (and to some extent the opposite fastigial nucleus). They run with other constituents of the juxtarestiform body to reach the four vestibular nuclei, in which they terminate. Other cerebellovestibular fibres are the axons of Purkinje cells in the anterior and posterior regions of the vermis which do not synapse in the intracerebellar nuclei, but pass directly to the lateral vestibular nucleus. The anterior vermian projection shows a somatotopic localization which corresponds with that of the origin of the lateral vestibulospinal tract (p. 875). Further vermian projections pass to the fastigial nucleus, and thence to the lateral vestibular nucleus in the fastigiovestibular tract—again these pathways are somatotopically organized (Brodal *et al.* 1962).

(12) **Cerebelloreticular fibres**, which start in both, but mainly the contralateral, fastigial nuclei. They pursue an indirect course, partially decussating and then proceeding as the *hook bundle of Russell*, which curves around the cerebellar end of the superior peduncle before joining the inferior peduncle. In the main these fascicles are distributed to the pontine and medullary reticular formation. Accordingly, different functional zones of the nucleus fastigii (*vide infra*) and *fastigiovestibular* and *fastigiobulbar* tracts have been recognized. However, the two tracts are partially admixed in both the direct juxtarestiform body pathway and in the less direct hook bundle described above. Some observers believe that a proportion of the hook bundle fibres pass through the medulla oblongata to enter the anterior funiculus of the spinal cord as a *cerebellospinal tract*. The evidences with regard to the latter, and those concerning direct *cerebellonuclear tracts* to brainstem motor nuclei remain meagre and unconvincing.

THE MIDDLE CEREBELLAR PEDUNCLE

The middle cerebellar peduncle (brachium pontis) is more massive than the superior and inferior peduncles, and passes lateral to them as it continues from the dorsolateral region of the pons, curving dorsally and then radiating to become continuous with the laminae of white matter within the cerebellar hemisphere (7.77). It is composed almost exclusively of the axons from the second neurons on the extensive *corticopontocerebellar pathway*. These neurons constitute the nuclei pontis which are scattered throughout the substance of the ventral (basilar) part of the pons. The fibres arising from the nuclei in one half of the pons almost all cross the midline, traversing the opposite middle peduncle to reach the cortex of the contralateral hemisphere. However, much of the vermis probably receives pontocerebellar fibres from both sides of the pons, whilst the lingula, some small regions of the anterior lobe and the flocculonodular lobe receive no pontocerebellar projection.

The fibres of each middle peduncle are arranged in three fasciculi, superior, inferior and deep. The *superior fasciculus* is derived from the upper transverse fibres of the pons; it is directed backwards and laterally superficial to the other two fasciculi, and is distributed mainly to the lobules on the inferior surface of the cerebellar hemisphere, and to the parts of the superior surface adjoining the posterior and lateral margins. The *inferior fasciculus* is formed by the lowest transverse fibres of the pons; it passes inferomedial to the superior fasciculus and is continued downwards and backwards more or less parallel with it, to be distributed to the folia on the under surface close to the vermis. The *deep fasciculus* comprises most of the deep transverse fibres of the pons. It is at first covered by the superior and inferior fasciculi, but crossing obliquely it appears on the medial side of the superior, from which it receives a bundle; its fibres spread out and pass to the upper anterior cerebellar folia. The fibres of this fasciculus cover those of the inferior peduncle.

Despite a number of investigations the precise distribution of pontocerebellar fibres from different regions of the pons in terms of the localization of their cerebellar terminals has not yet been satisfactorily explored. In general, the most lateral and also the most medial pontine nuclei project to the vermis, whilst the intermediate ones project to the contralateral hemisphere.

The pontine nuclei receive the terminals of corticopontine fibres which arise from many, perhaps all, parts of the cortex of the ipsilateral cerebral hemisphere, and they also receive collateral branches from some of the descending corticospinal fibres. While the origin of corticopontine fibres is undoubtedly extensive, the quantitative contribution from different cortical regions, and any precise somatotopic pattern of the projection from the different cerebral lobes on to specific groups of pontine nuclei, cannot yet be regarded as established in primates, including man. However, experimental investigations demonstrate that a fairly precise somatotopic pattern of corticopontine fibres extends from the sensorimotor cortical regions in the cat (Brodal 1968 *a* and *b*). Similarly, reports of *spinopontine* and *tectopontine* fibre systems in the cat have, as yet, received no definite confirmation in primate brains, although they are probably present. Recently another class of afferent fibres to the cerebellum that traverses the middle peduncle to reach both the intracerebellar nuclei and cortex has been demonstrated. These are aminergic and constitute the *cerebellar serotonergic pathway* derived from cell groups B5 (part of the nucleus raphe pontis) and B6 (part of the central pontine reticular grey matter)—*see* p. 950. Their precise terminations and functional roles are, as yet, undetermined.

THE SUPERIOR CEREBELLAR PEDUNCLE

The superior cerebellar peduncles (7.77, 90) emerge from the cranial part of the anterior cerebellar notch and are hidden from view by the anterior lobe of the cerebellum. When that structure is pulled aside they can be seen connected with one another by the superior medullary velum, and ascending in the lateral part of the roof of the fourth ventrical to disappear just caudal to the inferior colliculus.

A number of fibres *enter* the cerebellum through the superior peduncle (*vide infra*), but the great majority of the fibres which constitute the strand are *leaving* the cerebellum, and take origin for the most part in the cells of the nucleus dentatus. **The efferent fibres** emerge from the hilum of this nucleus and, having been joined by efferent fibres from the emboliform, globose and fastigial nuclei, they pass upwards, forwards and medially, covered over at first by the medial fibres of the inferior and the deep fibres of the middle peduncle. As they ascend in the roof of the fourth ventricle the fibres gradually incline anteriorly and sink into the tegmental region of the midbrain medial to the lateral lemniscus. They then sweep medially and the majority of the fibres decussate with the corresponding contralateral fibres. However, a proportion do not decussate and accordingly, considering the contribution from both peduncles, there is now, on both sides of the midline, a small uncrossed component and a much larger crossed component of the superior cerebellar peduncles. Both the crossed and uncrossed components now separate into ascending and descending bundles. Each of these will be considered briefly, but it must be emphasized that the *crossed ascending bundle* is by far the most prominent, and is often the only one referred to in elementary accounts.

The uncrossed component of the superior cerebellar peduncle which arises in part from the fastigial nucleus, is mainly distributed to the brainstem reticular formation. *Ascending fibres* terminate in the reticular nuclei of the midbrain tegmentum and the grey matter surrounding the aqueduct of the midbrain, whilst the *descending fibres* reach reticular nuclei of the pons and medulla.

The crossed descending fibres of the superior cerebellar peduncle are distributed mainly to the inferior and accessory olivary nuclei and neighbouring reticular formation. Some authorities describe additional fascicles which pass into the spinal cord and others which run in company with the medial longitudinal fasciculus to the motor nuclei of the nerves supplying the extrinsic eye muscles.

The crossed ascending fibres of the superior cerebellar peduncle are quantitatively the major outflow from the cerebellum. They arise from the neurons of the dentate, globose and emboliform nuclei (p. 926) and form the *cerebellorubral* and *dentatothalamic tracts*. **The cerebellorubral fibres** are principally axons from the globose and emboliform nuclei (of the opposite side) and they terminate on the cells of the red nucleus which lies in the midbrain tegmentum (p. 938). On the basis of animal experimentation, a somatotopic localization of the cells in the globose and emboliform nuclei and in the issuing cerebellorubral tract, which corresponds with that in the red nucleus and rubrospinal tract, has been described.

The dentatothalamic fibres, having issued from the cells of the opposite dentate nucleus and crossed the midline, now bypass the red nucleus and terminate in synaptic relationship with the neurons of the nucleus ventralis intermedius (lateralis) and, to a lesser degree, the nucleus ventralis anterior of the thalamus (*see* p. 958). From these thalamic centres fibres radiate to end in the 'motor' regions of the cerebral cortex. In this manner large areas of the cortex of the cerebellar hemispheres, through their connexions with the dentate nucleus, and then via the dentothalamic tract and the thalamocortical radiation, are able to influence the activities of the motor areas of the cerebral cortex.

In addition, some authors have described fibres in the crossed ascending component of the superior peduncle which terminate in other thalamic nuclei, including the nucleus centromedianus, the reticular nucleus, the nuclei ventralis posterior and lateralis posterior, and also in a variety of nuclei in the subthalamus and hypothalamus (Hassler 1950; Cohen 1958; Nimi *et al.* 1962; Snider 1967).

The afferent fibre systems which enter the cerebellum through the superior cerebellar peduncle include the anterior spinocerebellar, tectocerebellar, ceruleocerebellar tracts, and descending hypothalamocerebellar tracts.

The origin and constitution of the **anterior spinocerebellar tract** was considered previously (p. 879). As this superficial laminated tract ascends the cord it consists of some fibres which originated on the same side, but a majority which crossed from neurons on the opposite side of the cord. It continues to ascend superficially in the brainstem and then curves posteriorly along the lateral aspect of the superior peduncle to enter the cerebellum, within which many of the fibres which crossed the midline in the cord recross in the inferior cerebellar commissure to regain their side of origin. The fibres terminate in the 'hind-limb' receiving areas of the anterior and posterior vermian and paravermian regions of the cerebellar cortex (7.85A, B). As mentioned previously, the existence of a **rostral spinocerebellar tract** which is the fore-limb counterpart of the anterior spinocerebellar tract, has been recognized by physiological recording techniques in experimental animals. Its anatomical verification, and the demonstration of its existence in the primate brain, including that of man, is still awaited.

The tectocerebellar tracts descend from the tectum of the midbrain to the cerebellum through the neural substance of the superior medullary velum close to the midline. They probably arise from the inferior and superior colliculi of both sides, and their fibres terminate in the intermediate vermian and paravermian regions of the cerebellar cortex, including the posterior part of the anterior lobe, the declive and lobulus simplex, the folium, tuber and pyramid (7.85D). The precise origin and constitution of these tracts await further analysis. While it is widely assumed that they convey both auditory and visual information directly to the cerebellum, alternative routes have been proposed; these include *tectopontocerebellar* and *occipitopontocerebellar* pathways.

The ceruleocerebellar tract consists of noradrenergic fibres stemming from some of the aminergic neurons constituting brainstem reticular group A6 (the central core of the nucleus ceruleus—*see* pp. 933, 949). Having traversed the superior cerebellar peduncle they are distributed to both the intracerebellar nuclei and the cerebellar cortex. Their precise modes of termination and functional roles still await analysis.

Hypothalamocerebellar tracts composed, at least in part, of cholinergic fibres, have been described by Shute and Lewis (1965) as descending from the caudal hypothalamic nuclei, in company with the dorsal longitudinal fasciculus (of Schütz) to enter the cerebellum through the superior peduncle; their destination is uncertain. (For a review of possible cholinergic mechanisms in the cerebellum, and elsewhere, *see* De Feudis 1974.)

A Summary of Cerebellar Connexions

The foregoing account of the cerebellar peduncles and their contained tracts is rendered particularly lengthy, complex, and the overall pattern somewhat obscured, by the multiple nature of the topographic pathways involved and the plethora of tract names. In the following paragraphs some details of the topography of the peduncles and tracts will be ignored, and certain groupings of connexions emphasized, which would otherwise perhaps be less apparent.

THE CEREBELLAR INPUT

The input to the cerebellum may be *direct* or *indirect*. *Fibres passing into the cerebellum directly* without intervening synapses, to terminate predominantly in the cerebellar cortex, stem from neuron groups in the spinal cord, medulla oblongata, pons and midbrain. All other tracts which influence cerebellar activity do so *indirectly* by converging on one or more of the direct sources just mentioned.

The main direct cerebellar inputs are: (1) from the spinal cord via the various spinocerebellar pathways (including functionally the cuneocerebellar tract); (2) from the olivary, reticular, vestibular and arcuate nuclear complexes of the medulla oblongata; (3) from the pontine nuclei in the ventral part of the pons, and from the raphe nuclei and other reticular nuclei of the pontine tegmentum; (4) from the core of the nucleus ceruleus; and (5) from the tectum of the midbrain via the tectocerebellar tract. These are detailed in previous pages.

Reference has already been made to a useful approximate subdivision of the cerebellar cortex on phylogenetic and ontogenetic grounds into archicerebellum, paleocerebellum and neocerebellum (*see* 7.85A). Ignoring for our present purposes minor inconsistencies and some degree of overlap, the *archicerebellum* or 'vestibulocerebellum' receives principally vestibular connexions; the *paleocerebellum* or 'spinocerebellum' receives direct terminals from the spinal cord, the medullary reticular formation and the accessory olivary nuclei; the *neocerebellum* receives, laterally in the large hemispheres of the middle lobe, the massive *pontocerebellar* connexions and those from the inferior olive, whilst nearer the median plane, in its vermian and paravermian regions, it receives *tectocerebellar* connexions. (Perhaps to correspond to the rather imprecise but useful terms 'vestibulocerebellum' and 'spinocerebellum', the addition of 'pontocerebellum' and 'tectocerebellum' would seem appropriate.) This crude parcellation of the cerebellar cortex into the receiving areas for the main groups of *direct* afferent inputs, despite some overlap, can aid further discussion of the complexities added when indirect pathways are included, and it has also proved useful in clinicopathological description (*vide infra*).

The indirect routes by which cerebellar cortical activity can be modified must, as pointed out above, necessarily involve the convergence of pathways on to the direct pathways just summarized. In particular, other routes from the spinal cord, various subcortical nuclei and the extensive projections from the cerebral cortex must be considered.

In addition to the array of direct spinocerebellar pathways previously described, it will be recalled that both the accessory olivary nuclei and the medullary reticular formation also project to the spinocerebellum, and it is interesting that both the latter receive spinal cord projections through the spino-olivary and spinoreticular tracts. Further, circumscribed regions of the vestibular nuclei and the tectum both receive spinal connexions through the spinovestibular and spinotectal tracts, although the degree to which information flowing into the cerebellum along the

vestibulocerebellar and tectocerebellar tracts is modified by influences from the spinal cord remains uncertain. Nevertheless, it is clear that information from the cord may reach the cerebellum in many different orders of complexity. The direct spinocerebellar pathways convey relatively elementary forms of information; single fibres may carry impulse patterns which follow stimulation of a single type of cutaneous or proprioceptive peripheral receptor, whilst others may carry patterns derived from the convergence and interaction of fibres from two or more types of peripheral receptor—even here, however, impulse transmission at the first synapse in the pathway may be modulated by activity in descending pathways such as the corticospinal. In the indirect spinal pathways there are presumably mechanisms for the further integration of impulses from the cord with those flowing along the other pathways which converge on the medullary reticular formation, accessory olivary nuclei, etc., before transmission into the cerebellum (i.e. these are sites of '*cerebellar preintegration*').

Similar considerations apply to the numerous routes by which the cerebral neocortex may modify cerebellar cortical activity. As we have seen, the most massive is the corticopontocerebellar pathway with which many observers would link a cortico-arcuatocerebellar pathway. In addition it must be remembered that other cell stations from which axons reach the cerebellar cortex are also in receipt of connexions from the cerebral cortex. Thus, there are corticotectal, corticoreticular, and cortico-olivary tracts; and as mentioned above, even the cells of origin of the spinocerebellar tracts are influenced by descending corticospinal fibres. Accordingly, it will be appreciated that cerebral cortical activity may well influence the information flow into the cerebellum along most of the pathways that enter the organ.

However, the various brainstem centres which project to the cerebellum are *not homogeneous systems* with respect to their connexions; on the contrary, there is much evidence that, for example, the olivary complex is not only somatotopically organized in relation to its projections to the cerebellar cortex, but varies much in its different parts in terms of their afferent connexions. Thus, some parts may be largely concerned with particular *through routes*, e.g. the spino-olivocerebellar pathway; other regions may provide sites for the *pre-integration* of the information flow along various afferent channels which converge on the olivary nuclei. The latter include some of the afferents from the spinal cord and cerebral cortex just mentioned, and others from the corpus striatum, the red nucleus and the brainstem reticular formation.

Without elaborating further here, it is clear that for a fuller understanding of cerebellar mechanisms, much more needs to be known about all the forms in which information is presented to the cerebellar cortex. The relatively simple direct spinocerebellar and vestibulocerebellar pathways have already been analysed quite extensively, but the significance of the cerebral cortical control systems, and the degree to which complex transformations occur by pre-integration in the various brainstem centres remain obscure, but are the subject of much current research.

THE CEREBELLAR OUTPUT

The output from the cerebellum commences with the axons of the Purkinje cells of the cerebellar cortex and involves the four intracerebellar nuclei (fastigial, globose, emboliform and dentate), on both sides of the midline. Both the Purkinje cells and the nuclei will be further detailed in subsequent sections, but for our present purposes it must be stated that the vast majority of the Purkinje cell axons converge upon and synapse with the neurons of the nuclei just mentioned; the axons of the latter form the main outflow tracts from the cerebellum. However, some of the Purkinje cells situated in the cortex of the flocculonodular lobe and others in the anterior and posterior parts of the vermis send axons which *by-pass* the intracerebellar nuclei, to extend directly to their destinations outside the cerebellum.

The most obvious effects of cerebellar dysfunction are disturbances in patterns of muscle contraction, and it is instructive to consider the cerebellar outflow in relation to the regions known to be intimately concerned, at least in part, with locomotor control. Whilst a few cerebellospinal and cerebellonuclear fascicles have occasionally been mentioned in the research literature, it seems that direct cerebellar connexions to motor neuron pools in either the spinal cord or brainstem are either *non-existent*, or so *sparse* as to be of little functional significance. In contrast, *all the major motor control regions* of the *brainstem* and *cerebrum* receive, directly or indirectly, profuse connexions from the cerebellum. These include the vestibular nuclear complex, the brainstem reticular formation, the red nucleus, the tectum, and, via the thalamus, the corpus striatum and motor regions of the cerebral cortex. From these nuclei arise all the main descending pathways, corticospinal, tectospinal, vestibulospinal, rubrospinal, reticulospinal, etc. by which—usually through the intermediary of local interneurons—the patterns of activity in the α and γ motor neurons are varied. These pathways will not be further detailed here, but it is evident that for a comprehensive view of cerebellar control to emerge, it will be necessary to consider the control which is exerted at all these levels simultaneously. Further, despite the prominence of *locomotor* sequelae in states of deranged cerebellar function, there may well be many other activities in which the cerebral and cerebellar cortices cooperate and which are not revealed by current methods of investigation. Certainly a number of aspects of *autonomic* regulatory functions may be modified in cases of cerebellar disease or after experimental stimulation or ablation. There is also an increasing weight of evidence that the cerebellum may play a role in modifying the electrical activity of the sensory areas of the cerebral cortex; and through its connexions with the reticular formation and thalamus it may modulate transmission in *ascending* sensory pathways (Snider 1967).

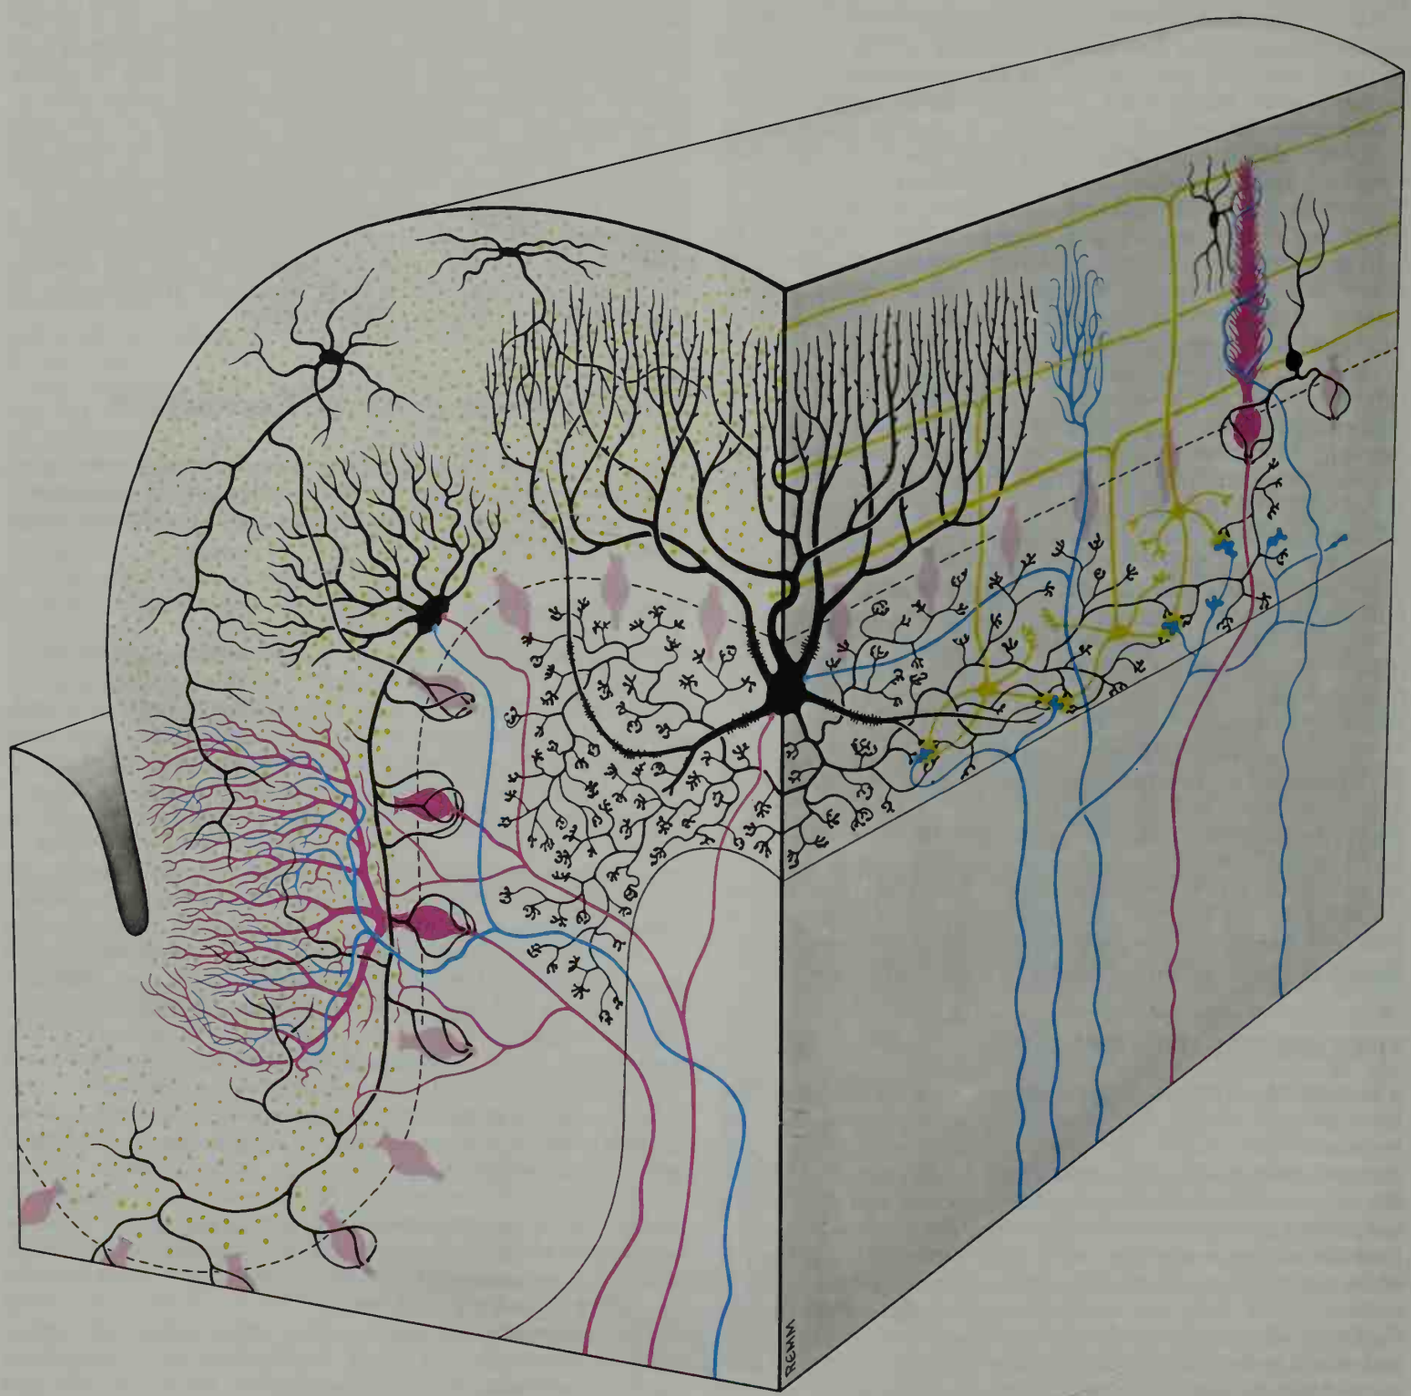
The Grey Matter of the Cerebellum

The cerebellar grey matter is distributed in two locations—as an extensive surface coat, the cerebellar cortex, and as independent masses deep within the substance of the organ, the intracerebellar nuclei.

THE CEREBELLAR CORTEX

The surface grey matter of the cerebellar cortex is, as we have seen (p. 912), folded by a large number of predominantly transverse but somewhat curved fissures. The latter are closely arranged, approximately parallel, and vary considerably in depth, dividing the organ into a series of lobes, lobules and folia. These subdivisions correspond to the primary, secondary, tertiary and sometimes quaternary laminae of the central cerebellar white matter. The smallest terminal laminae and their curved caps of grey matter constitute individual *cerebellar folia* (7.73, 84). So deeply grooved is the surface of the cerebellum, that if 'unfolded' the anteroposterior length of the cortex would be more than one metre, while its transverse dimension is only one-seventh of this at its maximum. Throughout its whole extent the cerebellar cortex shows a virtually uniform microscopic structure. Local differences which are so characteristic of the cerebral cortex do not occur in the cerebellum, so that it is impossible to distinguish between sections taken from different areas. Not only is the cerebellar cortex of man homogeneous structurally in all regions, but also a similar structure obtains throughout the mammalia and with only minor differences throughout the vertebrates.

The cerebellar cortex shows a high degree of geometric order, many of its elements being precisely arranged with respect to the surface and to the longitudinal and transverse axes of individual folia (7.79). It consists of: (*a*) the terminations of fibres entering the cortex ('climbing' and 'mossy' fibres); (*b*) five varieties of neuron—granule cells, outer stellate cells, basket cells, inner stellate (Golgi) cells, and finally, the Purkinje cells, whose axons leave the cerebellar cortex; (*c*) specialized neuroglial cells and blood vessels.



The cortex of the cerebellum consists of two main strata, external *molecular* and internal *granular layers*. Some authorities consider that a third *Purkinje cell layer* should be distinguished which is intermediate in position, but in this account it is treated as the deepest part of the molecular layer. In the following

paragraphs the constituents of each layer are listed and briefly summarized, and subsequently individual features are treated in greater detail. Nevertheless, the detailed researches on the anatomy and physiology of the cerebellar cortex are now so numerous and contain such a wealth of data, that all cannot be treated in depth here. For further details and extensive bibliographies the interested reader should consult Dow (1942); Jansen and Brodal (1954); Dow and Moruzzi (1958); Eccles *et al.* (1967); Fox and Snider (1967).

In brief, the exceedingly numerous granule cells of the inner layer are one of the two principal *input* stations of the cerebellar cortex, since they receive the synaptic terminals of the mossy afferents (i.e. *all* the fibre systems converging on the cerebellar cortex other than the olivocerebellar fibres). The large Purkinje cells form the *output* channel from the cerebellar cortex, most of their axons converging upon the deeply placed intracerebellar nuclei, from which the various outflow tracts leave the cerebellum for the numerous destinations described in the previous pages.

The dendritic trees of the Purkinje cells receive synaptic terminals from the profuse array of *parallel fibres* derived from the granule cell axons, and from the *climbing fibre* input to the cortex derived from the olivocerebellar tract. The remaining neurons, i.e. outer stellate cells, basket cells and Golgi cells, are essentially *inhibitory interneurons*, which interconnect the various elements in the cerebellar cortex in complex geometrical patterns (*vide infra*).

In broad outline, therefore, the cerebellar cortex receives *two lines of input*, the climbing olivocerebellar fibres which synapse directly with the Purkinje cells, and the mossy fibres which do so through the intermediary of numerous granule cells and their

7·79 The general organization of the cerebellar cortex: a single cerebellar folium has been sectioned vertically, both in its longitudinal axis (right part of the diagram) and transversely (on the left). Note: (1) Purkinje cells (red); (2) inhibitory interneurons (black) including outer stellate, basket and Golgi cells; (3) granule cells and their ascending axons which bifurcate into longitudinally disposed horizontal fibres (yellow); (4) climbing fibres and mossy afferents (blue). Note also the synaptic glomeruli formed between the terminals of the mossy afferent fibres, the complex dendrite tips of the granule cells and the ramifications of the Golgi cell axon. (Redrawn from: *The Cerebellum as a Neuronal Machine* by J. C. Eccles, M. Ito and J. Szentágothai. With the permission of the authors, and the publishers, Springer, 1967.)

parallel-fibred axon terminals. Both are excitatory to the Purkinje cells but are completely contrasting, as we shall see, in their structural arrangement and presumed modes of operation. The *single line of output* consists of the axons of the Purkinje cells; the latter are inhibitory to the cells of the intracerebellar nuclei, which in turn modify the activities of all the major motor control centres of the brainstem and cerebrum. Purkinje cell activity is further complicated by the operation of complex surrounding 'shells' of inhibitory interneurons.

THE LAYERS OF THE CEREBELLAR CORTEX

The molecular layer is some 300–400 μm in thickness and consists of a rather sparse population of different types of neuron, numerous dendritic arborizations, non-myelinated axons and neuroglial cell processes. In conventional histological preparations it appears rather featureless, hence its name, in contrast to the immense tightly-packed nuclear population of the granular layer. The molecular layer contains (7.79):

(1) In its deepest part a single layer of the flask-shaped cell somata of Purkinje cells which are flattened in the transverse axis of the folium, and appear narrow when the folium is sectioned longitudinally.

(2) The rich dendritic trees of the Purkinje cells which reach towards the surface of the cortex and are also flattened in the transverse plane of the folium.

(3) Recurrent collaterals from Purkinje cell axons.

(4) The dendritic trees of the Golgi cells whose somata occupy the outer granular zone; these dendritic trees also reach towards the surface of the cortex, but are not flattened, and they span the territories of a number of Purkinje cells both transversely and longitudinally.

(5) The cell somata, dendrites and axonal branches of the outer stellate cells which are superficially placed.

(6) The cell somata, dendrites and axonal branches of the more deeply placed basket cells.

(7) The axonal terminals of the more deeply placed granule cells which pass radially into the molecular layer, where each divides into two branches which proceed in opposite directions in the longitudinal axis of the folium, giving, with others, the parallel fibre bundles which intersect with the various dendritic trees just mentioned.

(8) The terminals of the olivocerebellar climbing fibres, which ascend from the deeper parts of the hemisphere through the granular layer to become closely applied to the surfaces of the Purkinje cell dendrites in the molecular layer.

(9) The radially disposed branches of large neuroglial cells which are sited in the granular layer; these branches surround or intervene between the foregoing neuronal elements, except at points of synaptic contact, and at the surface of the cortex form conical expansions which meet neighbouring ones to make an external limiting membrane for the cerebellar cortex.

The general disposition of these different elements is summarized in illustration 7.79.

The granular layer of the cerebellar cortex (7.79) varies in thickness, being about 100 μm deep in the furrows and 400–500 μm at the apex of the folia. It contains an almost unbelievably large population of 'microneurons', the *granule cells*, which are about $2{\cdot}4 \times 10^6$ per cubic millimetre for the cerebellar cortex of the monkey and $3–7 \times 10^6$ per cubic millimetre in the human cortex (Fox and Barnard 1957; Braitenberg and Atwood 1958). In summary the granular layer consists of:

(1) The cell somata of the granule cells just mentioned and the initial parts of their axons which ascend to the molecular layer to form the parallel fibres.

(2) The dendritic extensions of the granule cells, with their claw-like terminal expansions.

(3) The branching terminals of the mossy afferent fibres to the cerebellar cortex.

(4) The climbing fibres passing through to the molecular layer.

(5) The cell somata, basal dendrites and the profuse and complex axonal arborization of the Golgi cells.

(6) The cerebellar *glomeruli* which are synaptic complexes involving four types of neurite; the mossy fibre terminal establishes synaptic contacts with both granule cell and Golgi cell dendrites, whilst the granule cell dendrites also receive synaptic contacts from Golgi cell axon terminals (p. 922).

(7) The cell bodies of the large neuroglial cells mentioned above.

The cells and synaptic contacts of the cerebellar cortex will now be described in greater detail.

THE PURKINJE CELL

As mentioned above the Purkinje neurons are a highly differentiated type of cell, with a specific geometry, and throughout the vertebrates are characteristically found in the cerebellar cortex and in no other part of the nervous system.

Their flattened cell bodies are flask-shaped when viewed in a transverse section across a folium and appear as a vertical narrow strip in longitudinal section. They are arranged in a single stratum in the deepest part of the molecular layer of the cortex (7.79), immediately adjacent to the granular layer; individual Purkinje cells are separated by about 50 μm transversely and 50–100 μm longitudinally. Their cell bodies have a vertical diameter of 50–70 μm and a transverse diameter of 30–35 μm.

One, sometimes two large, smooth primary dendrites arise from the 'neck' of the flask, that is, the superficial pole of the cell, but its precise pattern of branching varies with the position of the cell. In the depths of the furrows between folia the primary dendrite branches almost immediately into two large smooth stems which recede from each other at nearly 180° in the transverse plane of the folium, and from these a remarkably rich arborization of second, third and subsequent order sub-branches arise and pass towards the surface of the cortex. Near the apex of a folium the primary dendrite passes superficially for some distance before branching at a more acute angle. In both cases, however, the branches of the dendritic tree are confined to a narrow 'sheet' of tissue which lies precisely in the transverse plane of the folium. The Purkinje cells are rather more tightly packed together at the apices of the folia than in the depths of the fissures, and this, together with the variations in dendrite branching, have been interpreted as Cartesian transformations, which correspond to the convexities and concavities of the surface, consequent upon the 'folding' of the tissue planes which occurs during development.

The primary dendrite and its first and second order branches have smooth surfaces, as noted above, but the third order branches and subsequent ramuli are densely covered over much of their surfaces by short, thick *dendritic spines* which form synaptic contacts with the parallel fibres derived from the granule cell axons (*vide infra*). The terminal *spiny branchlets* of the dendritic tree carry about 45 spines on each 10 μm of their length, and it has been computed (Fox and Barnard 1957) that on average each Purkinje cell carries about 180,000 spines on the whole of its dendritic tree—this is further discussed below.

The base of the cell body of a Purkinje cell, which lies near the granular layer, gives origin to the axon, which passes through the granular layer into the subjacent white matter. The initial 30 μm or so of the process, however, is narrow, non-myelinated, has ultrastructural features which correspond with those of the soma rather than the true axon, and its surfaces make specialized synaptic contacts with basket cell axon terminals. For these reasons some authorities prefer to call this initial region the *preaxon*; beyond this point it suddenly increases in diameter, acquires a myelin sheath and gives rise to a number of collateral branches. The principal part of the axon continues through the white matter and eventually breaks up into a basket-work of terminals which form synapses with cells of one of the intracerebellar nuclei, but a small proportion of the axons by-pass these nuclei and pass directly to the vestibular nuclei of the brainstem (p. 917). The collateral branches of the Purkinje axon interweave to form supra- and infra-ganglionic plexuses internal and external to the level of the Purkinje cells. Their termination is still rather an open question, but any significant number of these recurrent collaterals ending upon neighbouring Purkinje cells seems doubtful. The majority probably pass to make synaptic contacts with the dendrites of basket and Golgi cells in the same,

neighbouring and even quite distant folia, and may well form the so-called cortical association fibres, the significance of which has long remained obscure.

Synaptic contacts are made with Purkinje cells (7.80) by: (1) the parallel fibre bundles of the granule cell axons, which synapse with the dendritic spines of the Purkinje cell; (2) the climbing fibres from the olivocerebellar system; one climbing fibre is largely restricted to a single Purkinje cell and its numerous branches follow the subdivisions of the Purkinje dendrites and establish hundreds, perhaps thousands of synaptic contacts with the non-spiny (i.e. smooth interspine) areas of the spiny branchlets; (3) synaptic terminals from the outer stellate cells on the smooth surfaces of the large primary and secondary dendrites; (4) synaptic contacts from collaterals of basket cells, which end interspersed between those of the stellate cells; (5) complex 'beard-like' terminals of the basket cell axons which surround the Purkinje cell preaxon described above. These various contacts are summarized in 7.80.

The ultrastructure of the Purkinje cell has been well studied (Herndon 1963; Hámori and Szentágothai 1965, 1966 *a* and *b*; Léránth and Hámori 1970); it contains all the elements common to neurons (p. 825) and particular emphasis has been placed upon distinctive arrays of compressed lamellar systems of membranes which assist microscopic identification. They will not be further detailed here. Other than at points of synaptic contact with other neuronal processes, all parts of the cell surface are clothed with the processes of Bergmann glial cells.

THE GRANULE CELL

The varying thickness of the granular layer and its immense population of granule cells (up to 7,000,000 per cubic millimetre in man) has been mentioned above. Each granule cell has a spherical nucleus of only 5–8 μm diameter with a mere veil of cytoplasm 0·5–1·0 μm thick containing a few small mitochondria, ribosomes and a diminutive Golgi complex. From the deep aspect of the granule cell pass usually 3–5 dendrites (occasionally 1–7), and each dendrite is some 10–30 μm in length and often remains single, but sometimes branches before breaking up into claw-like terminal expansions. The latter receive the synaptic terminals of the mossy fibre input and the other components adjoining them to form the *cerebellar glomeruli*, which occupy the small clear crevices between the granule cells, seen when they are examined with conventional light microscope techniques.

The small-diameter axon of each granule cell passes from its superficial aspect into the molecular layer and then dichotomizes at a T-junction, the branches diverging parallel to the long axis of the cerebellar folium. The total length of the two branches is 2–3 mm, and together with those of other granule cells, they form the system of *parallel fibres* (7.79, 80). Near the point of bifurcation the parallel fibres are smooth, but throughout much of their course they develop intermittent fusiform dilatations of outline, and then near their termination a series of short hook-like or club-like surface projections. The dilatations and projections are sites of synaptic contact between the parallel fibre and the numerous types of dendrite in the molecular layer. Some quantitative aspects of these connexions will be mentioned below, but by far the most numerous are those with the dendritic spines of the Purkinje cells, less frequent are those with the spines of Golgi cell dendrites, and with the dendrites of the outer stellate and basket neurons. It may be noted that quantitative histological studies suggest that 150,000–300,000 parallel fibres cross, and probably synapse with, the dendrites of a *single* Purkinje cell.

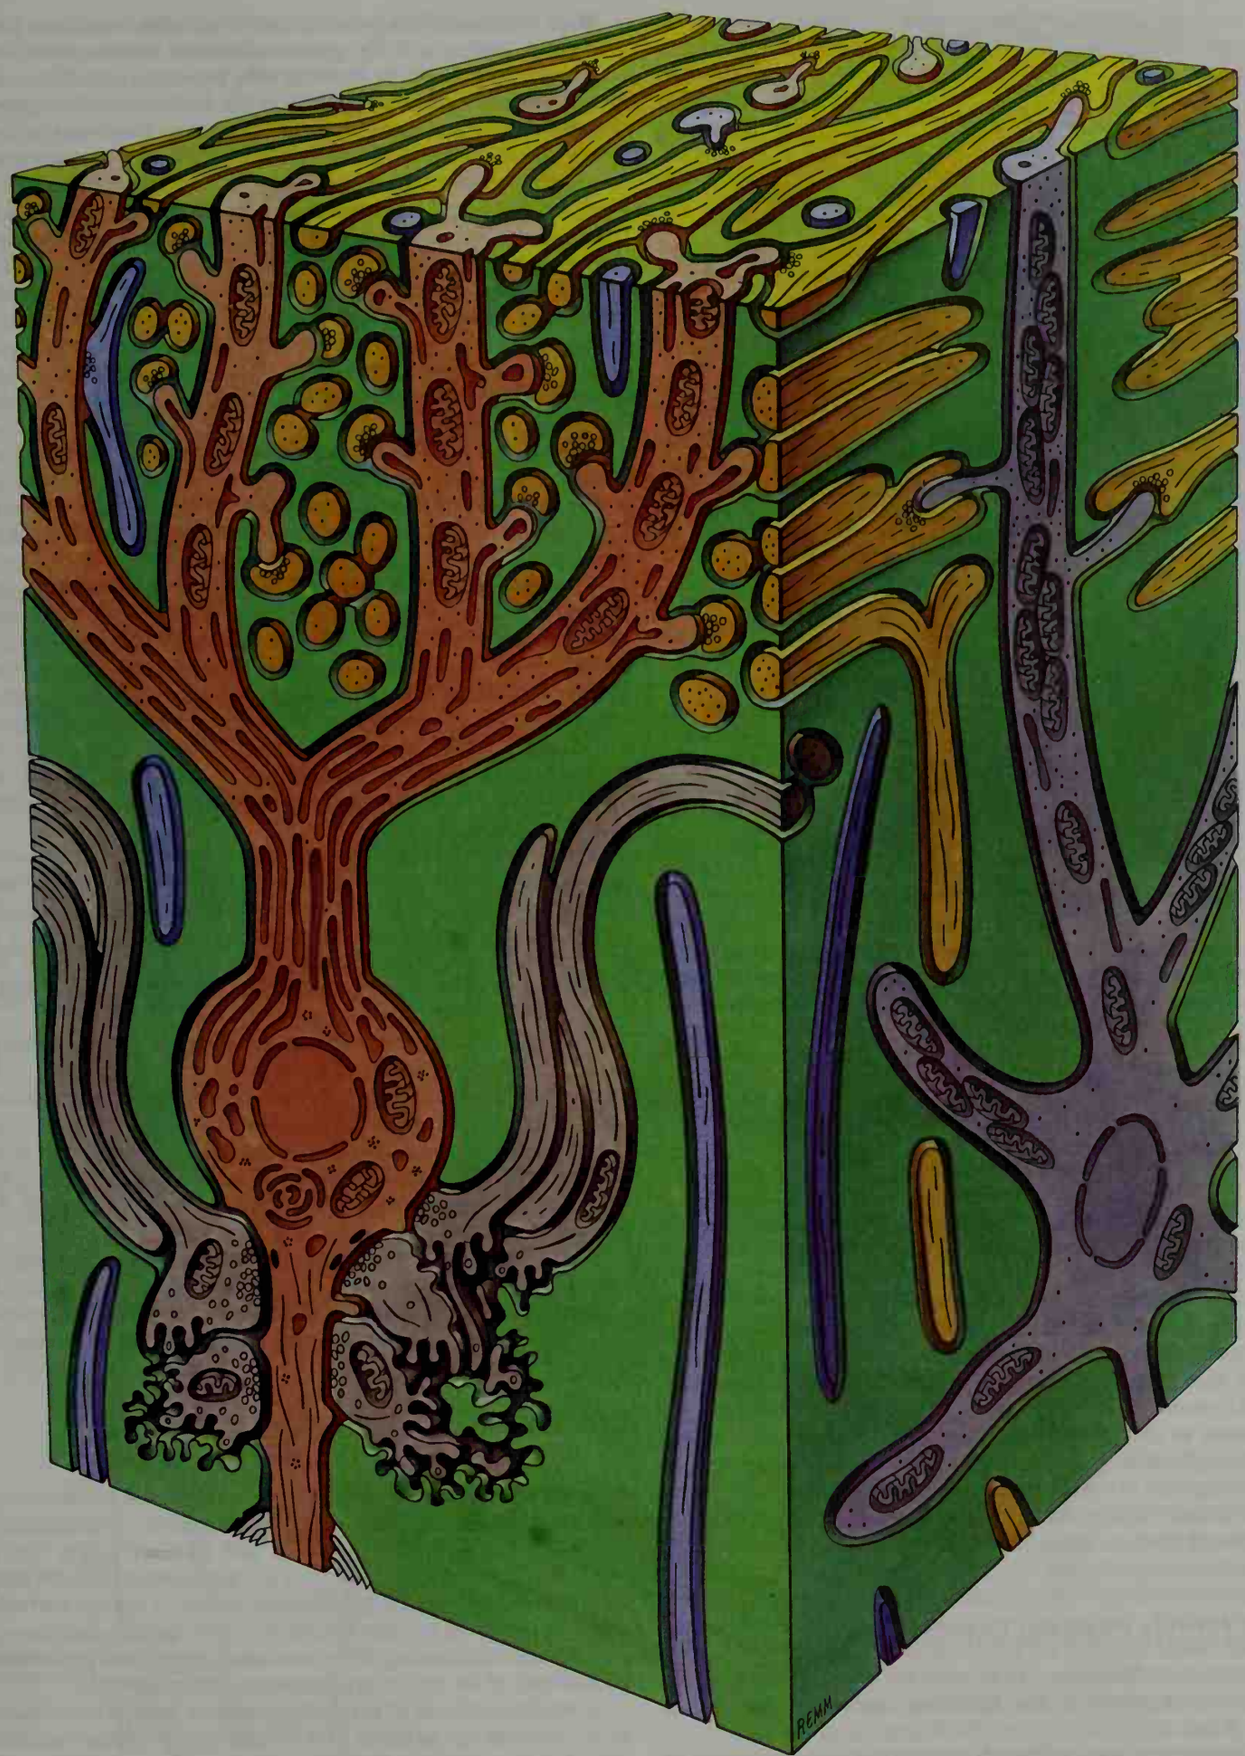
THE BASKET NEURONS

These neurons are of stellate form and occupy the deeper half of the molecular layer of the cerebellar cortex. Their dendritic trees have no special geometry in their details of branching, but again, like the Purkinje cells, their dendrites are confined to thin 'sheets' of tissue which lie strictly in the transverse plane of the cerebellar folia. The dendritic surfaces carry rather sparse, irregular, long, thin dendritic spines which make synaptic contact with the parallel fibres that intersect the dendritic tree at right angles. The cell body is also densely beset with axosomatic synapses, derived it is thought from climbing fibre collaterals and from recurrent collaterals of the Purkinje cell axons.

The basket cell axons course in the deeper part of the molecular layer just superficial to the layer of Purkinje cells, and again, the principal axon passes in the transverse plane of the folium. It continues for a distance of about 1 mm, covering the territories of about 10–12 Purkinje cells in its course. From the second Purkinje cell onwards, descending collateral branches pass towards the cell somata of the Purkinje cells, where they interweave with collaterals from other basket cells, forming the pericellular networks of fibres from which the cells derive their name. Side branches pass from each descending collateral and from the main axon, weaving longitudinally in the folium to reach an additional 3–6 rows of Purkinje cells on both sides of the main axon. Accordingly, 100–200 Purkinje cells may be reached by the synaptic terminals of a single basket cell. The general cell body surfaces of Purkinje neurons are devoid of synaptic contacts and those derived from the descending collaterals of the basket cell axons are clustered in a complex fashion around the point of origin and throughout the length of the preaxon mentioned above (7.80). The basket cell axons also give rise to a much less profuse system of ascending collateral branches which probably synapse with the smooth bases of the Purkinje cell dendrites.

Thus, the basket cells provide a unique synaptic system. Activity in a longitudinal bundle of parallel fibres will activate a longitudinal row of basket cells whose dendrites are intersected by the bundle. Because the basket cell axons pass transversely in the folium, they will therefore exert a powerful synaptic action on the origins of axons from Purkinje cells which lie in longitudinal strips on both sides of the parallel fibre bundle (*see* also below).

THE OUTER STELLATE NEURONS



Smaller than the basket cells, the outer stellate neurons are scattered through the superficial half of the molecular layer of the cerebellar cortex. Their dendritic trees, although smaller than those of basket cells, are similar in their general form, possession of spines and their transversal disposition in the folium. Again, they are intersected at right angles by bundles of parallel fibres, with which their spines and interspinous smooth areas establish synaptic contacts. The origin of the sparse axosomatic synapses which have been seen on these cells is uncertain.

The smallest stellate neurons have profuse local axonal arborizations, which terminate on Purkinje cell dendritic spines, whilst the longer axons of the larger stellate cells again pass transversely in the folium to similar destinations on more distant Purkinje cells. The deepest and largest stellate neurons are similar but possess a number of descending collaterals which accompany those of the typical basket cells.

THE GOLGI NEURONS

These are the largest neurons of a stellate form in the cerebellar cortex and they occupy the superficial zone of the granular layer, immediately below the Purkinje cell bodies. A series of large dendrites radiate from every aspect of the cell, but many eventually curve to enter the molecular layer, within which they arborize, their course within the latter being predominantly at right angles to the surface of the cortex. Their dendritic trees are not compressed into the transverse plane of the folium, and they appear much the same in both transverse and longitudinal folial section. In both these planes they overlap the territories of three Purkinje cells. Thus, the whole dendritic tree of a Golgi cell approaches, but does not overlap appreciably, those of adjacent Golgi cells, and each is intermingled, within the molecular layer, with the dendritic fields of about ten Purkinje cells. Some of the Golgi dendrites, however, do not enter the molecular layer, but divide within the granular layer and make a contribution to the cerebellar synaptic glomeruli (*vide infra*).

The Golgi cell axon arises from the deep aspects of the cell soma or from the base of one of its deeper dendrites, and immediately breaks up into a profuse arborization which permeates the full thickness of the granular layer, occupying a volume of tissue

7.80 Detailed cytoarchitecture of part of the cerebellar cortex which includes the layer of Purkinje cell somata and the zones immediately superficial and deep to this. The vertical block face to the right is in the longitudinal axis of the cerebellar folium; the vertical face to the left is in the transverse plane of the folium; the upper face is tangential with respect to the convex summit of the folium. The cell details are shown in the following colours: red—the soma of the Purkinje cell, its 'preaxon' passing from the lower pole, and its apical stem dendrite with its first-order branches bearing dendritic spines. Blue—climbing fibres. Orange/yellow—horizontal fibres derived from the bifurcation of the ascending axons of granule cells. Mauve—Golgi cell soma, dendrites with spines and initial segment of its axon. Pale brown—the descending basket cell axons forming complex synapses on the preaxon of the Purkinje cell. Green—areas occupied by glial cell processes. Note the synapses between the horizontal axons and the dendritic spines of the Purkinje cell and Golgi cell. (Compounded and redrawn from information and illustrations in: *The Cerebellum as a Neuronal Machine* by J. C. Eccles, M. Ito and J. Szentágothai.)

7.81 A stereodiagram illustrating the structure of a cerebellar synaptic glomerulus. *Blue:* mossy afferent fibre rosette. *Red:* granule cell dendrites. *Yellow:* terminals of Golgi cell axon. *Green:* Golgi cell dendrite. *Grey:* neuroglial capsule. Note that the essential synaptic contacts are axodendritic between: mossy afferent fibres and granule cell dendrites; mossy afferents and Golgi cell dendrites; Golgi cell axons and granule cell dendrites. (From: *The Cerebellum as a Neuronal Machine*, by J. C. Eccles, H. Ito and J. Szentágothai, by courtesy of the authors, and the publishers, Springer, 1967.)

which corresponds on a deeper plane, to that of its dendritic tree in the molecular layer, i.e. does not overlap that of adjacent Golgi cells.

The main synaptic input to the Golgi neuron is from the parallel fibres of the molecular layer which synapse with the rather sparse spines on its dendrites. The axonal terminals of the Golgi cell take part in the formation of the cerebellar synaptic glomeruli.

In relation to the Golgi cells, therefore, the cerebellar cortex may be thought of as consisting of a series of tissue units, each roughly hexagonal in surface view, which abut on each other but do not overlap. Within each unit are about 10 Purkinje cell territories and deep to these an enormous population of granule cells and synaptic glomeruli.

INPUTS TO THE CEREBELLAR CORTEX

As we have seen elsewhere, there are two lines of input to the cerebellar cortex, namely, the climbing fibres and the mossy afferents (7.79).

The climbing fibres, although recognized and illustrated by Cajal, were for long in doubt, as to origin, and only recently has it been established that many are olivocerebellar fibres. The precise point-for-point correlation between the olivary complex of nuclei and the cerebellar cortex has already been mentioned (p. 916). It may be noted that comparatively recently evidence has accumulated demonstrating electrotonic coupling (through nexuses or gap-junctions) between the inferior olivary neuronal origins of the climbing fibres (*see* Llinas *et al.* 1974; Sotelo *et al.* 1974).

Each climbing fibre passes straight without branching through the white matter and the granular layer to become attached to a single Purkinje cell. It then divides repeatedly and its terminal arborization is closely applied to the surfaces of the branching Purkinje cell dendrites throughout much of their length, making large numbers of synaptic contacts with the smooth areas of dendrites between the denritic spines.

A few collateral branches leave the climbing fibre and some of these descend to synapse with the cell somata and dendrites of Golgi neurons, whilst others make synaptic contacts with neighbouring basket or outer stellate cells. Physiological studies have now established that both mossy and climbing fibres are excitatory in their effects. Thus, climbing fibres are able to exert a powerful, localized, excitatory effect upon single Purkinje cells and also a much weaker effect upon the different varieties of interneuron in its neighbourhood.

The mossy afferent fibres are now widely considered to include all the afferent systems other than those of the olivocerebellar tract described above. They also are excitatory in their effects, but in all other respects they contrast markedly with the sharply localized climbing fibre input.

As each mossy fibre traverses the white matter of the cerebellum it gives off a series of collateral branches which diverge to a number of adjacent folia, and within each folium the branch runs through the central lamina of white matter, again giving off numerous sub-branches to the granular layer on both aspects of the folium. Each sub-branch then enters the granular layer and divides yet again into two or three terminal branchlets which expand into a group of grape-like synaptic terminals, or mossy fibre *rosettes*, each of which occupies the centre of a cerebellar *glomerulus* or *islet*.

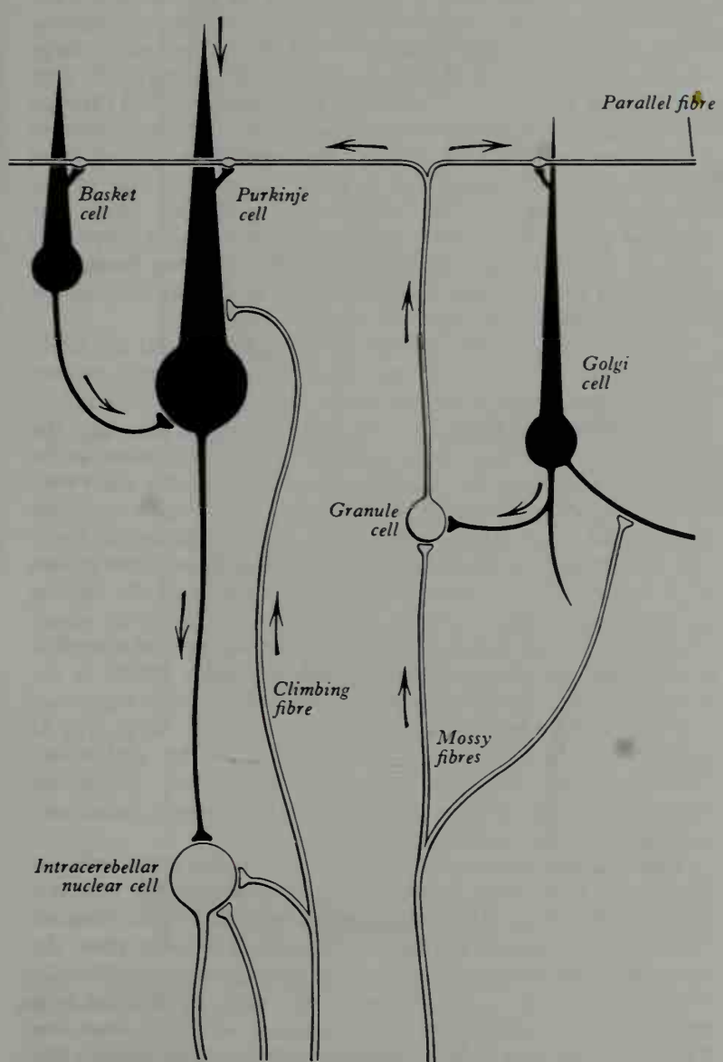
The cerebellar glomeruli are complex synaptic arrangements involving a central mossy fibre rosette, the dendrites of a number of granule cells, the synaptic terminals of Golgi cell axons; in addition, certain glomeruli are also invaded by a Golgi cell dendrite. Each glomerulus is roughly spherical or ovoid, about 20 μm in its greatest dimension, and the ratio of glomeruli to granule cells is about 1 to 5.

All synaptic contacts in the glomerulus are of the axodendritic type. The central rosette establishes contact with the internal surfaces of a surrounding leash of up to 20 granule cell dendrites and, when present, with the spine-studded surface of a Golgi cell dendrite. The terminals of the Golgi cell axons establish synaptic contact with the lateral or external surfaces of a number of the granule cell dendrites. These arrangements are most easily appreciated by reference to a diagram (7.81).

The mossy fibre terminals are excitatory and can thus excite the granule cell dendrites and, if included, a Golgi cell dendrite. Conversely, the Golgi cell, which is an inhibitory interneuron, can inhibit the granule cell through its axodendritic contacts.

SOME QUANTITATIVE ASPECTS OF CEREBELLAR CORTICAL STRUCTURE

Because of its regularly repetitive geometry, the cerebellar cortex has been much studied using quantitative neurohistological methods (Eccles *et al.* 1967; Fox and Barnard 1957; Fox *et al.* 1967; Braitenberg 1967, 1977). A few prominent features only can be mentioned here. In its different zones, it shows extremes in terms of neuronal population, in the convergence, divergence and one-to-one relationship of transmission paths, and in the complex geometries of its inhibitory interneuronal pathways.



A vertical column of cerebellar cortex 1 mm in cross-sectional area, taken at the summit of a folium in the human cerebellum, contains roughly 500 Purkinje cells, 600 basket cells, 50 Golgi cells and perhaps 3,000,000 granule cells, with some 600,000 synaptic glomeruli.

On the input side each climbing fibre synapses with *only one* Purkinje cell (but through its collaterals with an undetermined number of neighbouring interneurons). In contrast a single mossy afferent fibre shows an enormous divergence—it may make synaptic contact with 400 or more granule cells within a single folium, and if its branches to neighbouring folia are included, the number probably rises to several thousand. Conversely, each

granule cell probably receives synaptic contacts from 4 to 5 different mossy fibre terminals.

The ascending axons of the granule cells, as we have seen, bifurcate to form parallel fibres which run longitudinally in the molecular layer and enter into synaptic contact with the various dendritic trees in their paths, i.e. those of Purkinje cells, Golgi cells, basket cells and outer stellate cells. The total length of the parallel fibre from a single granule cell axon is about 2–3 mm and in its path it makes a synaptic contact with 300–450 Purkinje cells. Thus the divergence from a single mossy afferent fibre through the intermediary of granule cells is to perhaps hundreds of thousands of Purkinje cells. The uncertainty in the latter calculation stems from our lack of knowledge concerning the degree of overlap in parallel fibre territories. Finally, there is an enormous convergence of paths on to individual Purkinje cells, the dendritic tree of each cell receiving some 200,000 synaptic contacts from different parallel fibres.

Since the foregoing was written, when discussing the 'module concept' of *cerebral* cortical architecture Szentágothai (1975) has emphasized the *evolution* of quantitative knowledge of the cerebellar cortex. Its first recognition as a three-dimensional rectangular lattice (Braitenberg and Atwood 1958) was followed by the intellectual subdivision of the network into assumed functional spaces (Szentágothai 1963, 1965); later to be defined physiologically (Eccles *et al.* 1967) and structurally corroborated (Uchizono 1967) in terms of excitatory and inhibitory zones of interaction. Finally extensive and detailed analyses on the cerebellum of the cat (Palkovits *et al.* 1971 *a*, *b*, *c*, 1972) made it possible 'to describe the cerebellar cortical network statistically in numerical and geometric terms, giving considerable refinement to the earlier rather crude qualitative guesses on the spatial and numerical distribution both of excitatory and inhibitory interactions'.

7.82 An analysis of the essential circuitry and synaptic contacts between the climbing and mossy afferent fibres, the main neuronal elements of the cerebellar cortex, and the neurons of the intracerebellar nuclei, based upon cytological and microelectrode studies. Excitatory cells, neurites and terminals are white surrounded by a black line; inhibitory elements are solid black. (By courtesy of Professor J. C. Eccles.)

MECHANISMS OF THE CEREBELLAR CORTEX

The large volume of structural research on the cerbellum ranging from comparative morphology, developmental analysis, and gross connectivity studies, to the quantitative cytology, cell geometry and synaptic relationships pursued by ultrastructural techniques, has been paralleled by an equally impressive volume of neurophysiological research (for example: Dow 1942; Dow and Moruzzi 1958; Eccles *et al.* 1967; Ito *et al.* 1964; Ito and Yoshida 1966; Snider 1967; Szentágothai 1967; Eccles 1970; *see* also references on p. 920). The increasing interdependence of these approaches has led to the postulation of a number of elementary mechanisms which probably interlock during the normal functioning of the cerebellar cortex; only some brief comments indicating these kinds of approach will be included here.

It is clear, as repeated in previous sections, that the cerebellar cortex has two highly distinctive lines of input—the climbing and the mossy fibres—and only one line of output, the axons of the Purkinje cells (7.82). Both the climbing fibres and the mossy fibres ultimately convey information to the cerebellar cortex derived, at least in part, from similar sources, namely the exteroceptors and proprioceptors, the brainstem reticular formation and the cerebral cortex (*see* previous paragraphs). Further, both input channels are excitatory in their effects; but the climbing fibre exerts a one-to-one, powerful, all-or-none excitation on individual Purkinje cells, whilst each mossy afferent diffuses its excitatory effect through hundreds of excitatory granule neurons to thousands of Purkinje cells. The Purkinje cells are exclusively inhibitory in their action and their outflowing axons exert varying inhibitory patterns upon the intracerebellar and vestibular nuclei.

The remaining cells of the cerebellar cortex—basket, outer stellate and Golgi cells—each with its distinctive cell geometry, input and output, all function as inhibitory interneurons, the particular shape, site and kind of inhibitory effect varying with the cell type in question.

Whatever means of neurophysiological recording is employed, and whatever type of tissue preparation used, from the cerebellar cortex of the unanaesthetized animal to the chronically isolated slab of cortex, most of the cellular elements show a low level of 'background' impulse discharge even under conditions of minimal sensory input. Some researchers have used the term 'spontaneous' for this type of activity, but whether it represents an intrinsic characteristic of the individual neurons and their assemblies remains unclear; nevertheless, it is upon such a background that the more dramatic and orderly responses to specific patterns of input occur.

It has been suggested (Szentágothai 1967) that the climbing fibres and their terminal synapses, which are largely concentrated on individual Purkinje cells, do not provide an integrative mechanism, and it is presumed that for the climbing fibres their information flow has been *pre-integrated* from the various channels which converge and synapse with the cells of the olivary nuclear complexes. Further, it is suggested that the important *integrative units* of the cerebellar cortex involve the mossy afferent input, granule cells, parallel fibres, Purkinje cells and the varieties of interneuron. Some of their possible elementary interactions are summarized in 7.82, 83.

It may be imagined that activity in some of the mossy afferents has excited a small locus of granule cells with resultant activity in a narrow bundle of parallel fibres in the molecular layer of the cortex. The bundle of active parallel fibres, about 3 mm in length, courses longitudinally within the folium and exerts an excitatory effect upon the dendritic fields in its path, i.e. those of Purkinje, Golgi, basket and outer stellate cells. If the bundle is very narrow, or its activity of a low order, none of these cells will respond.

However, as the size of the bundle increases until it roughly corresponds to the width of the Purkinje cell dendritic fields, excitatory responses follow in a row of Purkinje cells and also in the related basket and outer stellate cells. Under these conditions the Golgi neurons do not respond, because only a small proportion of their much larger dendritic fields are receiving an input from the parallel fibre bundle. The net result, therefore, is that a single row of Purkinje cells about 3 mm long and parallel to the long axis of the folium respond with volleys of impulses along their axons. A crucial point to note is that because of the relatively slow conduction velocity of an impulse along the small diameter parallel fibres (a few decimetres per second) and the regular spacing of the Purkinje cells forming a row, the latter are excited *sequentially*. The difference in the time of arrival of a parallel fibre impulse between *successive* Purkinje cell dendritic trees being of the order of a tenth of a millisecond; this forms the basis for the concept of the cerebellar cortex as a *timing device* mentioned below. Because of the transverse disposition of the basket and outer stellate cell axons and their terminals, simultaneous activation of these inhibitory interneurons by the bundle results in longitudinal strips of cortex containing inhibited Purkinje cells which flank the active row on both sides. It is considered that with the continual fluctuations of activity in the mossy fibre input, the essential response of the cerebellar cortex is one of a constantly changing pattern of innumerable 'unit rows' of excited Purkinje cells flanked by inhibitory zones. The latter provide a process of neural sharpening by which the more active bundles of parallel fibres are selected from the general background of cortical activity. Should the active bundle of parallel fibres become too wide (i.e. much greater than the width of a single Purkinje cell row), another mechanism comes into play mediated by the Golgi cells. If sufficiently wide, the parallel fibres excite the Golgi cells via their dendrites and these, in turn, cause a reduction in the mossy fibre input via the granule cells by means of their inhibitory synaptic terminals on the granule cell dendrites in the synaptic glomeruli (p. 922). Hence, the principal function of the Golgi neurons appears to be in providing a 'choke' whereby excessive broadening of the active bundle of parallel fibres is prevented.

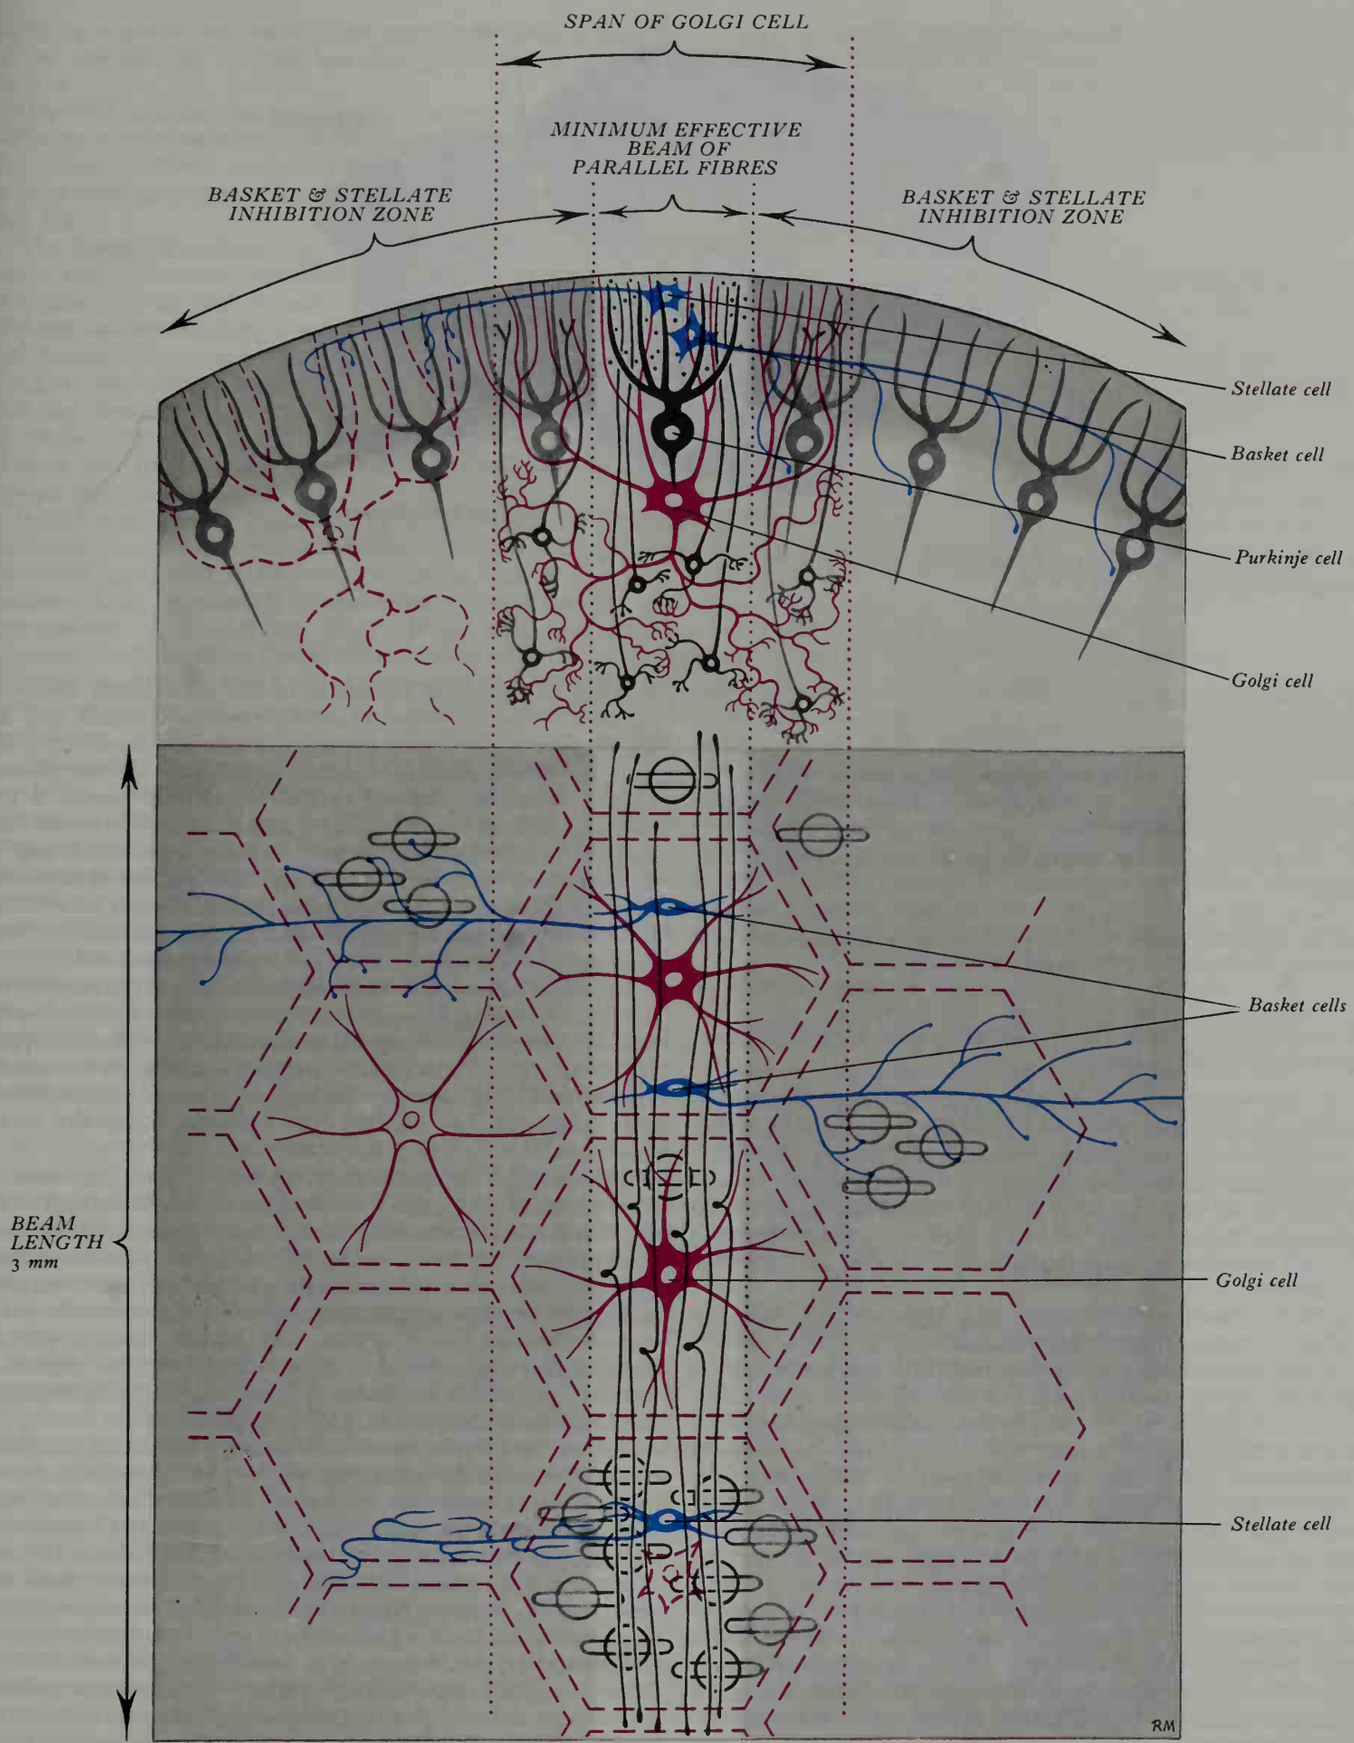
It is upon this incessantly changing pattern of *sequentially* excited, inhibited or relatively quiescent rows of Purkinje cells, that the sharply localized, powerful, excitatory effect of the climbing fibres is exerted, the resultant effect upon any individual Purkinje cell depending upon the strength of the climbing fibre stimulus and the state of the Purkinje cell upon its receipt. By mechanisms such as these, fluctuating inhibitory patterns are transmitted by the Purkinje cells to the intracerebellar nuclei, and thence to the motor control centres in the cerebrum and brainstem. It must be emphasized, however, that the manner in which cooperative interaction between localized climbing fibre activity and the time-base provided by active parallel fibres acts as a coordinator of striated muscle dynamics remains an enigma.

There are, of course, many other orders of complexity in the intracortical circuits of the cerebellum. These include the added complication of the effects of Purkinje cell and climbing fibre collateral branches on the various inhibitory interneurons, the problems posed by the presence of Golgi cell dendrites in the synaptic glomeruli, and differential 'on' and 'off' responses in the different categories of interneuron. Further interesting mathematical analyses of the structural arrangements in the cerebellum have, as intimated above, led to proposals concerning its possible mode of operation as an accurate timing device or *biological clock*, which incorporates critical *delay paths* in its design; these may be important in controlling the correct temporal sequence of events in, for example, rapid 'voluntary' movements (Braitenberg 1967). In the following decade these ideas and approaches were expanded and refined, the most recent exposition of the concept of the cerebellar cortex as a timing device being advanced by Braitenberg (1977) in his elegant monograph *On the Texture of Brains* which the interested reader should consult. Further details will not be pursued here, but perhaps enough has been said to indicate the general lines along which our knowledge of the *higher integrative units* of the cerebellar cortex is increasing. Despite such increases in understanding, they still fall far short of a comprehensive view of how the cerebellum as a whole integrates its total complex inflow of information, and utilizes it to regulate the overall locomotor patterns of the complete organism.

THE INTRACEREBELLAR NUCLEI

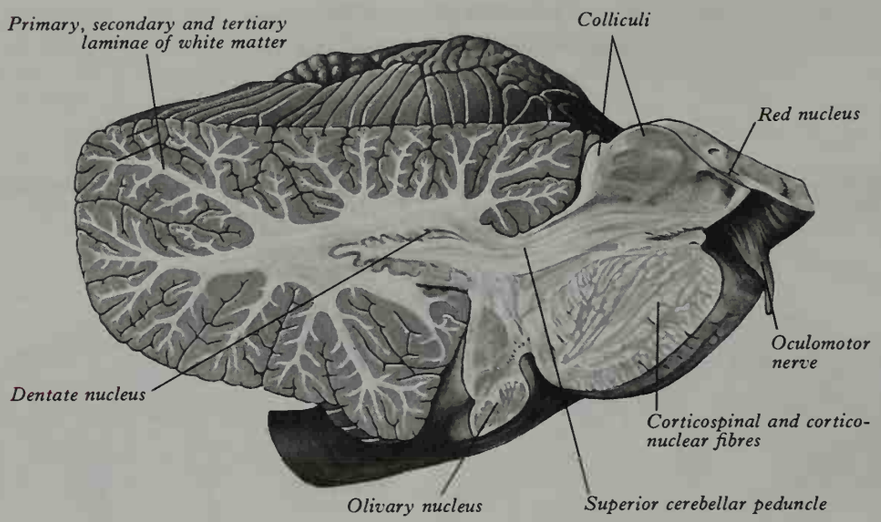
Four independent accumulations of grey matter are embedded in the white matter of the cerebellum of man on each side of the midline. These are the *intracerebellar nuclei*, sometimes also rather imprecisely termed the 'roof' nuclei because of the close relationship of *some* of them to the roof of the fourth ventricle.

Most laterally placed and the largest is the nucleus dentatus, on the medial aspect of which are the smaller nucleus emboliformis and nucleus globosus, whilst nearest the midline lies the nucleus fastigii. In most mammals, however, only three nuclei are recognized—a nucleus lateralis corresponding in part to the nucleus dentatus, a nucleus interpositus which corresponds largely to the globose and emboliform nuclei of man, and finally a nucleus medialis which corresponds to the nucleus fastigii. However, the precise homologies of the nucleus interpositus have been the subject of some debate (Jansen and Brodal 1954).



The nucleus fastigii is phylogenetically the oldest and is largely associated with the archicerebellum (vestibulocerebellum); the globose and emboliform nuclei are more recent and associated with the paleocerebellum (spinocerebellum), whilst the nucleus dentatus is the most recent and is associated with the neocerebellum (pontocerebellum). These associations are, however, approximate only, and are further discussed below.

The nucleus dentatus (7.84) sited near the white centre of the hemisphere, consists of an irregularly folded grey lamina containing white matter centrally, the fibres of which are derived in large measure from the axonal processes of the cell somata in the grey lamina. The grey lamina is deficient anteromedially and through this so-called 'hilum' of the nucleus, the white fibres stream to form a large part of the superior cerebellar peduncle (p. 917). **The nucleus emboliformis** lies close to the medial side of the nucleus dentatus and partially covers its hilum, whilst the **nucleus globosus** is still more medially placed and despite its name is elongated anteroposteriorly. **The nucleus fastigii** is larger than the latter and is situated close to the median plane in the anterior part of the superior vermis.



The most prominent cells of the cerebellar nuclei are fairly typical large multipolar neurons possessing rather simple, stellate but irregular dendritic arborizations, the numbers of dendrites increasing from the fastigial to the dentate nucleus. However, the dendritic trees of adjacent neurons overlap considerably in the fastigial nucleus and are much more distinct, having their own territories, in the dentate nucleus. These large multipolar neurons give rise to axons which make one or two characteristic loops before leaving the nuclei to form the **cerebellar outflow tracts** in the superior and inferior cerebellar peduncles for the various destinations in the brainstem detailed in the previous pages. During the looped part of their course the axons give off a number of recurrent collateral branches which terminate locally in the nuclei of origin. The intracerebellar nuclei also contain numerous small neurons, some of which are probably local Golgi type II interneurons, whilst others contribute to the peduncles. (Experimentally some of the small cells show retrograde chromatolytic changes after section of the peduncles—Jansen and Jansen 1955; Flood and Jansen 1966.)

The afferent connexions to the cells of the intracerebellar nuclei are from both cerebellar and extracerebellar sources. Primarily they receive both axodendritic and axosomatic synapses from the terminals of Purkinje cell axons. The latter enter the nuclei and each axon branches to form pericellular nests around a number of neurons, whilst conversely, each pericellular nest receives contributions from the branches of more than one Purkinje cell axon, i.e. there is both an element of divergence and of convergence in the construction of the nucleus.

It is now widely held that the Purkinje cells are exclusively inhibitory in their action and this fact has focused attention on other afferents, many of which are presumably excitatory to the intracerebellar nuclei. Fibres have been described as reaching these nuclei from the red nucleus, i.e. rubrocerebellar fibres

7.83 A diagram illustrating the concept of the complex neuronal integrative units of the cerebellar cortex. The neurons and their processes are shown in a transverse section of a cerebellar folium (above) and in surface view (below). Neurons in full colour (black, red or blue) or in full coloured outline, are in a state of excitation. Neurons in grey or interrupted outlines are inactive. *Full black or grey, black or grey outlines:* Purkinje cells, granule cells and their parallel fibre bundles; *blue:* basket and stellate cells; *red:* Golgi cells. The white longitudinal strip indicates activation of a locus of granule cells, their bundle of parallel fibres, and the associated longitudinal row of Purkinje cells. Simultaneous activation of the basket and stellate inhibitory interneurons by the parallel fibre bundle causes zones of lateral inhibition (grey shading) to flank the activated strip. These zones of inhibited Purkinje cells are in reality about ten rows wide—only four rows are illustrated here (grey profiles). If the active bundle of parallel fibres reaches a critical width, inhibitory Golgi interneurons become active, and reduce or stop mossy fibre input in the cerebellar glomeruli. The inhibitory territories of the Golgi cells are indicated by the array of red hexagons. See text for further description. (Redrawn from J. Szentágothai in: *Recent Development of Neurobiology in Hungary*, I. K. Lissák (ed.). By courtesy of the author and publishers, Akadémiai Kiadó, Budapest, 1967.)

7.84 Oblique vertical section through the right cerebellar hemisphere and right half of the brainstem.

(Courville and Brodal 1966), and also collateral branches from the spinocerebellar, pontocerebellar, olivocerebellar and reticulocerebellar tracts (Eccles *et al.* 1967). Recent evidence has shown that both noradrenergic and serotonergic fibres from particular cell groups in the brainstem reticular formation reach and innervate the intracerebellar nuclei. The outflow of information through the cerebellar peduncles, therefore, is thought to stem from an integration within the intracerebellar nuclei of the patterns of excitation delivered from these various extracerebellar sources with the inhibitory patterns delivered by Purkinje cell axons, and modified by the action of local interneurons.

STRUCTURAL AND FUNCTIONAL LOCALIZATION IN THE CEREBELLUM

Since the cerebellar cortex shows an identical microscopic structure and microcircuitry in all parts of the cerebellum, it may be assumed—and physiological investigations support this—that its operational characteristics in terms of this local circuitry is also identical in all regions. In this sense, therefore, a functional localization does not exist within the cerebellar cortex *itself* as it does, for example, in the different laminae of grey matter in the spinal cord.

Structural and functional localization in the cerebellum is thus a reflexion of the manner in which functionally dissimilar afferent tracts end preferentially in different regions of this homogeneous cortex. Equally, it is a reflexion of how the different areas of cortex project to particular intracerebellar nuclei, and therefore influence different brainstem centres. A vast number of investigations have been directed towards the problem of cerebellar localization and the foundations have been laid by comparative morphological, developmental and gross connectivity studies (Jansen and Brodal 1954; Smith 1903; Riley 1930; Larsell 1937, 1953; Nieuwenhuys 1967). These were supplemented by more detailed analysis of connectivity patterns using degeneration techniques in experimental animals (Brodal 1969). Neurophysiological studies of the changes in electrical potential evoked by the 'natural' or 'artificial' stimulation of peripheral receptors including the special sense organs, peripheral nerves, and different regions of the cerebrum, brainstem and spinal cord, have been carried out (Snider 1936, 1940, 1945; Snider and Eldred 1951, 1952; Dow and Moruzzi 1958). The type of recordings have varied from rather crude monitoring of the surface of the exposed cerebellum, through recording of focal potentials by electrodes inserted into the cerebellar tissues, to unit recording with intracellular microelectrodes. Stimulation of the exposed cerebellar cortex in animals has been used to determine whether discrete movements are elicited, and which cerebellar regions influence movements that have been initiated reflexly or by stimulation of the cerebral cortex. Another extensive field of research has involved the study of the behavioural effects of selective cerebellar ablation in experimental animals and the effects of cerebellar disease in man. For details of these important fields the interested reader should consult the articles quoted, some of which are devoted exclusively to these topics. A few examples only can be mentioned and illustrated here; further, since the various experiments have been carried out on a range of mammals, and because their considerable variations in cerebellar morphology cannot be treated here, the illustrations are referred to simplified plans of the cerebellum, and the areas indicated may well vary considerably between species and in mankind.

Reference has already been made to the primary division of the cerebellum into *archicerebellum*, *paleocerebellum* and *neocerebellum*, and how these correspond approximately, with some degree of overlap, to the major patterns of afferent cerebellar connexions summarized in the terms *'vestibulocerebellum'*, *'spinocerebellum'* and *'pontocerebellum'* (7.85A), the latter including the *'tectocerebellum'*.

Experimental determinations, in the cat, of the areas of termination of the primary vestibulocerebellar fibres, and of the spinocerebellar, cuneocerebellar and spino-olivocerebellar tracts are illustrated in 7.85B. The double areas of distribution of these various spinal tracts to separate anterior and posterior, vermian and paravermian zones should be noted. These areas make up the spinocerebellum noted above, and within them a general somatotopic separation of hind-limb and fore-limb regions is shown. The primary vestibular fibres are shown ending mainly in the flocculus, nodule and part of the uvula.

Illustration 7.85C shows the somatotopic map of the cerebellar cortex produced by recording the evoked potentials during stimulation of cutaneous receptors distributed over the body surface, based on the findings of Snider (1952), and Hampson *et al.* (1952). There is a marked correspondence between this and diagram 7.85B, which was based upon neuroanatomical degeneration techniques. Again, the anterior and posterior parts of the spinocerebellum are evident, but in this case the responses to stimulation of the face are also included. It is seen that the different regions of the body are represented in reverse order in the anterior and posterior receiving areas; further, in the anterior area the representation is ipsilateral, whereas in the posterior area it is bilateral. As would be expected, a rather similar map is produced on stimulation of proprioceptive endings, and therefore need not be reproduced here.

In illustration 7.85D is shown the area from which responses are recorded during visual and auditory stimulation, and also during stimulation of the occipital areas of the cerebral cortex. The visual and auditory areas are virtually coincident and include the central regions of the vermis and their adjacent paravermian zones, overlapping the face area of the anterior spinocerebellum determined by tactile stimulation. How far these visual and

auditory responses are due to direct tectocerebellar pathways, or to the involvement of other less direct pathways is uncertain (p. 918).

Repeated reference has been made in the previous pages to the strict point-to-point correlation that exists between the nuclei of the olivary complex and the opposite cerebellar cortex—the general correspondence of zones is illustrated in a simplified form in 7.85E.

The foregoing examples of cerebellar localization are based upon the differential distribution of afferent tracts to the cerebellar cortex, and broadly, the main receiving areas are arranged as a sequence of *transverse* strips which proceed from the (morphologically) anterior to posterior ends of the cerebellum. Equally clear evidences exist for a localization based upon the different destinations of Purkinje cell axons which leave the cerebellar cortex, but this is a *longitudinal* form of organization (Jansen and Brodal 1954; Eager 1966; Goodman *et al.* 1963; Voogd 1964; Korneliussen 1968).

It will be recalled that the majority of the Purkinje cell axons terminate in the intracerebellar nuclei, but some by-pass the latter and pass directly to the lateral vestibular nucleus. The main features of the corticonuclear projections in the cerebellum are summarized in illustration 7.85F. It is seen that direct cerebellovestibular fibres pass to the vestibular complex from the flocculus, nodule and much of the remainder of the vermis, but particularly from its anterior and posterior regions. The projections to the intracerebellar nuclei show an orderly longitudinal arrangement, and on both sides of the midline the cerebellar cortex is considered to be divided into *medial*, *intermediate*, and *lateral zones*. The fibres which leave the medial zone (vermis) converge upon the nucleus fastigii and their rostrocaudal sequence is preserved during this convergence and in their termination in the nucleus. The intermediate zone (a longitudinal paravermian strip) projects to the nucleus globosus and nucleus emboliformis, whilst the lateral zone (the cerebellar hemisphere) projects to the nucleus dentatus. In each case the orderly rostrocaudal sequence of the cortical origin of the axons is preserved through to their terminations in the nuclei. The vast majority of these corticonuclear projections are ipsilateral, but the fastigial nuclei receive some axons from the vermian cortex on both sides of the midline.

Recalling the main cerebellar outflow tracts and their nuclei of origin (pp. 919, 926), it will thus be appreciated that the vermis principally exerts a control over the vestibular nuclei and the brainstem reticular formation. The intermediate paravermian cortex controls the red nucleus and midbrain tegmentum, whilst the cerebellar hemisphere, through the nucleus dentatus and thalamus, mainly influences activity in the corpus striatum and cerebral cortex.

Interestingly, some parts of these outflow pathways have also been shown to be somatotopically organized. These include the direct and indirect vermian projections to the lateral vestibular nucleus (7.85G), and the intermediate projections to the red nucleus; this correlates well with the organization of the lateral vestibular and red nuclei themselves, and also that of the lateral vestibulospinal and rubrospinal tracts (Brodal *et al.* 1962; Courville 1966). Further, a similar localization has been shown in the nucleus ventralis lateralis of the thalamus which receives the dentatothalamic projections, and itself projects to the motor regions of the cerebral cortex (Walker 1934).

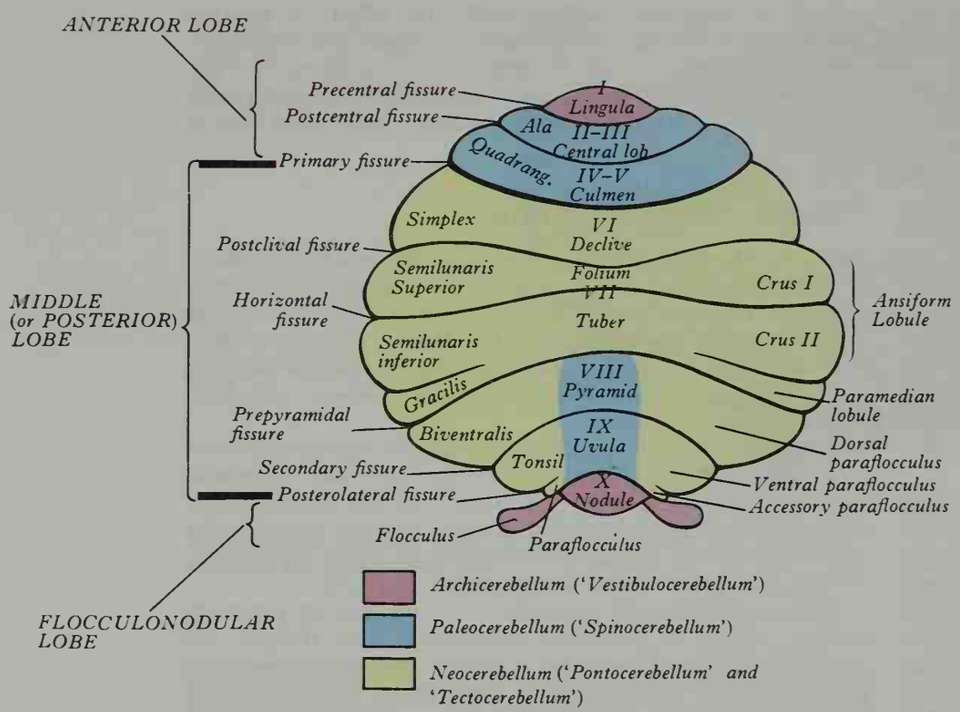
It should be emphasized at this point that the foregoing descriptions are based upon a range of experimental animals, but it is most likely that the general principles will apply to the cerebellum of man. Similarly, in experimental animals, interesting physiological parallels have been demonstrated. Cerebellar stimulation at different points often modifies movements which are being generated by simultaneous reflex or cerebral cortical stimulation, whilst cerebellar stimulation in the decerebrate animal elicits discrete movements (7.85H). Again, anterior and posterior areas which correspond to the spinocerebellum have been shown to display a somatotopic order in respect to such movement patterns (Hampson *et al.* 1952). The anterior area when stimulated gives ipsilateral responses whereas the posterior area gives bilateral responses.

Such investigations, combined with the effects of ablation (Chambers and Sprague 1955 *a* and *b*), suggest that the vermis controls the posture, tone, locomotion and equilibrium of the *whole body*, whilst the intermediate zone controls the posture and discrete movements of the *ipsilateral limbs*. The lateral zone is much less well understood.

CEREBELLAR DYSFUNCTION

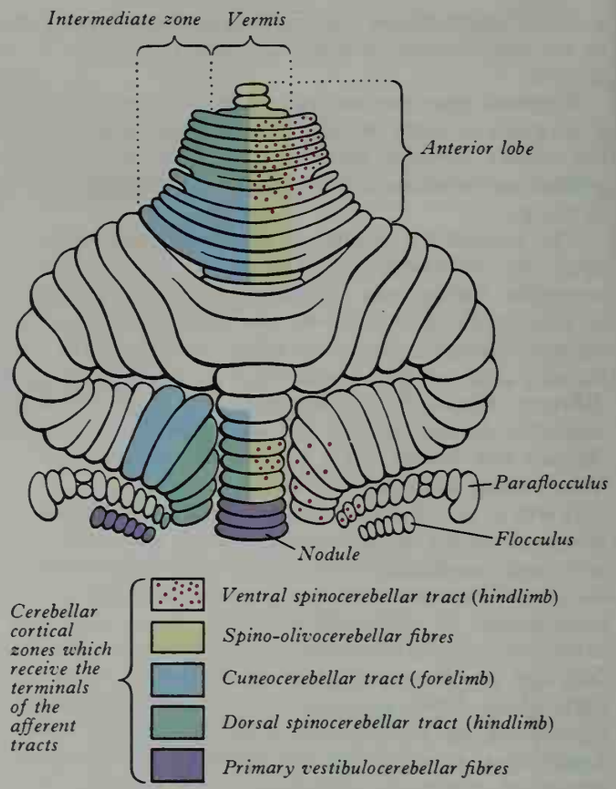
There have been innumerable reports on the behavioural effects of cerebellar disease in man and on those of selective or total cerebellar ablations in experimental animals. Only the briefest mention can be made here and the interested reader should consult the excellent reviews which are readily available (Holmes 1939; Wyke 1947; Brown 1949; Dow and Moruzzi 1958; Dow 1969).

In essence, the cerebellum receives an informational input from cutaneous receptors, proprioceptors, the eyes, ears, brainstem reticular formation and cerebral cortex, which is integrated and then discharged to the motor controlling centres of the cerebrum and brainstem. Its normal functioning is necessary for smooth, coordinated, effective locomotor responses to occur.



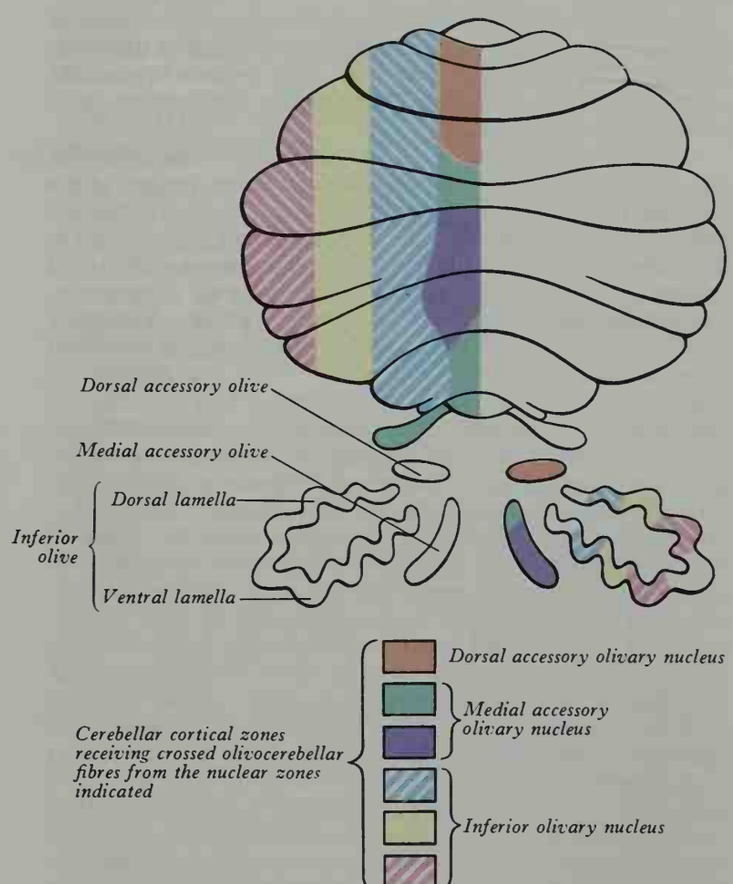
Without reference to particular cerebellar regions the more obvious effects of cerebellar dysfunction may include: (*a*) disturbances in equilibrium of the whole body; (*b*) disturbances in muscle 'tone' or their resistance to stretch, tendon reflexes and ability to stabilize joint positions; (*c*) incoordination of movements (*ataxia*) due to irregularities in the timing of onset, rate and force of contraction of synergistic muscle groups.

Disequilibrium in man is manifest by a tendency to fall forwards, backwards or laterally when standing, and by an unsteady staggering gait; it may be accompanied by sensations of spinning, nausea, etc.

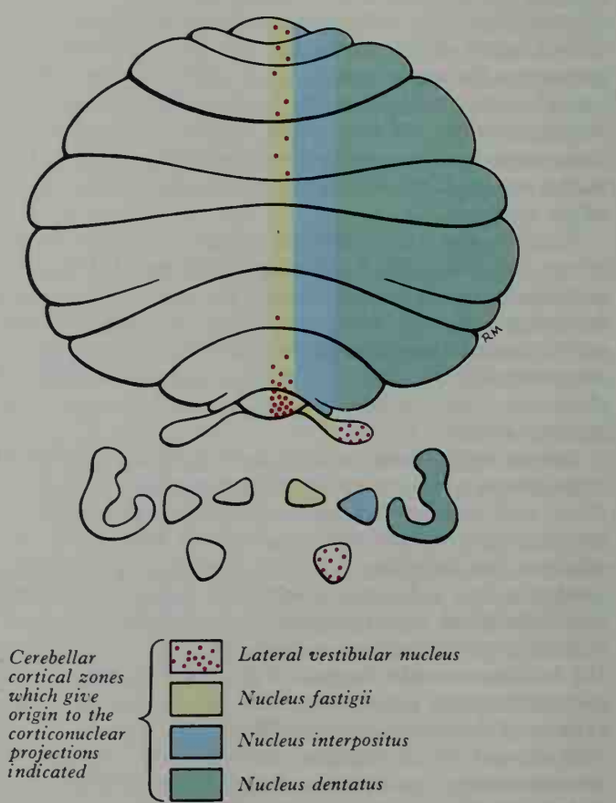


There is usually a 'softness' in the affected muscle bellies on palpation, diminished tendon reflexes and the muscles tire easily (*asthenia*). The lowering of joint control may progress to pendular swinging of a dependent limb segment after displacement, or to the condition of 'flail joints'.

Muscular incoordination is the essential feature of most varieties of cerebellar dysfunction. It may affect different regions of the body and to varying degrees; for this reason a variety of symptoms may occur, and a wide array of clinical tests have been devised to demonstrate its presence. Briefly, the term *asynergia* is often used to denote the diminished capacity for smooth, cooperative, sequential action between a series of muscle groups. A complex movement may be carried out as a sequence of irregular disjointed episodes—*decomposition of movements*. There may develop an inability to carry out rapid movements which alternate in direction, e.g. supination and pronation of the forearm and hand, *dysdiadochokinesis*; control of the range of movement may be lost with either 'undershoot' or 'overshoot'—*dysmetria*. Disturbances of locomotion with a *staggering gait* and a tendency to fall, and—particularly with closed eyes—deviations from the intended direction of progression, are common. Similarly, the inability to point with the finger in a particular direction—*past-pointing*—or to trace a specified course with either finger or heel may be present. *Tremor* is usually absent when the arm and hand are at rest, but a coarse transverse *intention tremor* may appear, which intensifies as the movement nears completion; tremor may also affect movements of the head or trunk. Muscular incoordination may lead to characteristic *defects of speech*, with a slowness of onset, slurring, jerky intermittent sound production which sometimes is intensified and has an explosive nature—so-called *scanning speech*. A *cerebellar nystagmus* may be present; there is an inability to fixate an object with the eyes, resulting in a repetitive conjugate drift of the visual axes away from the object, followed by a rapid return. The nystagmus is sometimes *positional*, i.e. more pronounced when the body adopts particular postures, or it may be *directional*, i.e. increasing when the subject attempts to gaze in a particular direction.

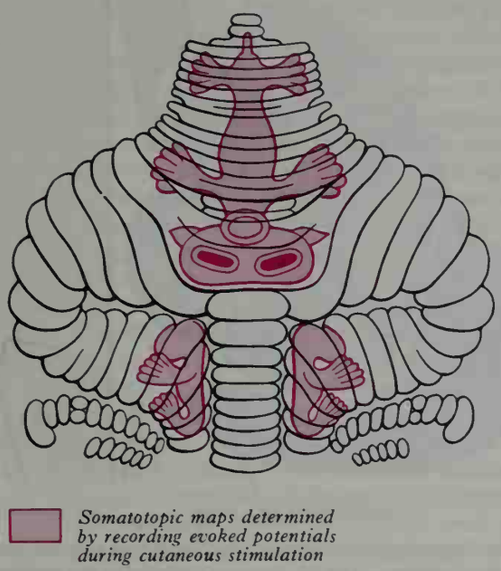


Attempts to correlate particular groups of clinical signs and symptoms of cerebellar disease in man with the different regions of the organ involved, or with the results of animal experimentation, have met with only partial success.

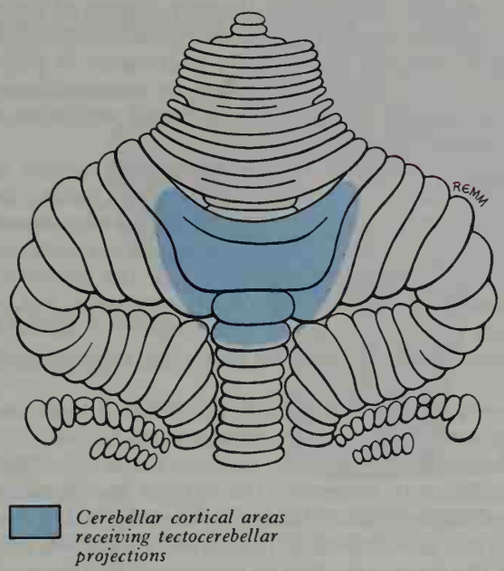


A Cerebellar terminology. The cerebellar lobes, lobules and fissures, and the approximate extent of the archi-, paleo-, and neo-cerebellum are indicated. The subdivisions of the vermis are both named and numbered (after Larsell). On the left are terms widely used in human neuroanatomy; on the right are additional terms often used in general mammalian neuroanatomy.

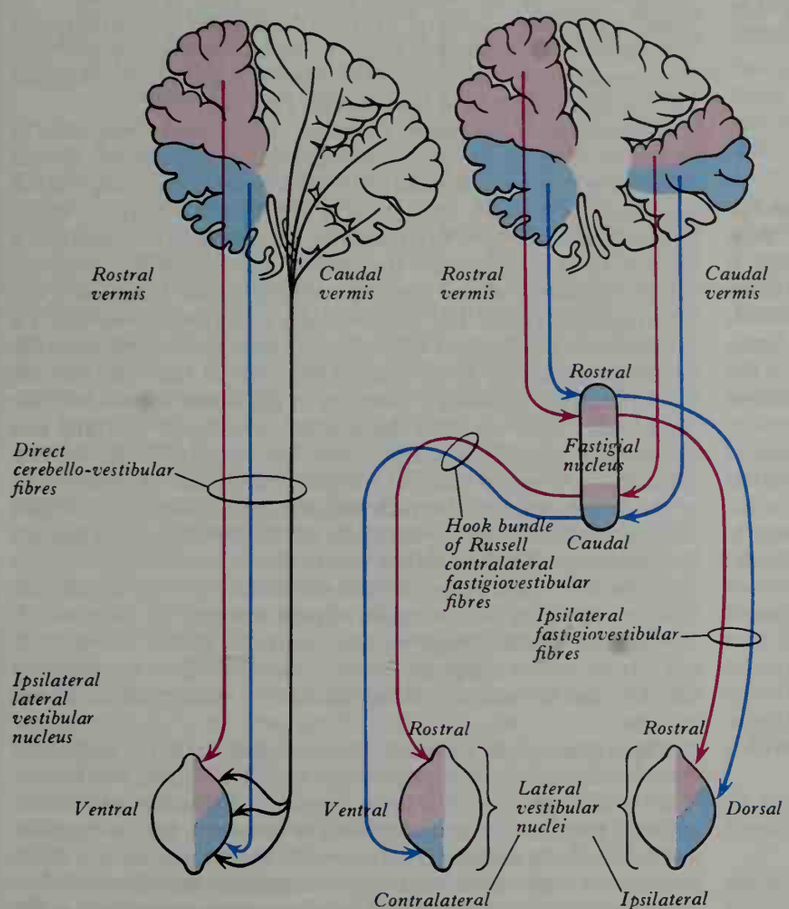
B The cerebellar cortical areas of termination of the afferent tracts indicated, derived from experimental studies.



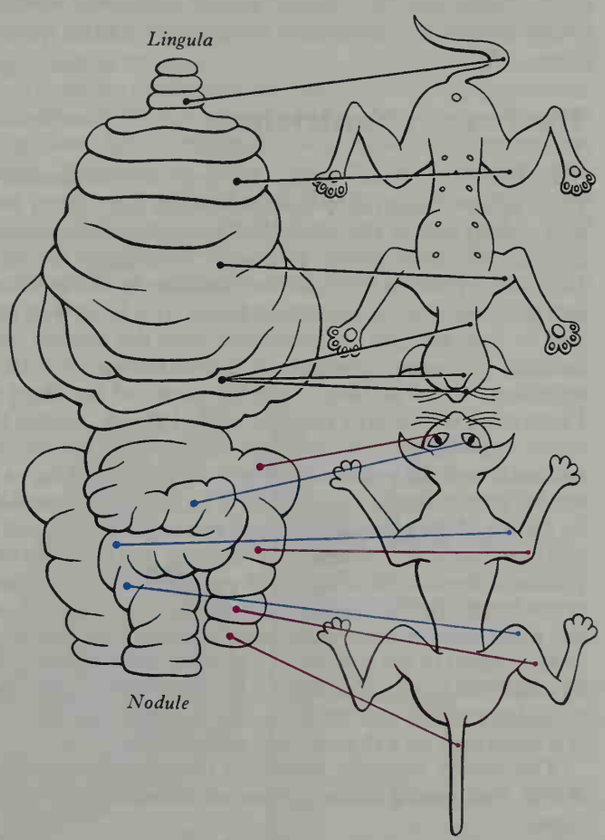
E An analysis of the topical organization of the cortical zones of the cerebellum which receive crossed olivocerebellar (climbing) fibres from the different parts of the inferior olivary complex of nuclei.



F An analysis of the topically organized projections of cerebellar cortical Purkinje cell axons on to the lateral vestibular nucleus, and the intracerebellar nuclei.



7.85A–H This series of diagrams illustrates certain features of the localization of structure and function in the cerebellum. G is a median sagittal section of the feline cerebellum; in all the remaining diagrams it is assumed that the cerebellum has been flattened and viewed from the dorsal aspect, so that its whole rostro-caudal extent can be seen. A, E and F are approximate outlines of the human cerebellum; B, C, D and H are of the feline cerebellum. Detailed descriptions of the information in these diagrams are in the text, and in the references quoted.

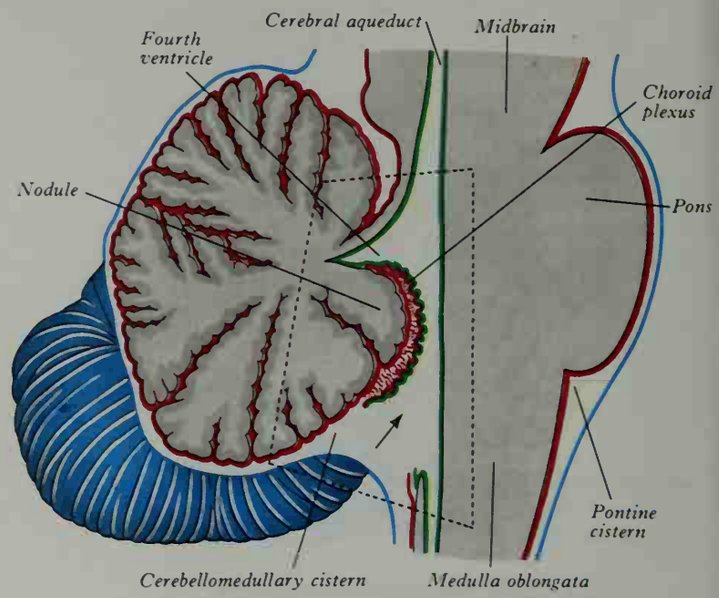


C The somatotopic arrangement of the evoked potentials recorded from the cerebellar cortex during cutaneous stimulation.

D The cerebellar cortical areas receiving tectocerebellar projections.

G The arrangement of direct cerebello-vestibular and indirect cerebello-fastigio-vestibular projections from the cerebellar vermis of the cat.

H The somatotopic pattern of movements elicited in different parts of the body during stimulation of the cerebellar cortex in the decerebrate cat.



(Illustrations B, F and G were redrawn and modified from *Neurological Anatomy*, 1969, by courtesy of the author Professor A. Brodal, and the publishers, Oxford University Press; C, D and H were redrawn and modified from *Publications of the Association for Research in Nervous and Mental Disease*, **30**, 1952, by courtesy of the authors Professor R. Snider (C and D) and of Professors J. L. Hampson, C. R. Harrison and C. N. Woolsey (H) and the publishers, The Williams and Wilkins Company)

In the *flocculonodular syndrome*, with damage to the nodule, uvula and flocculus, both in man and experimental animals, the principal features are loss of equilibratory control of the whole body, swaying when standing, staggering when attempting to walk, and a tendency to fall, usually backwards. A positional nystagmus is often present. These effects are attributable in general to the upset of integration between the vestibular nuclei and the *vestibulocerebellum*.

In the experimental animals *ablation* of the vermis of the anterior lobe increases the tendon reflexes and the rigidity already present in a decerebrate preparation, whereas vermian *stimulation* reduces the rigidity. The opposite responses occur with ablation or stimulation of the paravermian parts of the anterior lobe. Further, these effects are somatotopically organized; but, so far, corresponding results, which may stem from involvement of the anterior spinocerebellum, have not been clearly demonstrated in man.

The majority of cases of human cerebellar disease may be classified as *neocerebellar*, with involvement of one or both cerebellar hemispheres or their outflow tracts. In unilateral disease, if sufficiently extensive, the various manifestations of hypotonia and incoordination listed above appear on the *same side* as the lesion, but gross intention tremor and staggering gait only supervene if the dentate nucleus or superior cerebellar peduncle are involved. It should be emphasized that relatively small cortical cerebellar lesions cause little obvious effect, and even quite extensive disease, although causing a transient derangement of function, is followed by rapid and marked improvement in locomotor control. The mechanism of this *cerebellar compensation* remains obscure.

Finally, as mentioned above, despite the prominence of *locomotor* effects in states of cerebellar dysfunction, it is probable that the cerebellum is less obviously, but extensively, involved in other central nervous activities such as *autonomic homeostasis* and the *modulation of transmission* along sensory input channels.

7.86 Sagittal section through the brainstem and the cerebellum close to the median plane. The black arrow is placed in the median aperture of the fourth ventricle. The area enclosed by the interrupted lines is shown enlarged in 7.88. *Blue:* arachnoid mater. *Red:* pia mater. *Green:* ependyma.

The Fourth Ventricle

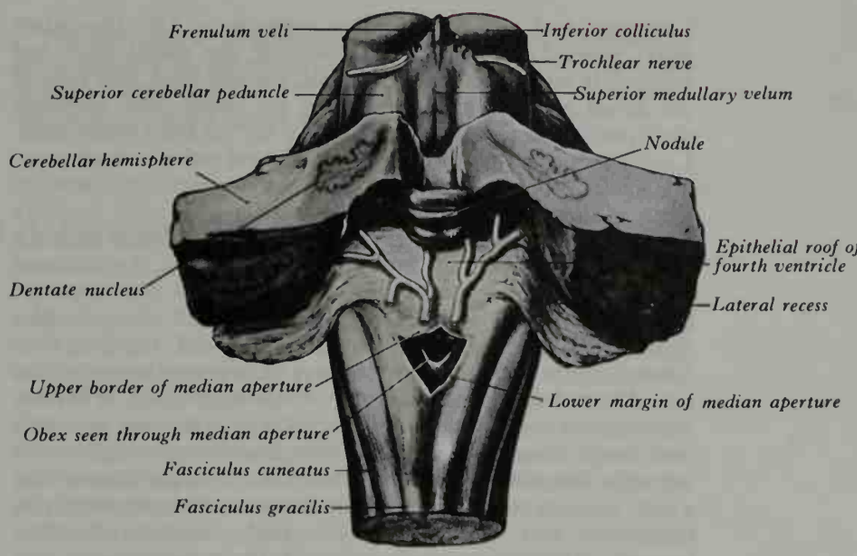
The fourth ventricle (7.86, 89, 90) is a somewhat tentorial space situated ventral to the cerebellum, and dorsal to the pons and cranial half of the medulla. Developmentally considered, it consists of three parts: a *superior* belonging to the isthmus rhombencephali (p. 163), an *intermediate*, to the metencephalon, and an *inferior*, to the myelencephalon. It is lined with ependyma, and its inferior limit is continuous with the central canal of the medulla oblongata; cranially, it is continuous with the cerebral aqueduct, which connects it to the cavity of the third ventricle. From its middle level a narrow, curved pouch, named the *lateral recess*, is prolonged on each side between the inferior cerebellar peduncle and the peduncle of the flocculus, reaching as far as the medial part of the flocculus itself. The recess is crossed anteriorly by the fila of the glossopharyngeal and vagus nerves and its lateral extremity is open, allowing a variable portion of the choroid plexus of the fourth ventricle to protrude into the subarachnoid space (7.55). In the median plane the cavity extends dorsally into the white core of the cerebellum, forming a *median dorsal recess* (7.86) cranial to the nodule; and on each side a *lateral dorsal recess* extends still further dorsally (7.143), lying cranial to the inferior medullary velum and caudal to the cerebellar nuclei, from which it is separated by a thin layer of white matter.

The fourth ventricle possesses lateral boundaries, a roof or dorsal wall, and a diamond-shaped ventral floor, the rhomboid fossa.

Lateral boundaries. The caudal part of each lateral boundary is constituted by the gracile and cuneate tubercles, the fasciculus cuneatus, and the inferior cerebellar peduncle, the cranial part, by the superior cerebellar peduncle.

The roof or dorsal wall (7.87). This extends backwards into the median and lateral dorsal recesses. The cranial portion of the roof is simple, and is formed by the superior cerebellar peduncles and the superior medullary velum. The *superior cerebellar peduncles* (p. 917), on emerging from the central white matter of the cerebellum, pass cranially and ventrally, forming at first the lateral boundaries of the upper part of the ventricle; on approaching the inferior colliculi, they converge, and their medial margins overlap the ventricle and form part of its roof. The *superior medullary velum* (p. 914) fills the angular interval between the superior cerebellar peduncles, and is continuous dorsally with the central white core of the cerebellum; it is covered on its dorsal surface by the lingula of the superior vermis (7.89).

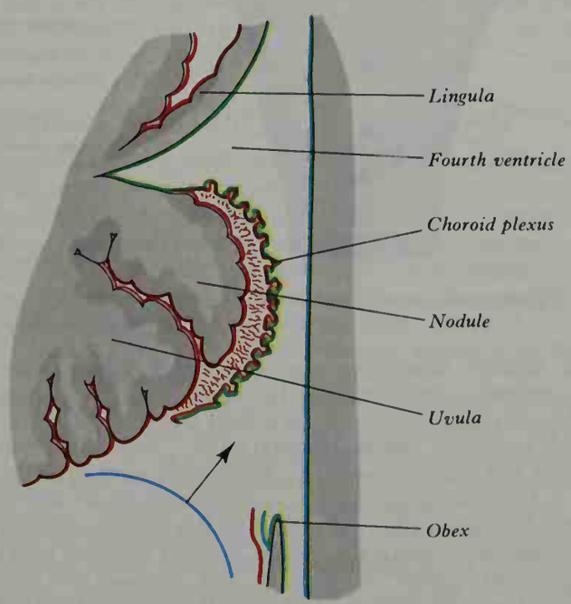
The *caudal part* of the roof is more complicated. Over most of its extent it consists of an exceedingly thin sheet, entirely devoid of nervous tissue and formed by the ventricular ependyma and the pia mater of the tela choroidea of the fourth ventricle, which covers it posteriorly (7.89). Caudally, the continuity of the sheet is broken by a gap, termed the *median aperture* (7.87), through which the cavity of the ventricle communicates freely with the subarachnoid space. The *tela choroidea of the fourth ventricle* is a double layer of pia mater which occupies the interval between the cerebellum and the lower part of the roof of the ventricle. Its posterior layer provides a covering of pia mater for the inferior vermis and, after reaching the nodule, is reflected ventrally and caudally in immediate contact with the ependyma. In the tela choroidea are highly vascular fringes forming the choroid plexus of the fourth ventricle. On each side, the layer of the tela choroidea in contact with the ependyma of the caudal part of the roof reaches the inferolateral border of the ventricular floor, which is marked by a narrow, white ridge, termed the *taenia*; the two taeniae are continuous below with a small, curved margin, the *obex*, which covers the inferior angle of the ventricle and is covered by ependyma on both aspects (7.89). Cranially, these taeniae pass laterally and horizontally along the inferior borders of the lateral recesses.



The openings in the roof. In the caudal part of the roof of the fourth ventricle are three openings, one median and two lateral. The *median aperture* is a large opening, situated caudal to the nodule (7.87); it varies considerably in its extent, and its irregular rostral border is drawn dorsally towards the inferior surface of the vermis in a somewhat funnel-shaped manner to face the cerebellomedullary cistern (7.89). The *lateral apertures* are situated at the ends of the lateral recesses and are partly occupied by parts of the choroid plexus, which protrude into the subarachnoid space (7.55). The ependyma and pia mater are continuous at the margins of these openings. Through these openings alone the ventricular cavity communicates with the subarachnoid space. Occasionally one of the lateral recesses may fail to open into the subarachnoid space, but the median aperture is constantly present.

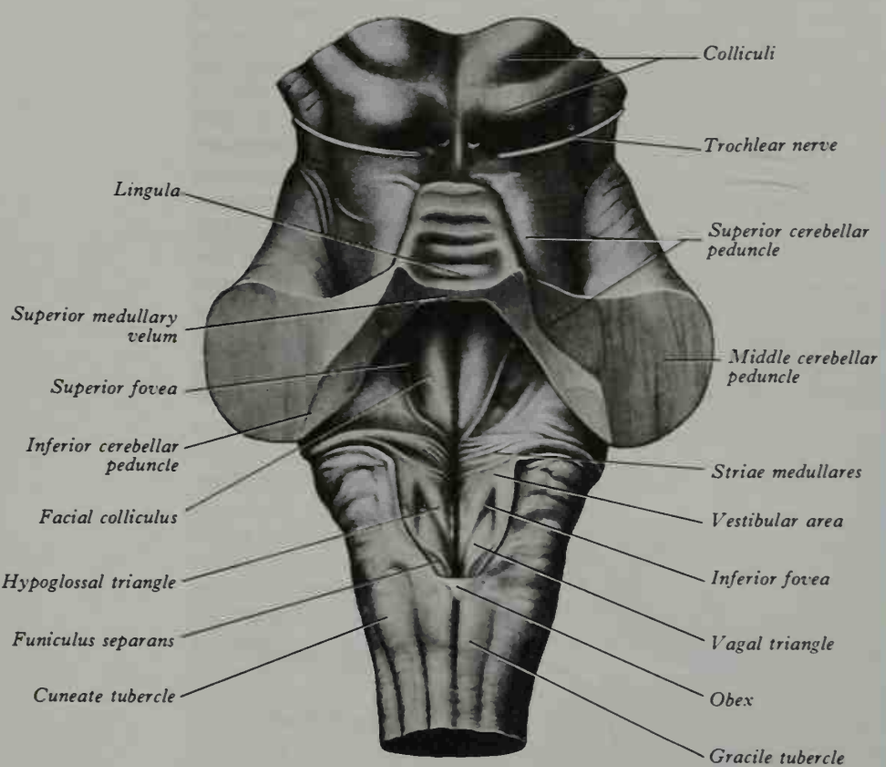
The choroid plexuses. Two highly vascular fringe-like processes of the tela choroidea contain the choroid plexuses of the fourth ventricle; they invaginate the caudal part of the roof of the ventricle and are everywhere covered by ependyma, which is modified to form a true secretory epithelium. Each consists of a vertical and a horizontal region. The former consists of two longitudinal fringes adjacent to the median plane, fusing at the cranial margin of the median aperture and frequently prolonged beyond this margin on to the ventral aspect of the vermis to which they adhere (Hewitt 1960). The horizontal portion projects into the fourth ventricle, passes into the lateral recess and emerges through the lateral aperture still covered by ependyma. The entire structure presents the form of the letter T, the vertical limb of which, however, is double. Wide variation in this form has been recorded by Lang and Schäfer (1977). The arterial supply of these plexuses is from the inferior cerebellar arteries (p. 696). A detailed study of these arterial rami and the venous drainage has been contributed by Maillot *et al.* (1976).

The rhomboid fossa (7.90). The floor of the fourth ventricle is rhomboidal in shape; it is formed by the posterior surface of both the pons and the cranial, open part of the medulla oblongata. It is covered by a layer of grey matter continuous with that surrounding the central canal of the medulla oblongata and spinal cord; superficial to this there is a thin lamina of neuroglia covered with ependyma. The floor consists of three parts, superior, intermediate and inferior. The *superior* part is triangular in shape and limited laterally by the superior cerebellar peduncles; its cranial apex is directly continuous with the wall of the cerebral aqueduct; its base is represented by an imaginary line at the level of the cranial ends of two small depressions, named the *superior foveae*. The *intermediate* part extends from this level to that of the horizontal sections of the taeniae of the ventricle and is prolonged into the lateral recesses. The *inferior* part is triangular, and its caudally directed apex is continuous with the wall of the central canal of the closed part of the medulla oblongata.



The rhomboid fossa is divided into symmetrical halves by a *median sulcus*, which reaches from its upper to its lower apex and is deeper below than above. On each side of this sulcus there is an elevation, the *medial eminence*, bounded laterally by a sulcus, the *sulcus limitans*. In the superior part of the floor the medial eminence has a width equal to that of the corresponding half of the floor, but opposite the superior fovea it forms an elongated swelling, the *facial colliculus*, which overlies the nucleus of the abducent nerve, and is in part produced by the ascending section of the root of the facial nerve. In the inferior part of the floor the medial eminence forms a triangular area, termed the *hypoglossal triangle* or *trigonum hypoglossi*. When examined closely with a lens the hypoglossal triangle is seen to consist of medial and lateral areas separated by a series of oblique furrows; the medial area corresponds with the cranial part of the nucleus of the hypoglossal nerve, the lateral with the *nucleus intercalatus* (*see* p. 903).

The *sulcus limitans* forms the lateral boundary of the medial eminence. Its superior part corresponds with the lateral limit of the floor and presents a bluish-grey area, named the *locus ceruleus*, which owes its colour to a group of pigmented nerve cells as seen through overlying tissue. The *nucleus ceruleus* corresponds to some extent with the locus of the same name in the floor of the fourth ventricle, but it ascends cranially beyond this as far as the caudal end of the mesencephalic trigeminal nucleus; it may even overlap the latter, appearing in the same sections in the most caudal level of the midbrain. Its cells are of medium size and some contain neuromelanin, especially so in the human midbrain, and it is this which is responsible for the colour of the locus ceruleus (Foley and Baxter 1958). At pontine levels the nucleus spreads into the neighbouring reticular formation and indeed has for long been, and is currently, regarded as a reticular element by many observers (*see*, for example, Russell 1955; Webster 1978). It has been demonstrated (Dahlström and Fuxe 1964; Fuxe *et al.* 1970) that all the centrally placed neurons of the nucleus are noradrenergic; these neurons are designated A6 (using the classification of the authors—p. 949) and they constitute by far the largest aggregation of noradrenergic cells within the mammalian brains so far examined. Stereotactic lesions of both nuclei coerulei (in rats) demonstrated that they are the main and



7.87 Dorsal aspect of the roof and the lateral recesses of the fourth ventricle, exposed by removal of parts of the cerebellum.

probably sole source of fibres constituting the *dorsal noradrenergic bundle*, part of the central tegmental fasciculus through which they approach some of their many destinations (Ungerstedt 1971). Ramón-Moliner and Dansereau (1974), however, have demonstrated in the feline nucleus ceruleus high concentrations of acetylcholinesterase, a finding not necessarily inconsistent with the above view, as they note in discussion. The afferent connexions of the nucleus are not particularly well authenticated but probably include projections from ascending spinal fibres, from neighbouring brainstem reticular nuclei, from trigeminal nuclei, and possibly descending systems from forebrain centres. The distribution of efferent projections from the nucleus ceruleus have, in contrast, been subjected to intensive investigation (*see*, for example, Macda *et al.* 1973; Lindvall and Björkland 1974; Freedman *et al.* 1975; Kievit and Kuypers 1975; Gatter and Powell 1977; Pickel *et al.* 1977; Bowden *et al.* 1978); these included both histofluorescence and autoradiographic studies. Briefly, the nucleus ceruleus presented descending, local

7.88 An enlargement of the part of 7.86 which is enclosed by an interrupted line. *Blue:* arachnoid mater. *Red:* pia mater. *Green:* ependyma. The black arrow traverses the median aperture of the roof of the fourth ventricle.

brainstem, and profuse ascending projections. The descending fibres entered the ventral funiculus of the spinal cord and apparently terminated in the ventral, intermediate, and base of the dorsal grey columns throughout the spinal cord, although their precise laminar destinations have not yet been established. Local fibres projected to many 'specific' and reticular bulbopontine nuclei; others pass through the superior cerebellar peduncle, some ending in the intracerebellar nuclei whilst the majority diverge in the cerebellar cortex either arborizing around Purkinje cell somata or continuing into the molecular layer. As indicated above the ascending fibres constitute the dorsal noradrenergic bundle; in the upper midbrain the bundles of the two sides interchange a proportion of their fibres, the bundles then continuing through the diencephalon as one constituent of the lateral hypothalamic medial forebrain bundle (p. 968), its further continuation being through the septal region into the supracallosal longitudinal stria and cingulum. Numerous complex side branches, described elsewhere, leave these principal channels for a truly remarkable diversity of destinations which can merely be listed here (for details and bibliography consult references quoted). Midbrain destinations include the periaqueductal grey matter, other reticular nuclei, and the colliculi; diencephalic arborizations occur in all the principal groups of thalamic nuclei, the geniculate bodies and the habenular nuclei (a direct supply to hypothalamic nuclei, although claimed on occasion, is less certain). Telencephalic destinations, widely accepted, are the

7.89 The rhomboid fossa, or 'floor' of the fourth ventricle.

major 'limbic' structures, e.g. the septal nuclei, amygdala, hippocampus, subiculum, and the cingulate, retrosplenial, and parahippocampal gyri; finally, it is held that the whole neocortex receives a uniform, diffuse, bilateral input. Thus, this remarkable, compact, but relatively small nucleus would seem to be involved in neural mechanisms concerned with somatic motor and visceral control, biological rhythms including the complex hierarchy of sleep 'centres', cognitive mapping, general affective behaviours (in particular 'reward' or 'pleasure' loci, learning and memory), and to be involved in modulating general neocortical and thalamic activity.

At the level of the facial colliculus the sulcus limitans widens into an angular depression, termed the *superior fovea*, and in the inferior part of the floor presents a distinct dimple termed the *inferior fovea*. Lateral to the foveae there is a rounded elevation named the *vestibular area*, which extends into the lateral recess, where it forms the *auditory tubercle* produced by the underlying dorsal cochlear nucleus and cochlear part of the vestibulocochlear nerve (p. 909). Winding round the inferior cerebellar peduncle, and crossing the vestibular area and the medial eminence to pass deeply at the median sulcus, are a number of white strands termed the *striae medullares* (*see* p. 910). Caudal to the inferior fovea, and between the hypoglossal triangle and lower part of the vestibular area, a triangular dark field, the *vagal triangle or trigonum vagi*, overlies the dorsal nucleus of the vagus nerve (p. 1076). The lower part of the vagal triangle is crossed by a narrow translucent ridge, named the *funiculus separans*, and between this funiculus and the gracile tubercle is a small tongue-shaped area, termed the *area postrema*. On section it is seen that the funiculus separans is covered by a strip of thickened specialized ependyma including tanycytes, and the area postrema has a similar lining over a loose, highly vascular, neuroglial tissue containing nerve cells of moderate size. In these regions the usual blood-brain barrier may be modified. The specialised ependyma is analogous to similar distinctive areas in the third ventricle and cerebral aqueduct (pp. 935, 981). The columnar ependymal cells and tanycytes may be involved in (1) secretory activities into the cerebrospinal fluid; (2) transport of neurochemical substances from underlying neurons, glia, or vasculature to the cerebrospinal fluid; (3) transport of neurochemical substances from the cerebrospinal fluid to

7.90 A dorsal view of the brainstem including the floor of the rhomboid fossa—for identification of structures compare with 7.89. In addition to the structures shown in the latter, note: (1) the crenated outlines of the right and left dentate nuclei in the sectioned surface of the cerebellar white matter opposite the widest part of the rhomboid fossa; (2) the midline pineal gland cranial to the superior colliculi; (3) the rounded pulvinar of the dorsal thalami which encroach on the uppermost part of the photograph; (4) the right and left habenular trigones immediately lateral to the base of the pineal; and (5) the medial geniculate bodies, lateral to the superior colliculi. (Dissection by Dr. E. L. Rees, Department of Anatomy, Guy's Hospital Medical School.)

underlying neurons, glia, or vasculature; and (4) it has been proposed that some cells of the area postrema may function as chemoreceptors (Brizzee and Neal 1954; Borison and Borison 1973).

The inferior part of the floor of the fourth ventricle towards its apex, presents the appearance of a pen nib, and is hence called the *calamus scriptorius*. (For the phylogenetic and ontogenetic development of the fourth ventricle consult Kier 1977.)

THE MESENCEPHALON OR MIDBRAIN

The mesencephalon or midbrain is derived from the intermediate of the three primary cerebral vesicles. In the course of its development in man and in its phylogenetic history it retains, from some standpoints, a rather simpler form than either the forebrain or the hindbrain. In lower vertebrates the leading feature of the midbrain is the development in its roof plate of higher visual (p. 941), and, later, higher auditory centres. In the mammals these become reflex centres and their original function as 'higher' or sensory centres becomes transferred to the cerebral cortex. As this change, *telencephalization*, increases, the midbrain is traversed by an increasing number of axons subserving cortico-spinal and spino-cortical pathways. Midbrain mechanisms also contribute extensively to the reticular system (pp. 943–953).

It should be noted that the foregoing statements are given merely as an aid to those embarking on an elementary course of neurology. Whilst some midbrain activities may justifiably be termed reflex, for example, the 'light', 'accommodation', 'visuospinal', and 'auditory' reflexes amongst many others, it would be an *over-simplification* to regard as reflex, the complex activities of such subdivisions as the colliculi, substantia nigra and the numerous entities constituting the midbrain reticular formation. In such regions all grades of convergent/divergent interaction, and subtleties of information processing occur, that affect many other regions of the nervous system. Thus the midbrain acts *in concert with*, and not merely as reflex side-channels of, the forebrain and hindbrain. *See*, in particular, p. 951.

EXTERNAL FEATURES

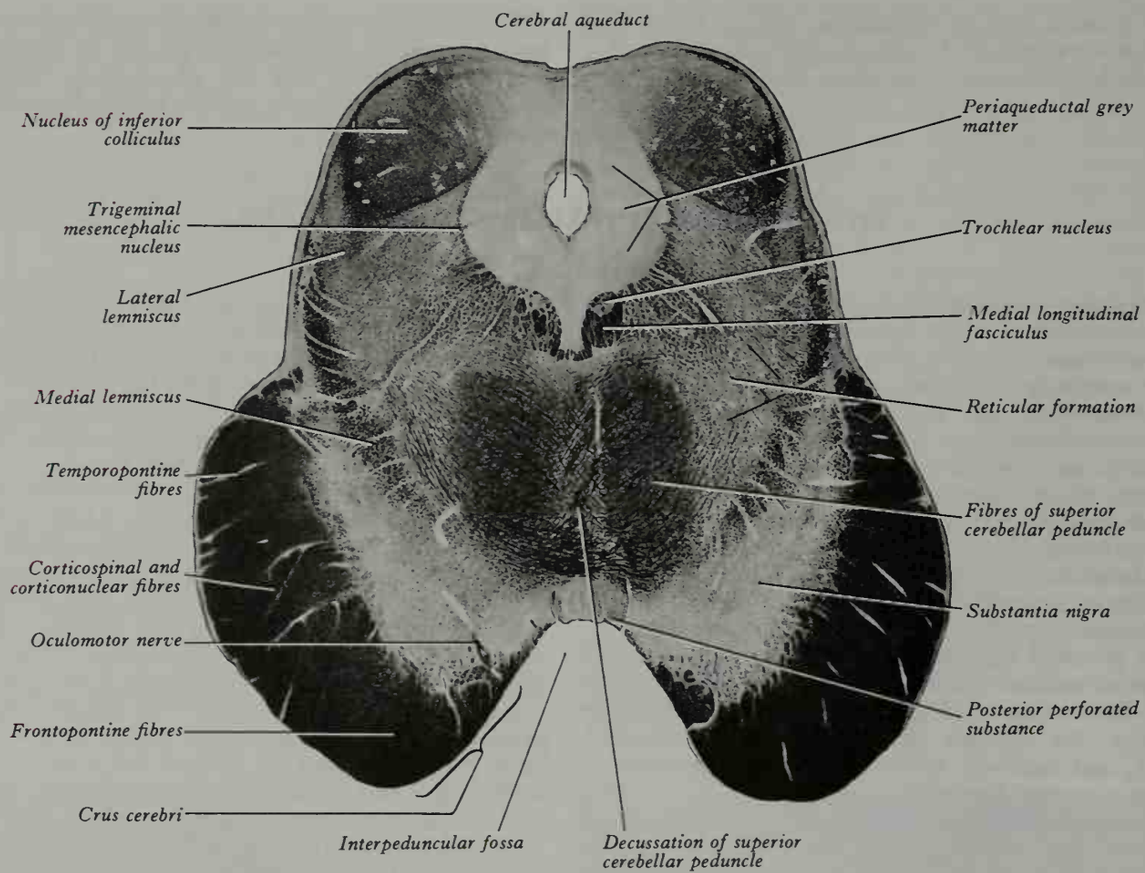
The midbrain lies athwart the hiatus in the tentorium cerebelli and connects pons and cerebellum with the forebrain. It is the shortest segment of the brainstem, being not more than 2 cm in length. On each side it is related to the parahippocampal gyrus, which hides its lateral aspect from view when the inferior surface of the brain is examined. Its long axis inclines ventrally as it ascends.

The midbrain can for description be divided into right and left halves, the *cerebral peduncles*, each of which is further subdivided into a ventral part, the *crus cerebri*, and a dorsal *tegmental part*, by a lamina of pigmented grey matter, the *substantia nigra*. The two crura are separate, whereas the tegmental parts are united. The tegmentum is traversed by the *cerebral aqueduct*, which connects the third and fourth ventricles. The region of the tegmentum dorsal to the cerebral aqueduct is called the *tectum* and comprises the *colliculi* which consist of four rounded elevations, symmetrically arranged in superior and inferior pairs; these include visual and auditory reflex centres respectively (but *vide supra*).

The *crura cerebri* are two white, superficially corrugated structures which emerge from the cerebral hemispheres, one on each side of the median plane. They converge as they descend and meet where they enter the pons; here they form the posterior boundaries of the *interpeduncular fossa* (p. 966). The surface of the posterior part of the interpeduncular fossa is formed by a greyish area, the *posterior perforated substance* (p. 966), through which pass the central branches of the posterior cerebral artery.

The ventral surface of each crus is crossed close to the pons, from medial to lateral, by the superior cerebellar and posterior cerebral arteries; near to the point of entry of the crus into the cerebral hemisphere, the optic tract winds backwards around it. Over the surface of the crus, also close to the pons, a thin white band, the *taenia pontis*, is frequently seen as it enters the cerebellum between the middle and superior peduncles.

The medial surface of each crus bears a longitudinal groove, the *medial sulcus*, from which the roots of the oculomotor nerve emerge (7.92). The lateral surface of each peduncle is in relation with the parahippocampal gyrus of the cerebral hemisphere and is crossed in a ventral direction by the trochlear nerve (7.97). This surface is marked by a longitudinal groove, the *lateral sulcus*; the fibres of the lateral lemniscus come to the surface in this sulcus, and then turn dorsally, some to enter the inferior colliculus, the rest passing into the brachium of the inferior colliculus.



The *colliculi* (*corpora quadrigemina*) (7.97) are four rounded eminences, situated cranial to the superior medullary velum, and caudal to the pineal gland and posterior commissure, the whole region inclining ventrally as it ascends. They are inferior to the splenium of the corpus callosum, and are partly overlapped on each side by the pulvinar of the thalamus. The colliculi are arranged in pairs (superior and inferior), and are separated from one another by a cruciform sulcus. The vertical part of this sulcus expands superiorly to form a slight depression in which the *pineal gland* (7.97) lies. From the inferior end of the vertical sulcus a white ridge, the *frenulum veli*, is prolonged caudally to the superior medullary velum; at the sides of this ridge the trochlear nerves emerge, pass ventrally on the lateral aspects of the cerebral peduncles and traverse the interpeduncular cistern to reach the posterior end of the cavernous sinus. The *superior colliculi* are larger and darker in colour than the inferior, and constitute centres for visual responses (p. 941). The *inferior colliculi*, though smaller, are somewhat more prominent than the superior and are associated with the auditory pathway (p. 941). The difference in colour is due to the greater accumulation of nerve cells near the surface of the superior colliculus (p. 941).

From the lateral aspect of each colliculus a ridge, termed the *brachium*, ascends in a ventrolateral direction. The *brachium of the superior colliculus* passes inferior to the pulvinar. It partly overlaps the medial geniculate body and is partly continued into the lateral geniculate body (p. 977), and partly into the optic tract. It conducts fibres from the retina and from the optic radiation to the superior colliculus. The *brachium of the inferior colliculus* ascends ventrally from the inferior colliculus; it conveys fibres from the lateral lemniscus and the inferior colliculus to the medial geniculate body.

INTERNAL STRUCTURE OF THE MIDBRAIN

On transverse section, each cerebral peduncle is seen to consist of a dorsal and a ventral part, separated by a deeply pigmented lamina of grey matter, termed the *substantia nigra* (7.91, 92). The dorsal part is named the *tegmentum*; the ventral, the *crus cerebri*. The crura are separated from each other, but the tegmental parts are continuous with one another across the midline, and the term *tegmentum* usually implies the bilateral mass between both nigral masses and the *tectum*. The latter is the part dorsal to the cerebral aqueduct and contains the colliculi.

The crus cerebri is semilunar on transverse section, and consists of corticospinal, corticonuclear, and corticopontine fibres (7.91). The *corticospinal* and *corticonuclear* fibres occupy the middle two-thirds of the crus; they descend through the pons and medulla oblongata, where the corticonuclear fibres end in the nuclei of the various cranial nerves, mainly of the opposite side: corticospinal fibres are continued into the pyramid of the medulla oblongata. The corticopontine fibres arise in the cerebral cortex and terminate in the nuclei pontis, where they are relayed mainly to the opposite cerebellar hemisphere. They are subdivided into two main groups: (*a*) *frontopontine* and (*b*) *temporopontine*. (*a*) The frontopontine fibres arise in the frontal lobe, principally areas 6 and 4 of Brodmann, traverse the anterior limb of the internal

7.91 Transverse section of midbrain through the inferior colliculi. Weigert Pal preparation. Magnification *c.* ×4·1.

capsule, and occupy the medial sixth of the crus cerebri. (*b*) The temporopontine fibres arise in the temporal lobe, traverse the posterior limb of the internal capsule and occupy the lateral sixth of the crus cerebri; they end in the nuclei of the pons. *Parieto-* and *occipito-pontine* fibres are also described in the crus cerebri, medial to the temporopontine fibres. The temporopontine projection is largely derived from the posterior (caudal) region of the temporal lobe, and the occipitopontine fibres do not include a projection from the striate area (Verhaart and Mechelse 1954).

A band of fibres, named the *tractus peduncularis transversus*, is sometimes seen emerging from the optic tract on the lateral aspect of the cerebral peduncle; it passes round the ventral surface of the peduncle about midway between the pons and the optic tract, and disappears by entering the interpeduncular fossa behind and lateral to the corpus mamillare, where it terminates in a small *nucleus of the transverse peduncular tract* which lies medial to the substantia nigra. The tract is a constant structure in many lower mammals, but is only identifiable in 30 per cent of human brains. Since it undergoes atrophy after enucleation of the eyeballs, it may be considered as being associated with the visual pathway; the nucleus projects to the oculomotor nuclei in some mammals (Gillilan 1941; but *see* also p. 975).

The substantia nigra is a lamina of grey matter containing numerous, deeply pigmented (neuromelanin-containing), multipolar nerve cells and extending throughout the whole length of the midbrain. Owing to its pigmentation it can readily be recognized with the naked eye in transverse or coronal sections (7.98) through the midbrain. Its pigment is related to the aminergic status of many of the mesencephalic reticular neurons; it increases with age, is greater in amount in primates, maximal in man (Marsden 1961), and is even present in albinos.

The substantia nigra is semilunar on transverse section, its concavity being directed towards the tegmentum; from its convex surface, processes extend between the fibres of the crus cerebri. Thicker medially than laterally, it reaches from the medial to the lateral sulcus, and extends from the upper surface of the pons to the subthalamic region; its medial part is traversed by the fibres of the oculomotor nerve as they stream forwards to reach the oculomotor sulcus. It is divided into a dorsal *pars compacta* containing medium-sized cells, many of which are pigmented, and a ventral *pars reticularis* intermingled with fibres of the crus cerebri and containing fewer cells, only some of which contain a small amount of pigment. The reticular part extends into the subthalamic region, where it is considered to be continuous with the globus pallidus, which it resembles structurally; both nuclei contain iron in unusual amounts. In vertebrates below mammals a well-developed *pars lateralis* is present; this is recognizable but has been claimed to be rather insignificant in man (Huber and Crosby 1933). It has nevertheless been shown to project to the tectum in primates (Woodburne *et al* 1946); see also below and p. 941.

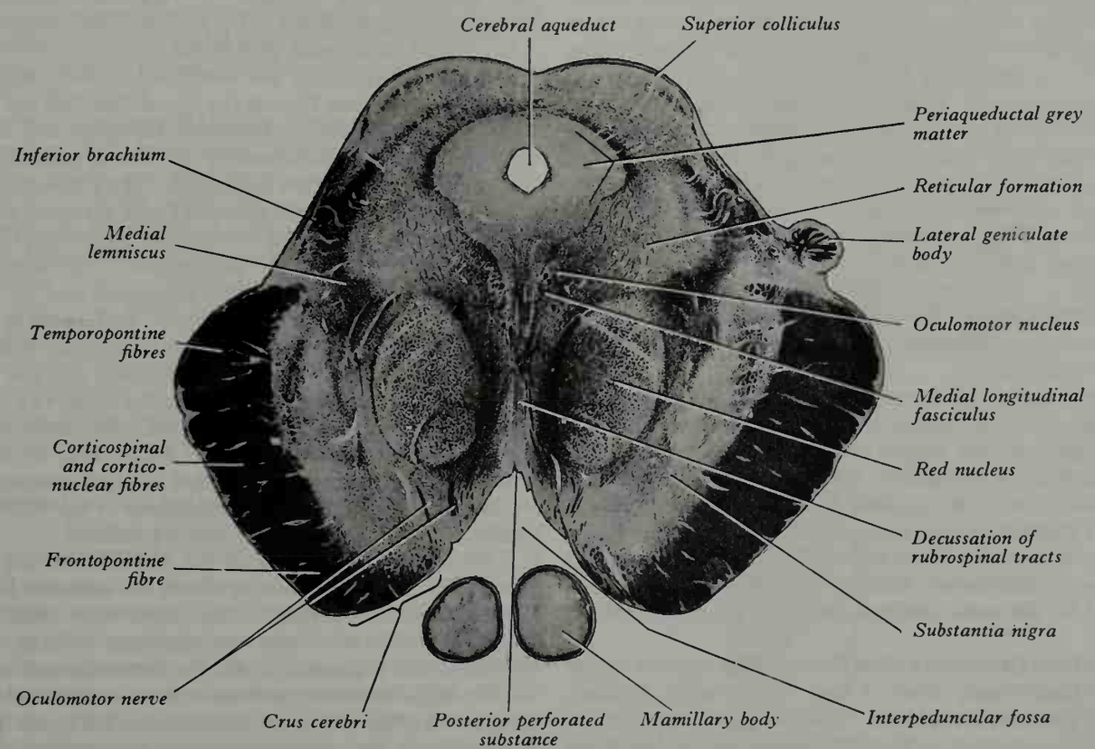
The substantia nigra is connected with the cerebral cortex, spinal cord, hypothalamus and basal nuclei. Corticonigral fibres arise from the precentral and, probably, the postcentral gyri and terminate on cells in the reticular region, but they are few in number, many being fibres of passage to the red nucleus and reticular formation. Collaterals from fibres in the sensory tracts ascending from the spinal cord are also said to terminate in the substantia. Fibres from the mamillary peduncle and subthalamic nucleus have also been traced on to its cells. The connexions with the basal nuclei are efferent nigrostriatal fibres which pass to the caudate nucleus, putamen and possibly also the globus pallidus (although the latter are strongly debated by many authors); afferent strionigral fibres also exist. Efferent fibres also pass into the tegmentum of the midbrain, probably to terminate on cells of the reticular formation, whence impulses arising in the substantia nigra are relayed to anterior column cells of the spinal cord. The nigrotegmental projection was observed to be a major efferent connexion in cats (Afifi and Kaelber 1965). Lesions in the medial part of the substantia, also in cats (Marcós 1969), suggest that some fibres pass to the ventral thalamus; nigrocortical connexions have been described in the same experimental animal (Negro 1969). A nigrothalamic projection has been confirmed in monkeys by autoradiographic tracing techniques (Carpenter *et al.* 1976);

terminals were identified in the medial part of the nucleus ventralis intermedius, magnocellular part of the nucleus ventralis anterior, and paralaminar part of the nucleus medialis dorsalis (*see* p. 959). Jayaraman *et al.* (1977), using the same techniques in monkeys, have described a projection to the tectum; the fibres are derived largely from the cranial and lateral region of the substantia nigra, and they terminate in intermediate strata of the caudal levels of the ipsilateral inferior colliculus.

It may be noted here that the pars lateralis of the substantia nigra includes the dopaminergic cell group A9, while the pars compacta constitutes group A10 (for further details *see* p. 949).

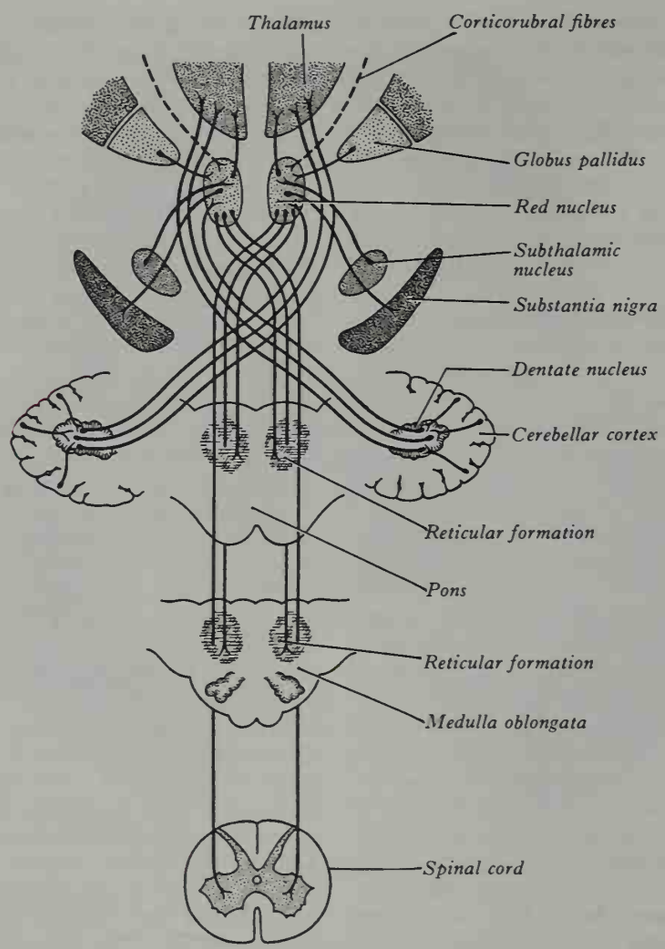
The tegmentum of the midbrain presents appearances which differ according to the level of the section examined. Caudally, it is directly continuous with the tegmentum of the pons and contains the same fibre tracts.

At the level of the inferior colliculi, the grey matter is restricted to the immediate environs of the cerebral aqueduct, to the scattered collections in the reticular formation (7.91) and to the tectum, which is described separately (p. 940).



The *nucleus of the trochlear (fourth cranial) nerve* lies in the ventral region of the central grey matter, close to the midline. It occupies a position homologous with the abducent and hypoglossal nuclei at lower brainstem levels. Closely related throughout to the medial longitudinal fasciculus, which is on its ventral aspect, the nucleus extends through the caudal half of the midbrain, and it is just caudal to the oculomotor nucleus. In some primates the nuclei are merged and only distinguishable by the arrangement of their cells, which are also smaller in the trochlear nucleus. Its *outgoing fibres* pass laterally and dorsally round the central grey matter. Descending dorsally on the medial side of the mesencephalic nucleus of the trigeminal nerve, they reach the cranial end of the superior medullary velum, wherein they decussate to emerge at the lateral side of the frenulum veli (7.90). A few fibres probably do not decussate. The trochlear nerve fibres emerge dorsally and largely decussate in all vertebrates. It has been suggested that the nerve originally supplied the muscles of the pineal eye, which would account for its dorsal course. Embryological evidence (Pearson 1943) and phylogenetic data support a more dorsal origin of this nucleus.

The *mesencephalic nucleus of the trigeminal nerve* is in the lateral part of the central grey matter. It extends from the cranial end of the main sensory nucleus of the trigeminal nerve in the pons to the level of the superior colliculus in the midbrain. It is accompanied by a tract composed of the peripheral and central branches of the axons of its cells. The large ovoid nerve cells of this nucleus are unipolar and resemble those of sensory ganglia. They occur in many small groups each containing only a few cells; these groups extend as curved laminae on each side, in the lateral margins of the periaqueductal grey matter. The greatest number of cells is apparent at the caudal end of the mesencephalic nucleus. Attempts to categorize the cells of the nucleus have been largely unsuccessful. These cells have very few dendrites and are usually so closely clustered together that somato-somatic contacts have been suggested. (For a discussion of nerve cells of the mammalian nucleus consult Hinrichsen and Larramendi 1969.) For connexions of this nucleus *see* pp. 1060, 1085.



Apart from these nuclei the tegmentum at this level contains large numbers of scattered nerve cells, most of which are included in the reticular formation (p. 945).

The *white matter* at this level of the midbrain contains all the tracts which have already been mentioned in the tegmentum of the pons, and it is characterized by the great decussation of the fibres of the superior cerebellar peduncles.

The *superior cerebellar peduncle*, which has already been described (p. 917), enters the dorsolateral part of the tegmentum and passes ventromedially round the central grey matter to reach the median raphe, where the majority of its fibres form with their fellows the *decussation of the superior cerebellar peduncles*. Having crossed the median plane, the fibres separate into ascending and descending bundles. Some of the *ascending* fibres and branches terminate in or give collaterals to the red nucleus, which they encapsulate and penetrate. Numerous others are continued cranially to end in the nucleus ventralis lateralis of the thalamus. Some of the fibres, however, are uncrossed, and branches are believed to end in the periaqueductal grey matter and reticular formation of the midbrain, in the interstitial nucleus (of Cajal) and the nucleus of the posterior commissure (sometimes, perhaps mistakenly—Ingram and Ranson 1953—called the nucleus of Darkschewitsch). The latter is considered to send efferent fibres to the medial longitudinal fasciculus and posterior commissure, the significance of which is uncertain. The *descending* branches end in the reticular formation of the pons and medulla oblongata, the olivary complex, and possibly the motor nuclei of certain cranial nerves (see also pp. 917, 919).

7.93 Simplified diagram of the principal connexions of the red nucleus.

The *medial longitudinal fasciculus* retains its intimate relationship to the somatic efferent column, and therefore lies dorsal to the decussating fibres of the superior cerebellar peduncles.

The *medial*, *trigeminal* and *lateral lemnisci* and *lateral spinothalamic tract* (spinal lemniscus) form a curved band lying dorsal to the lateral part of the substantia nigra. At this level some of the fibres of the lateral lemniscus terminate in the nucleus of the inferior colliculus, around which they form a capsule. These fibres synapse with cells in the inferior colliculus. Accompanied by fibres from cells in the inferior colliculus, the remaining fibres of the lateral lemniscus enter the brachium of the inferior colliculus, which commences at this level, and conducts them to the medial geniculate body. Some of these fibres give collaterals which also synapse with cells in the inferior colliculus.

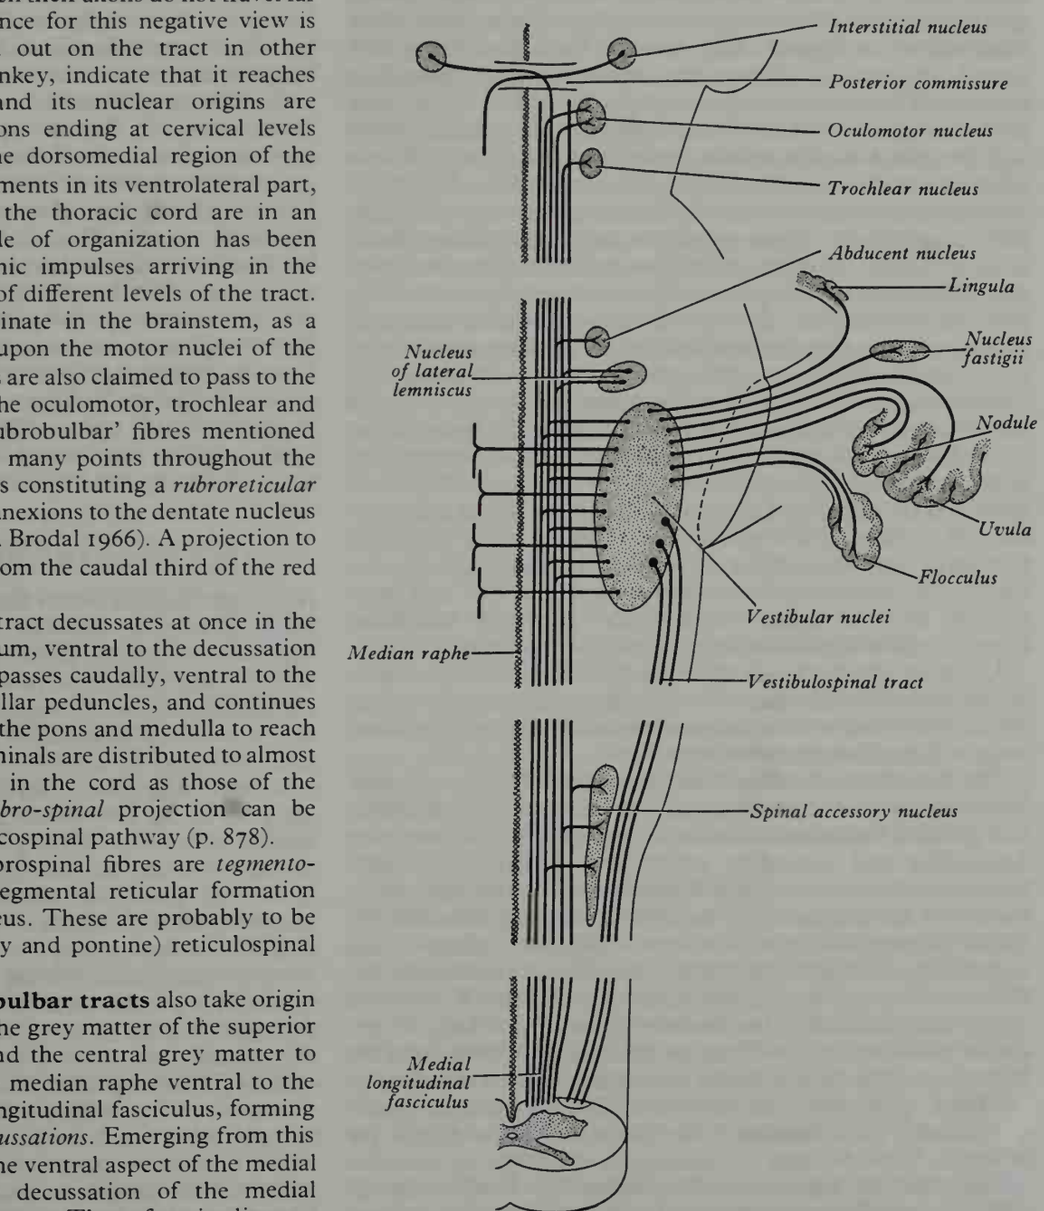
Rostrally, on a level with the superior colliculus, the tegmentum is strikingly modified by the appearance of a large nucleus, which extends upwards into the subthalamic region and is termed the *red nucleus*.

The *central grey matter* surrounds the aqueduct and contains in its ventromedial part the *nucleus of the oculomotor nerve*. This elongated nucleus is closely related on its ventrolateral aspect to the medial longitudinal fasciculus; inferiorly it extends to the trochlear nucleus (7.91). The nucleus of the oculomotor nerve is divisible into a number of cell groups which can be correlated with the motor distribution of the nerve. They include a visceral efferent *accessory oculomotor nucleus*, the Edinger-Westphal nucleus, dorsal to the main nucleus (and are all described on p. 999).

The red nucleus (nucleus ruber) is an ovoid mass of nerve cells with a pinkish tinge, about 5 mm in diameter, situated dorsomedial to the substantia nigra (7.92). The colour is most apparent in freshly sectioned, unfixed midbrains, and is due to the presence of an iron-containing pigment which occurs in many, but not all, of the cells in the nucleus. These are mostly multipolar and of varying sizes, rather large and small categories being predominant. The proportions and distribution of these types differ in various mammalian groups; in primates, including man, the *magnocellular* element is relatively decreased, with a reciprocal augmentation of the *parvocellular* complement of cells. These small multipolar cells occur in all parts of the nucleus, but in man the large cells are restricted to the caudal part of the nucleus. Condé and Condé (1973) categorized the rubral cells of the cat as multipolar, pyramidal, fusiform and spherical; they emphasized the heterogeneity of the cytoarchitecture of the nucleus, finding that the multipolar type predominated at caudal levels, the pyramidal and spherical cells at rostral levels. All types were, however, described at all levels. Rostrally, the boundary of the red nucleus is poorly demarcated from other cell groups, where it fades into the reticular formation and the caudal pole of the interstitial nucleus (Davenport and Ranson 1930). Some division of the red nucleus into caudal *compact* and rostral *diffuse* architectonic regions has been described, and the whole mass is traversed and encapsulated by fascicles of nerve fibres, including many of the fibres emerging from the oculomotor nucleus (7.92). These bundles impart a reticular appearance to the nucleus. Its magnocellular element is regarded as phylogenetically the older, which accords with the predominance of the parvocellular part especially in man, but also in other primates.

The *afferent connexions* of the red nucleus are complex and numerous, and only those for which the evidence is strong will be described here. Of these, some have been established only in experimental animals and are uncertain in man. An uncrossed corticorubral projection from the sensorimotor area is demonstrable in the cat (and other mammals); in the same animal an area anterior to the medial part of the precentral gyrus (p. 957), which is termed the 'supplementary motor area' in the feline cerebrum, projects bilaterally upon the red nuclei. A somatotopic arrangement of these corticorubral fibres and their terminations

in the nucleus has been demonstrated; this conforms with the localization of the cells of origin of the rubrospinal tract (*vide infra*). This projection is derived from neurons in the primary somatomotor and somatosensory areas—the sensorimotor cortex. Brown (1974) has described the fibres as terminating largely in the periphery of the red nucleus and as being axodendritic at their terminals. There are also bilateral connexions, probably in both directions, with the superior colliculi. The red nucleus also receives nerve fibres from the contralateral nucleus interpositus in the cat; this corresponds to the nuclei globosus and emboliformis of the human cerebellum. Afferents are also derived from the contralateral dentate nucleus. All these cerebellar connexions, and perhaps others (p. 917), pass through the superior cerebellar peduncle. They are said to display some degree of somatotopic organization. Connexions from other sources have been reported—from the globus pallidus, subthalamic and hypothalamic nuclei, substantia nigra, and spinal cord—but these are only putative in regard to the human red nucleus. (Some of the connexions of the red nucleus are outlined in 7.93.)



The main *efferent outflow* of axons is into the **rubrospinal tract** (p. 878), which is derived from both the large and small cells in the nucleus in other mammals, and probably also in mankind. As mentioned elsewhere (p. 878), this tract is currently dismissed as unimportant in man by many authorities, clinical and academic, who state that it is derived only from the magnocellular neurons in the nucleus, and that even their axons do not travel far down the spinal cord. The evidence for this negative view is exiguous; all the studies carried out on the tract in other mammals, chiefly the cat and monkey, indicate that it reaches lumbosacral levels. The tract and its nuclear origins are somatotopically localized, the axons ending at cervical levels being from cells segregated in the dorsomedial region of the nucleus, those for lumbosacral segments in its ventrolateral part, and those with a destination in the thoracic cord are in an intermediate position. This mode of organization has been confirmed by recording antidromic impulses arriving in the nucleus as a result of stimulation of different levels of the tract. Some of the efferent axons terminate in the brainstem, as a *rubrobulbar tract*, which projects upon the motor nuclei of the trigeminal and facial nerves. Fibres are also claimed to pass to the inferior olive, and the nuclei of the oculomotor, trochlear and abducent nerves; many of the 'rubrobulbar' fibres mentioned above are thought to terminate at many points throughout the brainstem reticular formation, thus constituting a *rubroreticular system*; in the cat *rubrocerebellar* connexions to the dentate nucleus have been described (Courville and Brodal 1966). A projection to the ventrolateral thalamic nuclei from the caudal third of the red nucleus has been described.

As it descends, the rubrospinal tract decussates at once in the ventral decussation of the tegmentum, ventral to the decussation of the tectospinal tracts, and then passes caudally, ventral to the decussation of the superior cerebellar peduncles, and continues through the reticular formation of the pons and medulla to reach the spinal cord. Since its spinal terminals are distributed to almost the same laminae of grey matter in the cord as those of the corticospinal tract, the *cortico-rubro-spinal* projection can be regarded as a kind of indirect corticospinal pathway (p. 878).

Closely associated with the rubrospinal fibres are *tegmentospinal* fibres which arise in the tegmental reticular formation lateral and caudal to the red nucleus. These are probably to be grouped with the other (medullary and pontine) reticulospinal tracts (p. 879).

The tectospinal and the **tectobulbar tracts** also take origin at this level. Their fibres arise in the grey matter of the superior colliculi and sweep ventrally round the central grey matter to decussate with one another in the median raphe ventral to the oculomotor nucleus and medial longitudinal fasciculus, forming the *dorsal part of the tegmental decussations*. Emerging from this the tectospinal tract descends on the ventral aspect of the medial longitudinal fasciculus until the decussation of the medial lemniscus in the medulla oblongata. Thereafter it diverges ventrolaterally and in the spinal cord it lies in the anterior column adjacent to the ventral end of the anterior median fissure. The tectobulbar tract is mainly composed of crossed fibres and descends close to the tectospinal tract. It ends in the pontine nuclei and motor nuclei of the cranial nerves, particularly those concerned with the innervation of the orbital muscles. It serves as a pathway for reflex movements of the eyes in response to visual stimuli. (See also references to the lateral tectotegmentospinal tract, p. 875).

The medial longitudinal fasciculus (7.94) is a heavily myelinated composite tract lying on the ventrolateral aspect of the oculomotor nucleus. At this level its fibres are more spread out than they are at lower levels in the brainstem, but the intimate relationship to the efferent nuclei is retained. The fasciculus extends cranially to the *interstitial nucleus* (of Cajal)—a collection of cells situated in the lateral wall of the third ventricle immediately above the cranial end of the cerebral aqueduct—which contributes fibres to it. (Closely related to the cranial ends and decussating fibres of the fasciculi are the *interstitial* and *dorsal* groups of *nuclei of the posterior commissure* which probably both receive fibres from, and contribute fibres to these complex bundles. Also closely related are the *nuclei of Darkschewitsch*, but their status in relation to the fasciculi remains uncertain.) As has already been seen, the medial longitudinal fasciculus retains its position relative to the central grey matter throughout the midbrain, pons and cranial part of the medulla oblongata. It is displaced ventrally by the successive decussations of the medial

7.94 Simplified diagram of *some* of the components of the *medial longitudinal fasciculus* and of the distribution of its fibres to cranial nerve nuclei.

lemnisci and the lateral corticospinal tracts, and becomes continuous with the anterior intersegmental fasciculus of the spinal cord.

The intimate relationship which the fasciculus bears successively to the nuclei of the oculomotor, trochlear and abducent nerves, to the emerging fibres of the facial, the fibres from the dorsal cochlear nucleus in the floor of the fourth ventricle and the nucleus of the hypoglossal nerve, renders it a very convenient pathway for the passage of fibres from one nucleus to another in the brainstem. Its continuity with the anterior intersegmental tract of the spinal cord provides a route for connexions between these nuclei and the cervical anterior grey column cells, principally those innervating neck musculature. The harmonious cooperation obviously existing between the facial and hypoglossal nerves in movements of the lips and tongue in speech is frequently attributed to connexions between their nuclei conveyed by the medial longitudinal fasciculus. It is, however, doubtful whether it is the medial longitudinal fasciculus which provides the pathway for these connexions. It has long been established that the most substantial contributions to the fasciculus are made by the *vestibular nuclei*, and to a much smaller extent by fibres derived from the nucleus of the lateral lemniscus, and that its chief function is to ensure the coordinate movements of the eyes and head in response to stimulation of the vestibulocochlear nerve. (*See* Maciewicz *et al.* 1977, and Yamamoto *et al.* 1978; also p. 1073.) Lesions of the fasciculus are associated with partial ophthalmoplegia. Fibres from the vestibular nuclei, both of the same and of the opposite side, join the fasciculus, where they ascend, descend or divide into ascending and descending branches. These vestibular fibres send collaterals to, or they may end in, the nuclei of the third, fourth, fifth and sixth cranial nerves and the spinal nucleus of the eleventh nerve (7.94). All four vestibular nuclei contribute ascending fibres to the fasciculus, those from the superior nucleus remaining uncrossed (McMasters *et al.* 1966), the others crossing in part. Some of these fibres, as stated, pass to the nuclei of the nerves of the eye muscles, some pass further to reach the interstitial nucleus and the nuclei of the posterior commissure, through which a proportion decussate before ending in these two nuclei (Matano 1970; see also pp. 963, 1073). Descending axons, from the medial vestibular nuclei, perhaps joined by some from the lateral and inferior nuclei, partially decussate and pass to the spinal cord, in the fasciculus, as the *medial vestibulospinal tract* (Brodal *et al.* 1962, and *see* pp. 875, 893). In addition, fibres join the fasciculus from the dorsal nucleus of the trapezoid body, the nucleus of the lateral lemniscus and the nucleus of the posterior commissure. It is probable, therefore, that the cochlear as well as the vestibular nerve is capable of influencing the movements of the eyes and head through the fasciculus. Some fibres conveying vestibular impulses may ascend in the fasciculus to the thalamus.

A number of other longitudinal nerve fibre systems have been described in the midbrain, some of which extend through much of the entire brainstem. It is not possible to detail all of these here, but two in particular must be mentioned.

The dorsal longitudinal fasciculus (of Schütz) runs in the central grey matter of the midbrain, pons and part of the medulla, in a position ventrolateral to the aqueduct. It is a pathway for descending and ascending connexions, largely uncrossed, between numerous hypothalamic and dorsal thalamic nuclei and a number of cell groups in the brainstem, including the accessory nuclei (Edinger-Westphal) of the oculomotor complex, the superior colliculus, nucleus ambiguus, the salivatory nuclei, and the facial, solitary and hypoglossal nuclei (Crosby and Woodburne 1951), and a number of brainstem reticular nuclei. Some fibres, *cholinergic* in nature, have been described as *descending* from the hypothalamic nuclei to enter the cerebellum through the superior cerebellar peduncle. The *dorsal ascending serotonergic bundle* accompanies the fasciculus to the diencephalon (for details *see* p. 950).

The central tegmental fasciculus (of Forel), already mentioned as a feature of the medulla oblongata (p. 904), is more ventral in the midbrain, being at first lateral to the medial longitudinal fasciculus and dorsolateral to the red nucleus and the decussation of the superior cerebellar peduncles. As it descends through the pons and into the medulla it swerves further laterally to end in the inferior olivary complex of the same side (Bebin 1956). Although few of its fibres are in fact derived from the thalamus, it was sometimes called the thalamo-olivary tract. Most of its descending fibres were said to proceed from nerve cells in the central grey zone surrounding the cerebral aqueduct at the level of the superior colliculus, but fibres from the basal ganglia and red nucleus also travel in it. Through the red nucleus, ansa lenticularis (p. 965) and the lenticular nucleus, the central tegmental fasciculus mediates a pathway from the motor cortex via these structures to brainstem reticular nuclei and the inferior olivary nuclear complex.

While these earlier described constituents of the bundle are still, in the main, accepted, much additional information has accumulated in recent years. Many of its fibres have proved to be the ascending, descending (or both) longitudinal axons of neurons intrinsic to the brainstem reticular formation, their collaterals and final terminals innervating other 'reticular' or neighbouring 'specific' nuclei (p. 943). Additionally, the newer staining techniques have demonstrated that within the confines of the central tegmental fasciculus are the *dorsal* and *ventral ascending noradrenergic bundles*, the *ventral ascending serotonergic bundle*, and some, at least, of the *dorsal* and *ventral ascending cholinergic bundles* (for further details *see* pp. 948, 949, 950).

The brachium of the inferior colliculus forms a rounded strand on the lateral aspect of the upper part of the midbrain (7.107). Its fibres are derived from the inferior colliculus and from the lateral lemniscus and ascend to reach the medial geniculate body. In their course they separate the dorsolateral fibres of the medial lemniscus from the surface. Quantitative examination of the brachium by Ferraro and Minckler (1977) in 28 autopsy specimens (from individuals aged from birth to 97 years) revealed a nerve fibre density of about 68,000/mm², with little variation between left and right sides and no significant diminution until the ninth decade. The total number of fibres in an average brachium was estimated as 354,314 (right) and 346,810 (left) near the inferior colliculus, rising to 557,122 (right) and 561,359 (left) near the medial geniculate body. These total counts must be treated with some reserve, since the brachium was dissected away from the brainstem. However, the actual counting was done with great care. Ramon-Moliner and Dansereau (1974) have examined the 'peribrachial' region of the pontomesencephalic junction in detail, and have proposed an arbitrary topological division of this part of the tegmental brainstem.

THE TECTUM OF THE MIDBRAIN

Although the tectal part of the midbrain exhibits dorsal swellings from the earliest vertebrate stages, its full differentiation into superior and inferior pairs of colliculi (corpora quadrigemina) appears only in the mammals (7.90). Even in the first mammals, the prototherian monotremes, only a single pair of elevations, the *optic lobes* (corpora bigemina), can be distinguished. The optic lobes are highly developed in fishes, being actually larger than the olfactory lobes in Osteichthyes. It is interesting to note that at this and later levels of vertebrate evolution the olfactory lobes are in volume the major development of the forebrain. With the emergence of the cerebral hemisphere, i.e. a forebrain development with more than olfactory connexions, the optic lobes become relatively smaller, but remain substantial structures in amphibians, reptiles and birds. Their connexions and functions show a progressive cranial shift from reptiles through to mammals, a process called *telencephalization*. In this process the dominant position of the optic lobes, which in earlier vertebrates are probably concerned with *all* sensory modalities other than olfactory, shows a gradual diminution. This may be coupled with a decrease in the complexity of cytoarchitectonic organization in the optic lobes which is considered to reach its acme in primates, whose highly developed cerebrum has taken over much of the activity of the primitive tectum. The differentiation of the optic lobes into superior and inferior colliculi appears in the eutherian mammals, the inferior being perhaps a derivative of the optic lobes. Though it has been usual to link the superior colliculi with visual and the inferior pair with auditory behaviour, to accept this

as an *exclusive* interpretation is likely to mislead; the superior colliculi in particular appear to be concerned in other ascending afferent pathways from cutaneous receptors and perhaps in auditory connexions. The inferior colliculi are certainly interconnected with the superior; it will nevertheless be more convenient to consider them separately.

Each inferior colliculus consists internally of a central main nucleus, ovoid in form, derived embryologically from the periaqueductal grey matter, with which it preserves some degree of continuity. This nucleus is surrounded by a laminar zone of nerve fibres, many of which are from the lateral lemniscus (p. 909) and terminate in the nucleus. Small and medium-sized nerve cells, many being stellate or multipolar, predominate in the nucleus, and some of these are scattered in the nerve fibres surrounding it, particularly on its lateral and medial aspects. These are sometimes regarded as constituting a separate nuclear entity, and they almost certainly have a different origin, being continuous through scattered cells with the superficial lamina of the superior colliculus. The nuclear and neuronal organization of the inferior colliculus have been described in considerable detail in the cat (Morest 1966; Geniec and Morest 1971; Rockell and Jones 1973; Meininger and Baudrimont 1977) and to a lesser extent in man. With minor differences, there is a general agreement that the main or *central nucleus* (described above) is divisible into *dorsomedial* and *ventrolateral* parts, chiefly on the basis of neuronal characteristics. The 'laminar zone', also described above, forms a lateral peripheral feature in the cat. Disagreements persist in regard to the distribution of different sizes of neurons; Meininger and Baudrimont (1977) in the most recent analysis, carried out using careful stereological techniques but on a very small series of cats, described the dorsomedial nucleus as consisting of small neurons, those of the ventrolateral nucleus being larger. The two inferior colliculi are connected by a substantial *commissure*, which contains not only axons derived from their own cells but also lateral lemniscal fibres passing across the midline to end in the contralateral colliculus. The chief afferent pathway to the colliculi is the lateral lemniscus, whose origins have been described elsewhere (p. 909); similarly, its major contingent of efferent fibres passes through the inferior brachium to the medial geniculate body, a largely ipsilateral projection, though a crossed connexion, through the intercollicular commissure, may exist (Ades 1944). The lemniscal fibres relay only in the main collicular nucleus (Goldberg and Moore 1967). Some of them pass through without relay to reach the medial geniculate body, and similarly some of the colliculogeniculate fibres do not actually relay in the body, but pass on with those which do into the auditory radiation (p. 1074) to reach the auditory cortex (area 42). As in other sensory pathways there is a *descending* projection from the same cortical area to the inferior colliculus via the medial geniculate body, through which some may pass without relay. This descending pathway may produce effects at various levels, from the medial geniculate body onwards; it is likely that it links with efferent cochlear fibres, through the superior olivary and cochlear nuclei, as previously noted (p. 910). A tonotopical projection of the lateral lemnisci on the inferior colliculi has been described in cats; it is likely that some similar orderly arrangement extends throughout these auditory connexions, ascending and descending (*see* Auditory Cortex, p. 963 and Moore and Goldberg 1966).

Projection pathways from the inferior colliculi to the brainstem and spinal cord appear to pass first to the superior colliculi, through which connexions with the tectospinal and tectotegmental tracts are effected. These collicular projections are relatively small, and it is possible that the customary view of the inferior colliculi as reflex centres for auditory responses may require amplification. There is, however, considerable evidence that they are concerned in the ability to localize the source of sounds (Masterton *et al.* 1967).

The superior colliculus, unlike the inferior, which reaches full development only in the mammals, is generally regarded as much simplified in the higher vertebrates, and particularly so in the primates. In man, however, it still exhibits much of the complex laminar organization of earlier forms. At least six laminae have been described in the human colliculus and considerably more intricate arrangements in some other mammals (Cajal 1909–11; Angaut and Repérant 1976). In this pattern of organization the superior colliculus closely resembles the cerebellar and cerebral cortex which, indeed, it surpasses in complexity in lower vertebrates. This resemblance has prompted the view that the optic lobes, from which the superior colliculi are derived, were the first suprasegmental development of the vertebrate brain, which mediates as a summating or integrating mechanism on a much wider basis than the term optic lobe indicates. Such considerations are worthy of attention, if only as a corrective to the widely current teaching that the superior colliculus is exclusively concerned with visual activities.

The laminae of the human colliculus have been variously named, and official terms for them are not yet established. From the exterior inwards strata zonale, cinereum, opticum and lemnisci are recognized, the stratum lemnisci itself being divisible into strata griseum medium, album medium, griseum profundum and album profundum. These seven layers have also been termed zonal, superficial grey, optic, intermediate grey, deep grey, deep white and periventricular strata (Crosby *et al.* 1962). The two systems of description do not completely accord, but as a generalization the layers may be considered to be alternately composed of nerve cells or their fibres and dendrites, though some admixture occurs. For example, the most external, the *zonal layer*, consists chiefly of myelinated and non-myelinated nerve fibres derived from the occipital cortex (areas 17, 18 and 19—*see* p. 960), and arriving as the *external corticotectal tract*; but among these fibres are a few small cells, typically horizontal in arrangement. The next layer, the *superficial grey layer* (stratum cinereum) consists of numerous small multipolar interneurons, with which the cortical fibres in part form synapses, the whole mass forming a cap-shaped lamina, thicker at its centre, over the deeper layers. The *optic layer* consists partly of the fibres of the optic tract which reach the colliculus, a much diminished afferent element in higher primates; as they terminate, these fibres invade neighbouring layers with numerous collateral branches. The optic layer also contains nerve cells, some being large multipolar in type; efferent fibres to the retina are said to start in this layer in man (Wolter and Liss 1956) and other mammals. The remaining four layers are sometimes considered together as the stratum lemnisci, but will be briefly outlined here as separate strata. The next two, the *intermediate grey* and *white layers*, are collectively the main reception zone of the colliculus. As the names indicate these layers consist of nerve cells of various sizes intermixed with numerous axons and dendrites. Its main afferent source is the medial corticotectal pathway from the occipital cortex (area 18) and possibly preoccipital cortex (area 7); these areas are concerned with following movements of the eyes (p. 960). These layers also receive afferents from the spinal cord through spinotectal and spinothalamic routes, and probably from the inferior colliculus. Finally, the *deep grey* and *deep white* layers appear most deeply situated, immediately adjacent to the periaqueductal grey substance, again containing a mixture of cell types, with dendrites extending peripherally as far as the optic layer and axons forming many of the efferent connexions of the colliculus. (For recent evaluation of the literature and details of neurons of the neonatal superior colliculus consult Labrida and Laemle 1977.)

The superior colliculus thus receives *afferents* from a wide area (Wolter and Liss 1956; Meikle and Sprague 1964), including fibres from the retina, spinal cord, inferior colliculus and occipital and temporal cortex, the first three conveying visual, tactile, and probably thermal, pain and auditory impulses, the cortical projection acting as a 'command' and possibly modulating pathway. Its *efferents* pass out to the retina and to a wide array of brainstem and spinal nerve cell groups. Thus, *tecto-oculomotor* fibres project to nuclei of the ocular muscles. In the cat (Edwards and Henkel 1978) neurons in the rostral third of the superior colliculus project to the periaqueductal grey substance dorsal to the rostral third of the oculomotor complex, some also making contacts with dendrites of oculomotor neurons. Neurons of this central grey region also project to both abducent nuclei. *Tectospinal* fibres (p. 875) travel caudally to the cervical segments of the spinal cord, *tectotegmental* projections reach various

reticular masses in the tegmentum, passing also to the substantia nigra, red nucleus and probably as far as the spinal cord. *Tectopontine* fibres, which probably descend in the tectospinal tract, terminate in the dorsolateral part of the pontine nuclei, whence a relay carries this path into the cerebellum (p. 918). All these descending fibres decussate, mostly in the *dorsal tegmental decussation*, but also to a lesser extent through a commissure which unites the two superior colliculi. For a review of these connexions *see* Altman and Carpenter (1961). The tectoreticular projection has been studied in cats by Kawamura *et al.* (1974). Stereotactic lesions in the superior colliculus produced terminal degeneration in ipsilateral mesencephalic and contralateral pontomedullary reticular nuclei, namely the nucleus reticularis gigantocellularis, the nucleus reticularis pontis caudalis, the nucleus reticularis pontis oralis, and other reticular groups. The distribution of these tectoreticular projections correspond closely to those from cortical, fastigial and vestibular neurons, and thus to the main sources of reticulospinal fibres. A tecto-olivary projection, from the deeper laminae of the superior colliculus to the rostral third of the medial accessory olivary nucleus has been identified in primates (Frankfurter *et al.* 1976). The connexion is crossed and provides a link with the posterior vermis in the execution of eye movements.

The relative paucity of the retinal projection to the superior colliculus in primates throws doubt upon the validity of the commonly accepted view of it as primarily a centre for visual reflexes, though it certainly has this function in many other mammals. But while the projection of the retinal quadrants on the superior colliculi in cats and rodents has been established with a satisfactory measure of agreement, both by degenerative and stimulation techniques, attempts to extend such experiments to monkeys have been much less successful, probably because of the great reduction in the retinocollicular projection in primates. Clinical evidence merely suggests that a similar pattern of organization may exist in man, this pattern being an association of the craniomedial half of each colliculus with the inferior retinal quadrants and the caudolateral with the superior quadrants. Even the connexions to the eye muscle motor nuclei, which are held to accord with the collicular somatotopic pattern, have been put in doubt by experiments on cats, though it is suggested that these may be merely interrupted by a relay in the pretectal area. For the moment these matters must remain *sub judice*.

Much attention has been focused upon behavioural observations in experimental animals subjected to various types of damage to subcortical parts of the visual pathway in recent times (Ingle and Schneider 1969). In addition the visual projection on the optic tectum has been mapped and compared by electrophysiological techniques in a wide series of lower vertebrates from fish to mammals. In general a similar pattern of retinal representation exists in the widely different groups examined, the chief difference in mammals being the degree of ipsilateral projection. This accords with the findings with respect to the movements elicited by stimulation of different parts of the tectum. For example, central collicular stimulation produces a contralateral movement of the head, natural in character, in the cat (Hess *et al.* 1946). A considerable array of similar responses, identical with those occurring in the intact animal, have been observed in a number of experimental species, involving eyes, ears, head, trunk and limbs, suggesting that the superior colliculus is concerned in complex integrations between vision and widespread bodily activity (Schaefer and Schneider 1968). In view of the bilateral representation of the retinae in the colliculi the results of various brain splitting experiments are of special interest. Division of the tegmentum, for example, leads in cats to profound changes in visual behaviour, not so much in reflex responses as in the ability of the animal to interpret its visual environment and to adapt to it (Voneida 1965). Responses to threatening stimuli are permanently abolished, and the ability to locate edges and follow them is also lost. Similar results have been observed in the monkey. These results have something in common with the split brain syndrome in human patients (p. 967).

A descending projection from the *auditory cortex* has been described by several experimentors in various mammals, including the cat (Diamond *et al.* 1969) and monkey (Whitlock and Nauta 1956). Paula-Barbosa and Sousa-Pinto (1973) have confirmed this finding and explored the projection in greater detail in the cat. In this animal a bilateral projection from each secondary auditory area (AII) reaches the superficial laminae of each superior colliculus. No such projection was found to occur from the primary auditory area (AI). Although the projection is derived from parts of the auditory cortex which do not have, as far as is known, any visual connexions, it is suggested that this corticocollicular pathway may be involved, together with known connexions between the superior and inferior colliculi, in complex integrations between visual and auditory behaviour.

The pretectal nucleus is a somewhat indistinctly demarcated mass of nerve cells in the pretectal area, at the junction of the mesencephalon and diencephalon. It extends from a position dorsolateral to the posterior commissure towards the superior colliculus, with which it is in part continuous. It receives fibres through the superior brachium from the occipital and preoccipital cortex and from the lateral root of the optic tract (*see* Kuhlenbeck and Miller 1949; and p. 975). Its efferent fibres pass to both accessory oculomotor nuclei (of Edinger-Westphal)—*see* Ranson and Magoun (1933). Those which decussate pass ventral to the aqueduct or through the posterior commissure. By the autonomic outflow from these nuclei, with a relay in the ciliary ganglia (p. 999), the sphincter muscles of the iris in *both* eyes are made to contract in response to impulses from either (7.108). This light reflex appears to be the only activity mediated by the pretectal nucleus, but some of its efferent axons are said to enter the tectobulbar and tectospinal tracts. The significance of the descending cortical projection is not yet established.

EXTRAGENICULATE VISUAL PATHWAYS

As a corrective and extension to the above account it is apposite to refer briefly to the volume of literature which has accumulated in regard to the visual pathways in mammals (e.g. Jones 1974) and particularly birds (reviewed *in extenso* by Webster 1974). It is almost a dictum of comparative neuroanatomy that the vertebrate visual system was primarily mesencephalic in its connexions. The concept of 'telencephalization' has also long been established as a part of a greater process of 'encephalization', the evolutionary forward or cranial migration of 'centres' intermediating sensorimotor activities from spinal to *encephalic* levels. The intrusion of visual projections into the *telencephalon* via the thalamus in mammals with a volumetric reduction in *mesencephalic* visual arrangements, has been and still is frequently cited as a major example of *telencephalization*. Moreover, the change is often regarded as in some respects more advanced in mammals, especially primates, than in birds. Compared with the mammalian condition the avian colliculi, or optic lobes, are indeed relatively larger and more complex in their laminar pattern, and, furthermore, the avian corpus striatum is more highly developed than its superincumbent cortex, proportions which appear to be reversed in the mammalian cerebral hemisphere. The generalizations thus engendered have tended towards assigning the avian and mammalian visual systems to opposite balances in a supposed *duality of pathways*—a mesencephalic level vaguely regarded as 'reflex' and a telencephalic level loosely labelled as 'perceptual'. This is oversimplification. Much relatively recent work on avian visual neuroanatomy and physiology has shown that both visual pathways, whether passing through the midbrain tectum or direct to the dorsolateral thalamus, involve thalamic and cortical projection, as well as striatal connexions. In mammals both these and other pathways exist, in particular a pretectal route (in addition to the tectal superior collicular path) via the pulvinar of the thalamus to the occipital cortex. Physiological and behavioural studies have also demonstrated that it is misleading to consider the two, 'major' visual pathways, either in birds or mammals, as being in one case perceptual and the other reflexive. In both vertebrate classes there is evidence that the mesencephalic level is involved in processes of perception, and is not merely at a level of intrinsic and extrinsic ocular musculature reflexes. For example, in the avian brain neurons of the tecto-striate projection exhibit responses not only to movement but also to colour, though

not to shape or orientation. In contrast, the more direct route through the thalamus to the cortical region known as the '*wulst*' in birds (the equivalent of the mammalian geniculostriate pathway) has so far not been shown, by unit recording, to evince any special sensitivities, except perhaps to movement. In mammals, including mankind, perhaps even more than in birds, the complexity of the inflow paths of visual information, and the multiplicity of their lateral and descending interconnexions, provide a 'system' of intricate projection and 'feed-back' which at present defies analysis. Despite a great accumulation of data regarding, in particular, the response peculiarities of individual neurons at every level, it is becoming more difficult, rather than easier, to ascribe different aspects of visual information to identifiable neuronal aggregations, and perhaps it is inherently misleading to seek to do so. Even in man, clinical evidence in cases of injury to the visual cortex suggests that the customary ascription of 'conscious' vision to cortical levels may be an obfuscation of the intimate interaction between various parts of the occipital cortex with the tectum and pretectum of the midbrain. Although it is not possible at present to effect a functional synthesis from the mass of structural and physiological findings available, it seems clear that visual function involves very widespread networks of neurons at all levels of the brain.

The cerebral aqueduct is a narrow canal, about 15 mm long, connecting the third with the fourth ventricle. (Since it is in the midbrain, and certainly does not conduct fluid *to* the cerebrum, it is misnamed.) Its form, as seen in transverse sections, varies at different levels, being T-shaped below, triangular above, and oval in the middle, at which level it is slightly dilated (Flyger and Hjelmquist 1957). It is lined with ependyma which is surrounded by a layer of grey matter named the *central grey*; the latter is continuous below with the grey matter in the floor of the fourth ventricle, and above with that of the third ventricle. Remains of the sulcus limitans, apparent on each lateral wall in embryonic development, may persist. Dorsally the aqueduct is partly separated from the grey matter of the colliculi by the fibres of the stratum lemnisci; ventral to it are the medial longitudinal fasciculi, and the reticular formation of the midbrain. Scattered throughout the central grey matter are numerous nerve cells of various sizes, interlaced by a network of fine fibres. Besides these scattered cells it contains three groups, which constitute the nucleus of the mesencephalic tract of the trigeminal nerve and the nuclei of the oculomotor and trochlear nerves.

THE RETICULAR FORMATION

It has long been recognized that scattered amongst the more conspicuous fibre bundles and nuclei of the brainstem are extensive fields of intermingled grey and white matter collectively termed the **reticular formation**. Throughout the present section of this volume there are numerous references, some brief and some in greater detail, to the supposed distribution, connexions and possible functions of various parts of this 'system'. When appropriate, reference should be made to these accounts, and to the detailed reviews which have appeared. *See*, for example Moruzzi and Magoun (1949); Meessen and Olszewski (1949); Olszewski (1954); Olszewski and Baxter (1954); Brodal (1957); Jasper *et al.* (1958); Taber (1961); Valverde (1961 *a* and *b*, 1962); Ramón-Moliner and Nauta (1966); Horridge (1968); Brazier (1969); Scheibel and Scheibel (1970); Webster (1978).

GENERAL CONSIDERATIONS

A strict scientific definition of the criteria to be used when designating a particular region of the nervous system as 'reticular' or not has proved impossible to achieve. Simple inspection of sections of the vertebrate nervous system prepared by the usual neuroanatomical methods, however, allows some measure of distinction. Many areas consist of either predominantly grey or white matter (p. 810) and their contained neurons or fibre bundles have definite and recognizable quantitative cytological variations which are polarized with respect to the three principal planes of the body. Thus, many regions of white matter contain fibre bundles with a characteristic fibre diameter spectrum, and a definable direction, either longitudinal, transverse, oblique or curved, which carries them between a series of more or less well-defined origins and destinations. Similarly, many areas of grey matter contain populations of neurons with their somata, axon collaterals, dendritic trees and synapses organized into fairly precise three-dimensional arrays; further, depending upon the criteria used, they appear to possess fairly distinct 'boundaries'. These constitute the main nuclei, cortical formations and fibre tracts of the nervous system. Obvious examples are the well-defined cell columns or laminae in the dorsal and ventral appendages of the spinal cord (p. 869) and their homologues in the brainstem, many other brainstem, diencephalic and telencephalic nuclei, the cerebral and cerebellar cortices, the tectum, and the named tracts of white matter throughout the nervous system, the majority of which are described individually in the present section. Between these geometrically organized *non-reticular* nuclei and tracts are found areas where the grey and white matter is admixed, the fibre bundles interlace in many directions, and the scattered neurons have diffuse, ill-defined patterns of connectivity (*vide infra*); these constitute the *reticular regions* of the nervous system. However, although many authorities agree concerning the geometric organization and non-reticular nature of the majority of the main nuclei and tracts, the status of a number of regions remains unclarified, and the following points should be noted.

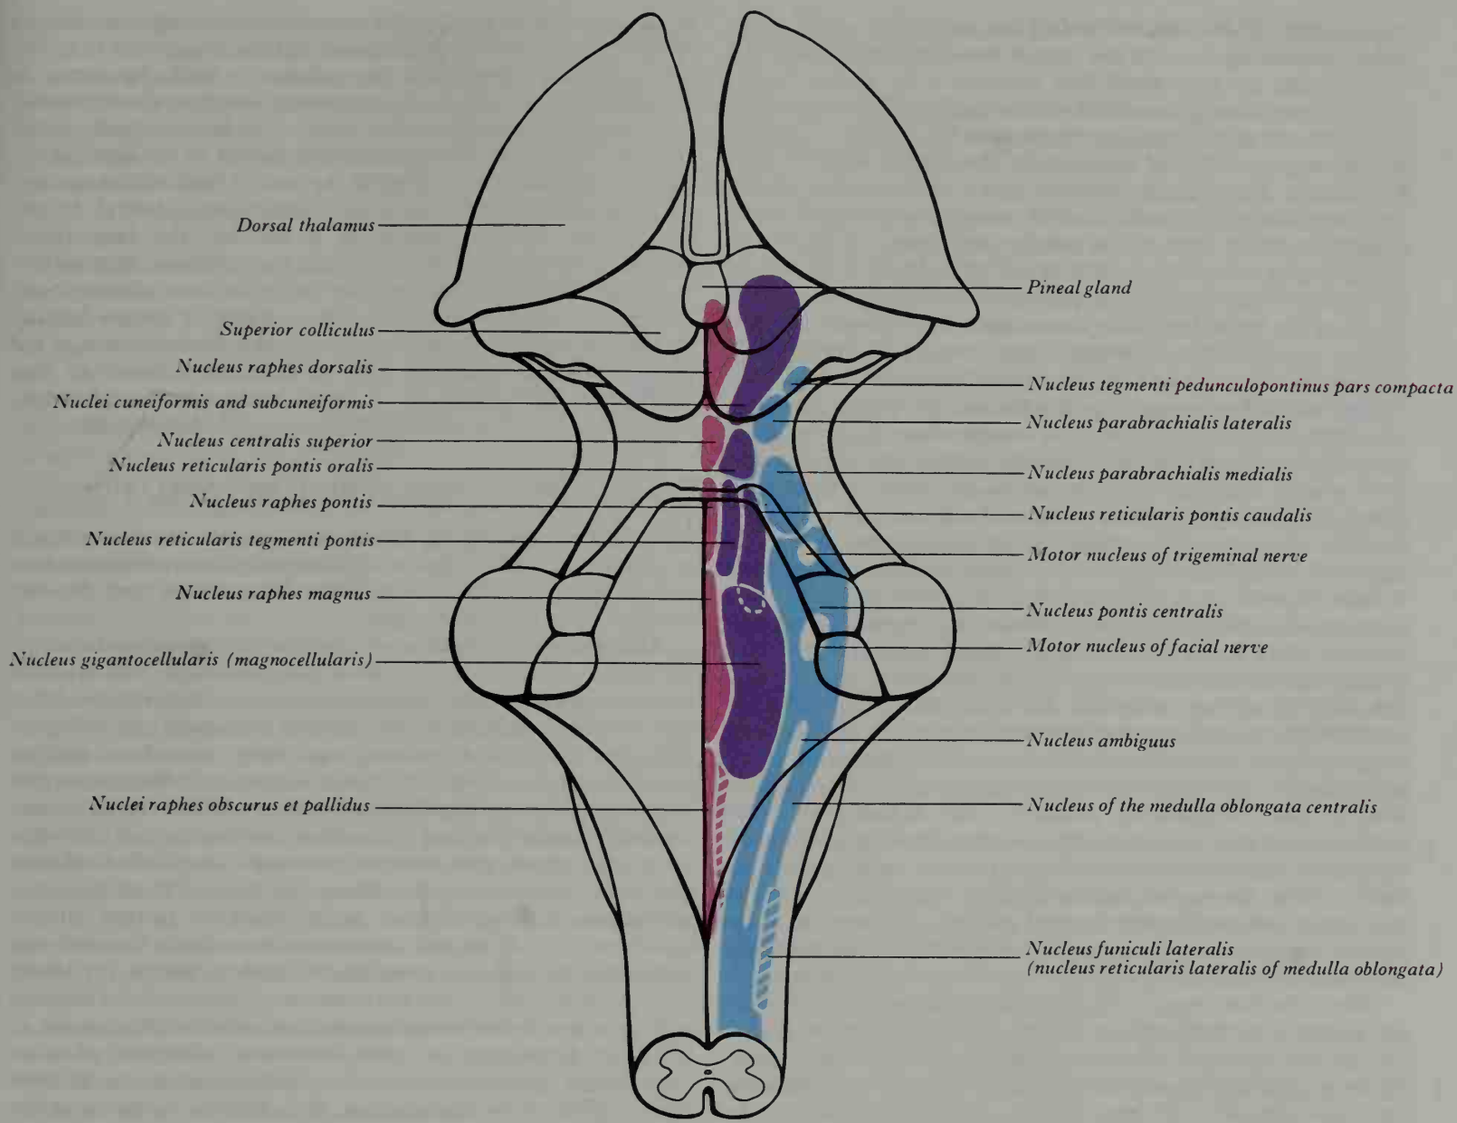
The structural extremes of a mathematically precise, repeating geometric organization on the one hand, and a truly random nerve network on the other, are abstractions which do not exist in nervous systems. Even the highly regular cerebellar cortex shows considerable quantitative variation in different regions when examined critically (p. 925), and the most 'reticular' parts of the nervous system show some regionally distinctive structural features. Thus, a graded range of levels of structural organization exists and, inevitably, those with a more diffuse structure prove the more difficult to investigate. For this reason, coupled with the fact that detailed knowledge of the quantitative aspects of neuronal morphology and connexions is still in its infancy, many authorities have expressed divergent views about which regions of the nervous system should be embraced by the term *the reticular formation*. Most are agreed about the inclusion of certain deeply placed parts of the medulla, pons and midbrain (*vide infra*), and some would restrict the use of the term to these regions. The status of other cell groups in these parts of the nervous system such as the olivary complex, the parvocellular part of the red nucleus, the pars reticularis of the substantia nigra, the nucleus of the posterior commissure, the interstitial nucleus, the intracerebellar nuclei and others, is uncertain, being included by some and excluded by others. Further disagreement reigns concerning the inclusion of the central regions of grey matter of the spinal cord which have been termed a 'reticular core' by some investigators (p. 894), and whether the non-specific nuclei of the thalamus (p. 960) and certain hypothalamic nuclei should be included. These terminological debates merely serve to emphasize the undesirable nature of rigidly categorizing some centres as reticular or non-reticular, and the need for further researches, in the light of which the necessity for such crude parcellations of the nervous system will gradually recede.

No attempt will be made in the present account to draw precise boundaries between such areas, but it should be appreciated that *all* levels of the neuraxis, including the spinal cord, brainstem and diencephalon, have regions with a relatively high level of ordered

structure, which are *interlocked* both structurally and functionally with neighbouring reticular regions where the organization is much more diffuse.

The more obviously reticular regions of the nervous system are often regarded as phylogenetically ancient, representing a supposed 'random nerve network' of early ancestors, upon which background, during subsequent evolution, the more circumscribed, highly organized, discriminative parts of the nervous system have appeared. But, as pointed out elsewhere (p. 808), even the most primitive known nervous systems possess both diffuse and more highly organized regions, which cooperate in their responses to different environmental stimuli. It is undoubtedly preferable to regard *both* these elements as evolving together, each providing *indispensable* and *interdependent* contributions to the total response patterns of the organism.

THE RETICULAR PARTS OF THE NERVOUS SYSTEM



In general terms, the reticular parts of the nervous system consist of: (1) deeply placed, rather poorly defined groups of neurons and fibres with diffuse patterns of connexions; (2) the conduction paths through these regions are difficult and often impossible to define anatomically, but physiological evidence indicates that they are complex and often *polysynaptic*; (3) both *ascending* and *descending* components can be recognized; (4) stimulation of a locus on one side often elicits responses both on the ipsilateral and the contralateral side, i.e. both the ascending and descending systems contain *crossed* and *uncrossed* elements; (5) they mediate both *somatic* and *visceral* functions.

While the earlier investigators discerned little structural variation in different regions, and simply dubbed all regions, other than the long-recognized 'specific' named nuclei and tracts as reticular, more recently, a series of critical studies have emphasized that zonal variations in structure (and presumably 'functional' associations) are present in these reticular areas. These include differences in cell size, number, packing density, geometry of neurites, cytochemistry including putative neurotransmitter production, and in some measure, differences in their connexions. On such bases (and therefore largely dependent upon the technique employed) a series of *reticular nuclei* have been named by some authors in a variety of animals. However, the 'borders' of such nuclei are often defined with difficulty, their dendritic fields interweave over wide areas, and interspecific variation exists, as does the map yielded by different techniques and the employment of different criteria. Thus, the results of electrophysiological or pharmacological exploration, and focal stimulation or ablation of different regions must be subject to the most severe critical interpretive scrutiny; even greater caution is necessary before ascribing functional roles to particular reticular zones or nuclei. The complex geometry of reticular neurons and their neurites has, in the main, been pursued by means of Golgi metallic impregnation techniques, and the latter, in combination with cytoarchitectonic examination of the form and distribution of cell somata, have led to the basic terminologies for reticular zones and nuclei proposed by different groups of workers. The smaller subdivisions, details, and variations cannot be pursued here and for these the references quoted should be consulted; however, some general features, a simplified but useful plan, and brief allusions to overall connectivity and histochemical analyses are given below.

Studies with the Golgi technique (*see* especially Ramón-Moliner and Nauta 1966; Horridge 1968; Brazier 1969; Scheibel and Scheibel 1967, 1970) have shown that in the brainstem few of the reticular neurons are of the classical Golgi type II with short axons which branch locally (*vide infra*). Their dendritic trees are in general spread at right angles to the long axis of the brainstem forming transversely orientated flattened sheets. In the majority of instances the dendrites are long, with a relatively simple branching pattern that has been likened to 'the spokes of a rimless wheel' and classified as the *isodendritic configuration* by Ramón-Moliner and Nauta (1966): they were described as forming an *isodendritic core* for the brainstem, the territory of which encompasses many of the less well-defined, 'diffusely' connected reticular nuclei. Their radiating dendrites may cover up to 50 per cent of the transverse sectional profile of that half of the brainstem in which the neuron lies, and the dendritic trees are intersected sequentially by, and synapse with, the complex aggregation of ascending and descending fibre bundles that constitute the *central tegmental fasciculus of Forel*. The latter includes components from many sources, one prominent one being the axons of large numbers of reticular neurons themselves: thus, the main stem of a reticular axon usually pursues a longitudinal course, either ascending, descending, or bifurcating to pass in both directions, and in so doing traversing considerable lengths, perhaps the whole, of the length of the brainstem and even beyond these confines. As an extreme example, a reticular neuron of the magnocellular medullary nucleus (*vide infra*) may generate an axon which bifurcates, its ascending component passing through the upper medulla, pons, midbrain tegmentum, thence proceeding to subthalamic, hypothalamic or dorsal thalamic centres in the diencephalon; its descending component traverses the reticular core of the lower medulla and may then continue into the intermediate grisea (laminae V and VI) of the cervical spinal cord. Many reticular neurons may, of course, have unidirectional and considerably shorter axons than the extreme example just described. During their longitudinal course such axons synapse with the radiating dendrites of innumerable other reticular neurons *en route* and also give off a series of collaterals that approach, enter and synapse with cells in neighbouring 'specific' brainstem nuclei or cortical formations such as that of the cerebellum. It is clear, therefore, that the multiple sources of afferent fibres that converge on individual reticular neurons and the myriads of synapses and profusion of destinations of their outflowing axons provide the structural basis for the polymodal responses frequently elicited during physiological investigation, and also the reason for the generation of such terms as 'diffuse' and 'non-specific'. Equally, such arrangements pose perplexing questions for the investigative neurologist and currently it is certainly unwise, and intellectually misleading, to attempt to attach unitary or even complex functional/behavioural labels to individual neurons or small aggregations of neurons; obviously there are myriad opportunities for convergence and divergence of information paths in such a system as the reticular core.

A contrasting type of dendritic pattern is termed the *idiodendritic configuration* in which the profusely branched dendrites are short, highly sinuous or curved, and so arranged that they pursue a re-entrant course at the periphery of a nuclear group, providing a rather precise boundary between the nucleus and surrounding neural tissue. Such neurons characterize many cranial nerve nuclei, pontine nuclei (in the basilar pons), the olivary complexes, nuclei of the 'specific' sensory pathways, the nucleus funiculi lateralis (the so-called lateral 'reticular' nucleus) of the medulla, and a complex of midbrain tegmental nuclei (of Gudden). Neurons with an intermediate degree of complexity of dendritic pattern are found within and around such nuclei, and with varying densities throughout much of the remainder of the reticular formation—these have been termed *allodendritic*: further, in different zones the proportion of neurons with somata of different sizes varies greatly, some regions consisting exclusively of small to intermediate sized multipolar cells (the *parvocellular* regions), while in certain restricted localities these are intermixed with extremely large multipolar neurons—the '*gigantocellular*' or '*magnocellular*' nuclei.

In *general terms*, therefore, the reticular formation has been described as consisting of a continuous isodendritic core which traverses the whole of the medullary, pontine and midbrain brainstem, is continuous caudally with the reticular intermediate grey laminae of the spinal cord, and cranially merges into the subthalamus and parts of the hypothalamus and dorsal thalamus. Either bordering, partially encompassed by, or completely embedded within the core are numerous more easily defined, circumscribed nuclei, only a small proportion of which are considered to merit the name reticular (for discussion and details *see* Leontovich and Zhukova 1963; Ramón-Moliner and Nauta 1966). On such a view the reticular formation may be regarded as consisting of a 'diffuse network' roughly divisible into *three longitudinal columns*, the first consisting of neurons occupying the median plane and a narrow immediately adjacent paramedian

7.95 An outline of the human brainstem (*black*) extending from the caudal end of the medulla to the dorsal thalami: note the margins of the rhomboid fossa, the lateral angles of which indicate the pontomedullary junction; note also the profiles of the transected surfaces of the cerebellar peduncles, the colliculi and pineal gland. The principal nuclear derivatives of the brainstem reticular formation are indicated in approximate outline, those from the median and paramedian nuclear column are in *magenta*; medial column derivatives in *purple*; lateral column derivative in *blue*. In reality, of course, considerable overlap of the nuclear profiles would be present when the third dimension is considered. A number of 'non-reticular' nuclei are also included.

zone, the second or medial column containing the majority of the large reticular neurons, and the third or lateral column containing predominantly small to intermediate neurons. Regional localization is conferred on the system solely by the (overlapping) zones of termination of afferents (*vide infra*) and sources of efferents for their multiple destinations. A further corollary of this view is that unitary functional localization of individual neurons, small neuronal groups, named reticular nuclei, or groups of nuclei is absent, the 'system' largely operating as a whole, enhancing or depressing the 'general background activity' of all the major elements of the central nervous system. (For a stimulating discussion of these and alternative views of the reticular elements of the brain consult Webster 1978.)

In contrast to the foregoing, the parcellation of the reticular formation into named nuclei on cytoarchitectonic grounds was pursued vigorously by a number of observers; perhaps the most devoted exponent of this approach being Olszewski who described over 40 such nuclei in the mammalian brainstem (*see* Olszewski and Baxter 1954; also consult Brodal 1957). Whilst such subdivisions are undoubtedly useful for the experimental neurologist, only a limited number have specific and well-authenticated patterns of connectivity and for the reasons implied above their individual functional significance is obscure.

It would be quite inappropriate to attempt any detailed listing and description, be it concerned with cytoarchitectonics and neurite geometry, overall three-dimensional topography, or what little is known of individual connectivity, of this plethora of named nuclei, in a volume such as this. What follows is the briefest summary of the names of the principal columns and nuclear groups (based on traditional neuroanatomical techniques) accompanied by a diagram of their approximate territories (7.95) as viewed from the dorsal aspect of the brainstem. The reader will also appreciate that their positional relationships can only be studied in a closely spaced, and therefore numerically large, specialized, series of transverse sections: they have therefore not been included *in extenso* in the relatively elementary account of brainstem anatomy attempted in the preceding pages—for such details consult, for example, Olszewski and Baxter (1954); Brodal (1957); Jasper *et al.* (1978); Ungerstedt (1971); Nieuwenhuys *et al.* (1978).

The median column of reticular nuclei extends throughout the medulla, pons and midbrain, and their cell somata are, in the main, aggregated in bilateral, narrow, vertical sheets that blend in the median plane and occupy the immediately adjacent

paramedian zone: collectively they are called the *nuclei of the raphe*. Extending through the cranial two-thirds of the medulla and crossing the pontomedullary junction is the *nucleus raphes obscurus* (and closely associated *nucleus raphes pallidus*): partially overlapping the latter and continuing into the pons is the *nucleus raphes magnus*, followed cranially by the *nucleus raphes pontis*. Continuing from upper pontine levels towards the caudal mesencephalon is the *nucleus raphes centralis superior*, and finally expanding at the level of the inferior colliculus and ultimately narrowing to extinction at superior collicular levels is the *nucleus raphes dorsalis* (*rostralis*). A proportion of neurons making up the nuclei of the raphe have been demonstrated to be *monoaminergic* (more specifically *serotonergic*) and some of their better authenticated connexions will be mentioned below.

The medial column of reticular nuclei whilst consisting throughout of a background of intermediate-sized reticular neurons, in some regions possesses the largest neurons found in such nuclei; the great majority are isodendritic in form (*vide supra*). In the caudal medulla the medial column is indistinct but possibly represented by a thin lamina of cells near the lateral aspect of the rapheal nuclei; in the cranial medulla, however, the column expands into a prominent nuclear mass of extremely large neurons, the *medullary gigantocellular* (*magnocellular*) *nucleus* situated lateral to the rapheal nuclei, ventrolateral and ventral to the hypoglossal and dorsal vagal nuclei respectively, and dorsal to the inferior olivary complex. Crossing the pontomedullary junction the cell column continues as the *pontine gigantocellular* (*magnocellular*) *nucleus* situated in the medial tegmentum; quite abruptly the constituent neurons diminish in the size of their somata and, progressing cranially, the systematists have distinguished first the practically co-extensive *nucleus reticularis tegmenti pontis* and the *nucleus reticularis pontis caudalis*; these are succeeded by the *nucleus reticularis pontis oralis*. From the latter the medial column expands into the midbrain tegmentum as the *nucleus cuneiformis* and *nucleus subcuneiformis* which gradually become less distinct as cranial midbrain levels are approached.

Other nuclear masses which some authorities classify as associated with the foregoing column derivatives are the *nucleus ceruleus* (p. 933) and *subceruleus* which cross the pontomesencephalic junction beyond the confines of the locus of the same name (p. 933); near the same junction and closely related to the mesencephalic dorsal and medial longitudinal fasciculi are the *dorsal* and *deep tegmental nuclei* (of Gudden) together with numerous aggregates of neurons in the *mesencephalic periaqueductal grey matter*.

The lateral column of reticular nuclei is almost exclusively formed of well-dispersed *small* neurons and hence many authorities simply term it the *parvocellular reticular column* or *zone*, and its derivatives the *parvocellular 'nuclei'*; in the main, its neurons are of the allodendritic or idiodendritic form (*vide supra*). The column extends throughout the length of the brainstem and forms a rather poorly differentiated 'background' with few systematically named, discernible 'reticular' nuclei; partially embedded or totally enclosed within this background, however, are a series of well-defined 'specific' nuclei which many authorities prefer to exclude from the reticular formation. (In some cases, however, the distinction, as intimated above, appears to be based on quite arbitrary criteria.)

Extending through the caudal two thirds of the lateral part of the pontine tegmentum and upper medulla, the lateral column skirts the lateral aspect of the gigantocellular nucleus and lies medial to the sensory trigeminal nuclei; continuing caudally the column expands to form most of the reticular formation lateral to the rapheal nuclei, and then continues, to blend with the intermediate grey laminae of the cervical spinal cord. In the medullary part it is sometimes considered to constitute a *central medullary reticular nucleus* and a *ventral medullary reticular nucleus*: these are confluent and enclose the distinctive nucleus ambiguus (pp. 905, 1074), whilst bordering them laterally is the *nucleus of the lateral funiculus*—often, despite its cytoarchitecture the latter is named the *lateral medullary reticular nucleus*. Similarly, the *nucleus of the anterior funiculus* is also often called the *medullary nucleus reticularis paramedianus*. The *pontine parvocellular column* or *nucleus* embraces the motor nuclei of the facial and trigeminal cranial nerves; continuing cranially to approach and cross the pontomesencephalic junction to enter the mesencephalic tegmentum the column is held, by some, to differentiate into two large, somewhat inappropriately named *lateral* and *medial parabrachial nuclei*. The lateral column of the reticular formation is not prominent cranial to the level of the inferior colliculi where, beyond the rostral limit of the nucleus parabrachialis lateralis is found, immediately lateral to the decussating superior cerebellar peduncles, the large-celled *nucleus tegmentalis pedunculopontinus, pars compacta*; beyond this at the inter-collicular and superior collicular level, the parvocellular *pars dissipata* of the latter nucleus gradually merges into the cranially extending nuclei cuneiformis et subcuneiformis of the medial reticular column. The small-celled product of this confluence then continues to blend with many subthalamic, hypothalamic and dorsal thalamic nuclei and fibre systems.

CONNEXIONS OF THE RETICULAR FORMATION

The majority of these, based on classical neuroanatomical techniques, have been described elsewhere in the present section and will only be listed here. (For more recent and detailed analyses, *see* subsequent pages.)

Afferent projections reach the reticular formation from: (1) the spinal cord via the *spinoreticular pathways*, and also via *collateral branches* of the *long ascending tracts*, although the latter may not be as profuse as was thought previously; (2) collateral branches from some primary, and many secondary, afferent neurons associated with the *cranial nerves*, including the central *vestibular* and *acoustic* pathways; (3) the *cerebellum* via the various *cerebelloreticular pathways* described previously; (4) indirectly from the *visual* and *acoustic* pathways, and other afferent channels, via *tectoreticular fibres*; (5) from various *thalamic*, *subthalamic* and *hypothalamic nuclei*, which are further detailed elsewhere; (6) from the *corpus striatum*, both directly and indirectly through its complex of outflow paths; (7) direct *corticoreticular fibres* from the *sensorimotor regions* of the cerebral cortex, with smaller contributions from other cortical areas; an unknown proportion of such fibres are collaterals of other corticofugal systems such as the corticospinal tract; (8) from various parts of the *limbic system*, including the *septal areas*, the *amygdaloid nuclei* and the *hippocampus* through a variety of descending pathways.

Thus, many different afferent pathways converge upon the reticular formation, and although there is some evidence for a degree of zonal localization in the levels of termination of diverse afferents, there is also abundant evidence for much overlap and convergence of different channels. Unit recording with intracellular microelectrodes has provided much information that supports this view. Single units have been studied in experimental animals during multimodal forms of stimulation of cutaneous receptors and proprioceptors in many parts of the body, and during stimulation of a wide variety of peripheral nerves, the special sense organs, and diverse parts of the central nervous system including the spinal cord, the cerebral and cerebellar cortices, the hippocampus, corpus striatum, etc. For example, units are found which respond solely to nociceptive stimuli applied to different body regions; others respond to a wide range of cutaneous stimuli, again from extensive bilateral receptive fields; yet others respond to stimulation of many different regions of the cerebral cortex, and so forth. Further, individual units can be identified which respond to the stimulation of a number of different types of afferent channel, e.g. visual, acoustic, cortical, cerebellar, etc. These different afferent channels also interact in various ways, some with mutual enhancement, others with mutual inhibition. Although the different levels of the reticular formation are not all equivalent in terms of their input and output, there is still a high degree of convergence of afferent channels, and a profusion of interconnexion between its neurons. The question of how such a bewilderingly complex and fluctuating array of information channels is used to direct cooperative responses, remains one of the central and most intractable problems in neurology (Klimer *et al.* 1968; Webster 1978).

The efferent connexions of the reticular formation are: (1) to

the autonomic and locomotor control centres, and interneuronal pools of the *spinal cord* via the *reticulospinal tracts*; (2) by short descending pathways to similar centres in the *brainstem*; (3) to the *cerebellum*; (4) to the *red nucleus*, *substantia nigra* and *tectum* of the midbrain; (5) to numerous nuclei in the *subthalamus*, *thalamus* and *hypothalamus*; (6) indirectly, through radiations of the latter diencephalic nuclei, to the corpus striatum and to the cerebral cortex, including most regions of the neocortex and many areas of the limbic system.

Further comments on reticular connectivity. It has already been noted that the majority of neurons forming the *medial reticular column* nuclei together with many *rapheal nuclear neurons* are of isodendritic form (*vide supra*) with radiating, spoke-like, flattened, extensive dendritic trees which are intersected at right angles (i.e. longitudinally) by innumerable ascending and descending fibres which synapse with successive neurons. Their dendrites also receive inputs from ascending spinoreticular fibres (*vide infra*), from cranial nerve sensory nuclei, cerebellar (particularly fastigial) efferents, descending fibres from the limbic forebrain complex and hypothalamus, the neocortex, tectal fibres, and medially directed axons from a proportion of the lateral column parvocellular nuclei. The ascending, descending, or bifurcating axons and their collaterals, of these isodendritic neurons may remain intrinsic to the reticular system completing local reflex loops or acting as intermediaries in longitudinal polysynaptic chains, whilst others project to spinal centres, neighbouring brainstem centres, or ascend to the forebrain, that is, they are the source of the majority of the outflow channels to the more distant destinations. In contrast the allodendritic and idiodendritic neurons of the parvocellular lateral zone nuclei appear to be mainly in receipt of inputs from sensory cranial nerve nuclei and collaterals from corticoreticular fibres of neocortical origin. Some of their axons pass medially presumably modulating medial column nuclear activity, but the majority surround, interlace and synapse with, brainstem cranial nerve motor nuclei thereby completing reflex loops or mediating corticonuclear control.

As examples of zonal or nuclear variations of activity in the reticular formation we may summarize the components assumed to form part of the so-called ascending activating system and also some reticular nuclei with well-defined connexions. The *ascending activating system* (further described below) is widely held to be the structural substrate for the *arousal reaction* and *desynchronization* of the electroencephalogram, prerequisites for wakening, attention, and 'specific' cortical activities (p. 952). It comprises (*a*) spinoreticular inputs, (*b*) collaterals from other long ascending pathways, (*c*) cranial nerve sensory nuclear inputs, (*d*) reticulo-diencephalic projections, and (*e*) hypothalamo-limbic and diffuse 'non-specific' thalamo-cortical radiations; probably the thalamo-striate and pallido-thalamic loop should also be included. The majority of these connexions are considered elsewhere in this section and only a few points will be emphasized here. The spinoreticular projections reach most parts of the medial reticular column nuclei, but at many levels their terminals are sparse, rich populations of terminals being restricted to the medullary gigantocellular (magnocellular) nucleus, the oral part of the central medullary reticular nucleus and the nucleus reticularis pontis caudalis. Similar nuclear zones receive the majority of the terminals from the pontomedullary trigeminal sensory nuclei and the nucleus of the tractus solitarius. In contrast the vestibulocochlear and retinotectal inputs are concentrated on the mesencephalic reticular nuclei. The origins of the reticulo-spinal tracts and some of the constituent bundles that effect reticulo-diencephalic connexions are considered further on pp. 875, 879, 893, but in general they broadly correspond to the inputs just described.

Certain reticular nuclei have relatively precise boundaries and (doubtless amongst many others) well defined afferent or efferent projections. Thus, for example, the 'lateral reticular nucleus', magnocellular nucleus, and nucleus reticularis paramedianus, all medullary aggregates, and the nucleus reticularis tegmenti pontis all have profuse and precise cerebellar connexions. The nucleus ceruleus is described on p. 933; the nucleus tegmenti pedunculo-pontinus, pars compacta receives a discrete pallidofugal input.

COMPARTMENTALIZATION OF THE RETICULAR FORMATION

In the preceding pages it will have become apparent that different investigators using widely varying techniques as these become available, have found it appropriate to compartmentalize the reticular formation in a number of contrasting ways, each having its own limited usefulness. These have ranged from:

(1) Considering the formation as a diffuse, 'non-specific', virtually *random nerve network*, with multiple inputs and outputs, polymodal interaction between neurons, and the view that the 'system' should be treated as a whole, with perhaps the application of 'network theory' combined with computer analysis (Scheibel and Scheibel 1967).

(2) The concept of the formation as consisting of a central isodendritic core extending from spinal cord to diencephalon and surrounded by, or surrounding, 'islands' of allodendritic and idiodendritic neurons and their 'specific' nuclei.

(3) The view that the formation, essentially bilateral but with numerous cross-connexions, consists on each side of three longitudinal columns, 'median', 'medial', and 'lateral', each with its characteristic varieties of neuron.

(4) The extreme parcellation of the foregoing columns into named nuclei using traditional cytoarchitectonic techniques.

(5) Attempts to locate columnar 'zones', individual nuclei or parts thereof, as the sites of termination of definable bundles of afferent fibres, or the sources of recognizable efferent bundles with distinct destinations: these have been pursued with the older degeneration techniques (p. 815) and the more recent fibre tracing methods (p. 819).

(6) Efforts to analyse the results of micro-electrophysiological recording, and the structural and behavioural effects of micro-stimulation or ablation of these zones or nuclei. Such manoeuvres often result in dramatic focal effects, the nodal point often being termed a 'centre' by neurophysiologists. However, much coincidence or overlap is often present and the relation to named nuclei has not been established.

(7) More recently it has become fashionable to consider the formation 'to be a collection of more or less specific neuron populations, but populations that are to a large extent mixed together rather than separated into spatially isolated groups' (*see* review by Webster 1978): the criteria employed entails the use of techniques that allow the mapping of the distribution of groups of neurons that produce a common neurotransmitter substance (*see* p. 832). Thus, terms such as '*the cholinergic nervous system*', and '*the aminergic nervous system*', and its variations, are being employed with ever-increasing frequency.

With regard to the latter approach it is, however, essential to appreciate certain general points. Quite a large, and increasing number of substances are being proposed as putative neurotransmitters (*vide infra* and p. 831), but as yet only a limited number have met all the rigid criteria that allow them to be firmly classed as such—whilst some may be true transmitters, others may be precursors or metabolic products of transmitters. When a reasonably complete list of undoubted transmitters becomes available, together with sensitive histochemical or other means for the demonstration of their spatial and quantitative distribution, it is obvious that each will yield its own distinctive 'map'. Doubtless much overlap and interlacement, particularly of neurites, will be present. Furthermore, in any complex neural aggregate, individual neurons will in most instances receive synaptic terminals from several varieties of neuron each producing its characteristic transmitter, the responses of the neurons' receptor sites also being neuron specific. Thus, the intellectual problem arises as to what extent it is valid to group all the neuron aggregates that possess a common neurotransmitter as a 'system'. Certainly cooperative behavioural responses in the intact normal organism result from complex, balanced interactions between many such systems. Equally, however, *disordered* or *modified* behaviour often results from the pathological, experimental, or pharmacologically induced over- or under-activity of a particular transmitter. The most precise localizing histochemical techniques yet available relate to the biogenic amines (*vide infra*) and they have therefore become favourite objects of study; the

distribution of cholinergic neurons, and those containing other putative transmitters is less certain.

THE CHOLINERGIC RETICULAR SYSTEM

Despite the elegance of the early researches and innumerable subsequent investigations that firmly established acetylcholine as a neurotransmitter, the spatial distribution of cholinergic neurons throughout the nervous system has proved a much less tractable problem (*see* for example, the excellent reviews by Shute and Lewis 1967; and De Feudis 1974). Nevertheless, the latter author felt that sufficient biochemical, pharmacological, structural and behavioural evidence had accumulated to write a monograph entitled *Central Cholinergic Systems and Behaviour*. Standard techniques for the localization of acetylcholinesterase have long been employed (Koelle and Friedenwald 1949) and this substance is widespread in the nervous system; however, its presence is not necessarily an indication of the presence of cholinergic neurons since it is often abundant in tissues devoid of neural elements or, for example, in neuron aggregates that are strongly monoaminergic. However, these earlier techniques have now been supplemented by traditional histochemical techniques for the localization of a synthetic enzyme choline acetyltransferase (Burt 1969, 1970; Kasa *et al.* 1970 *a* and *b*) and more recently immunohistochemical methods for the same substance (Chao and Wolfgram 1973; Eng *et al.* 1974; McGreer *et al.* 1975) and these are generally regarded as more critical, particularly when *combined* with biochemical assays.

On these bases it is accepted that acetylcholine acts as a transmitter in virtually all parts of the central nervous system but varies greatly in concentration in different zones. Bearing in mind the difficulties in localization, it appears that cholinergic neurons are found scattered in the majority of the brainstem reticular nuclei. In the medulla and pons they are related to those areas adjoining both sensory and motor cranial nerve nuclei and particularly in those reticular nuclei, noted above, as constituting part of the 'ascending activating system'. In the midbrain and pontomedullary junction all the principal reticular nuclei described above have a cholinergic component (this includes the nuclei raphes dorsalis, cuneiformis, subcuneiformis, deep and dorsal tegmentalis, and tegmentalis pedunculopontinus; also the non-dopaminergic part of the substantia nigra pars compacta). The dorsally sited nuclei have axons forming a loose series of bundles, the *dorsal tegmental cholinergic pathway*, from which they radiate to terminate in the inferior and superior colliculi, the pretectal nuclei, the nuclei of the geniculate bodies and the more dorsally and anteriorly placed nuclei of the dorsal thalamus, including a number of the midline and intralaminar nuclei (particularly the nucleus centromedianus). The reticular nuclei sited in the ventral mesencephalic tegmentum have issuing axons that associate with those emerging from the compact part of the substantia nigra to form the *ventral tegmental cholinergic pathway*. The fibre bundles of the latter then diverge to end in numerous nuclei in the subthalamus, ventral and anterior nuclear groups in the dorsal thalamus, and most of the nuclear complexes of the hypothalamus, both lateral and medial, including the mamillary, supra-optic and pre-optic groups. For details of these pathways, a critical appraisal of methodology, bibliography, and further cholinergic projections from these nuclei to telencephalic structures the reader should consult Shute and Lewis (1967), and for an extensive review of the cholinergic innervation of limbic structures *see* Kuhar (1975), and Moore (1975).

THE MONOAMINERGIC RETICULAR FORMATION

With the advent of the Falck-Hillarp technique (Falck and Hillarp 1959, Falck 1962; Falck *et al.* 1962) in which it was demonstrated that following pre-treatment with formaldehyde, neurons and their neurites containing certain biogenic monoamines exhibited a characteristic fluorescence when examined using ultraviolet light. Those containing the catecholamines dopamine or noradrenalin showed a greenish fluorescence whilst those containing the indoleamine, serotonin, (5-hydroxytryptamine) were a distinct yellow. For a period it was difficult to distinguish between the two catecholamines (except for slight morphological differences—*vide infra*), but subsequently this became practicable by the application of quantitative photofluorometry combined with pharmacological manipulation. These reliable and reproducible techniques have, in recent years, led to the accumulation of a wealth of data concerning the differential distribution of aggregations of dopaminergic, noradrenergic, and serotonergic neurons in the brainstem and diencephalon of usually rats, cats and monkeys (*see*, for example, Dahlström and Fuxe 1964, 1965; Pin *et al.* 1968; Ungerstedt 1971; Björklund and Nobin 1973; Felton *et al.* 1974; Jacobowitz and Palkovits 1974; Palkovits and Jacobowitz 1974; Lindvall *et al.* 1974; Webster 1978), but general confirmation has also been obtained on adult and fetal human brains (Nobin and Björklund 1973; Olson *et al.* 1973 *a* and *b*). The reader should note the general points concerning interpretation—the axons of these cells are characteristically extremely fine, often branch profusely, and present minute varicosities along their course, from each of which it is assumed that transmitter is released. Thus, they may form innumerable synapses *en passage*, or perhaps produce miniature 'lakes' of transmitter influencing numerous neurons in their neighbourhood—a 'paracrine' effect. Furthermore, some investigators have emphasized that the varicosities on noradrenergic fibres are almost spherical, closely and regularly spaced, exhibiting an intense greenish fluorescence, whereas those of dopaminergic fibres are usually fusiform, somewhat smaller, more widely and irregularly spaced, and their fluorescence is less prominent. It should also be noted that the *dendrites* of these monoaminergic neurons are also fluorescent; such dendrites may invade the territories of neighbouring nuclei, and whilst they *may* be involved in forming, say, dendrodendritic synapses, they may also give the spurious appearance of an aminergic innervation to a group that is, in fact, devoid of one. Intensive studies continue, and new data appear almost daily.

The investigators who have studied the rat's brain in detail have recognized 15 catecholaminergic groups (classified as groups A1–15 of which A1–7 are noradrenergic and A8–15 dopaminergic), and 9 serotonergic groups (classified as groups B1–9). There has been considerable correspondence between the different groups of animals studied, but it must be realized that the aminergic groups thus classified only rarely correspond spatially to the confines of one of the reticular nuclei defined and named on classical cytoarchitectonic grounds: usually they form part of, lie adjacent to, or across the boundaries between, one or more of these nuclei.

THE NORADRENERGIC RETICULAR FORMATION

A brief account of the general location of the main noradrenergic neuron groups (A1–7) will be followed by a summary of their principal projections: the groups, initially identified in the rat, have mostly but not exclusively been identified in primates. They are confined to the medullary and pontine parts of the brainstem.

Group A1, in the caudal medulla, lies ventral to the lateral reticular nucleus but has extensions which partly surround the latter; A2 is part of the *nucleus commissuralis*, one of the *parahypoglossal nuclei*, which encloses the dorsolateral aspect of the hypoglossal nucleus and approaches the ependymal floor of the fourth ventricle. Group A3 is part of, and extends dorsal to, the dorsal accessory olivary nucleus (a subdivision of the inferior olivary nuclear complex); its noradrenergic status in primates is still under investigation. Group A4, the *nucleus pigmentosus tegmentocerebellaris*, lies subependymally embracing the ventricular aspect of the superior cerebellar peduncle. Group A5 is situated ventral or deep to the subcerulean nucleus partially invading the territory of the superior olivary complex and closely related to the motor nucleus of the facial nerve. Group A6 is the compact aggregation of neurons that form the *core* of the *nucleus ceruleus* previously described (p. 933). Group A7 constitutes the *nucleus subceruleus*, sited in the parvocellular lateral reticular column of the oral part of the pons and partly confluent with groups 4 and 6, particularly in some primates (Hubbard and Di Carlo 1973).

Concerning the patterns of connectivity of these groups, the majority of the noradrenergic (and some of the serotonergic groups) exhibit both complex *ascending* and *descending* pro-

jections in addition to *local* destinations in the brainstem. Because of their contrasting ascending brainstem pathways it is convenient to consider group A6 first, and then the remaining groups separately, although the separation into two may well not be as distinct as was first envisaged.

Group A6—the central noradrenergic cells of the nucleus ceruleus—has been described in some detail previously (p. 946) but for completeness and convenience will again be summarized here. The *descending fibres*, joined by some from A7 neurons provide collaterals to a number of bulbar nuclei including vagal and inferior olivary complex nuclei, then traverse the ventrolateral white column of the spinal cord providing noradrenergic inputs to the ventral, intermediate and base of the dorsal grey columns of the cord; these bundles constitute the *ventrolateral ceruleospinal tract*. The local brainstem terminals are largely collaterals of the principal ascending pathway, but a substantial bundle joins the superior cerebellar peduncle, the *ceruleocerebellar tract* to distribute both to the cerebellar roof nuclei and cortex (p. 918). The ascending fibres form the *dorsal tegmental noradrenergic bundle* (part of the central tegmental fasciculus) which traverses the midbrain ventrolateral to the periaqueductal grey matter, continues through the lateral hypothalamic part of the diencephalon largely as part of the medial forebrain bundle, thence through the septal region to join the cingulum and supracallosal longitudinal stria. Side branches have terminals in the mesencephalic periaqueductal grey matter, reticular nuclei and colliculi; diencephalic terminals include the dorsal thalamic nuclei, geniculate and habenular nuclei; telencephalic terminals include all major limbic structures—the septal and amygdaloid nuclei, hippocampus, subiculum, and the cingulate, retrosplenial and parahippocampal gyri; the neocortex receives a uniform diffuse bilateral input, fibres of the two dorsal bundles having interchanged some fibres across the midline in the upper brainstem. It has even been claimed that the profusely branching axon of a *single* cerulean neuron may diverge so widely as to provide terminals in the spinal cord, brainstem, and forebrain! (For further comments *see* p. 933.)

Groups A1, 2, 5 and 7 (with possible accessions from A3 and 4, but the status of these is less certain in primates) provide ascending branches that converge to form the *ventral tegmental noradrenergic bundle* (part of the central tegmental fasciculus). Proceeding through the ventral reticular regions of the midbrain it approaches the dorsal bundle at upper midbrain levels; both bundles exchange fibres across the midline, the ventral bundle then continuing mainly as a constituent of the medial forebrain bundle through the lateral hypothalamus. *En route* the ventral bundle provides collaterals that terminate at mesencephalic levels in the neighbouring reticular nuclei (p. 945) and periaqueductal grey matter; in the diencephalon it diverges to nuclei throughout the *hypothalamus*, particularly profuse terminals being found in the dorsomedial, periventricular, tuberal, paraventricular, and supra-optic nuclei; it finally appears to terminate as sprays of endings in the bed nucleus of the stria terminalis and the pre-optic area. Thus, the dorsal and ventral tegmental noradrenergic bundles are mainly to be contrasted in their diencephalic zones of termination and the extremely wide continuation of the dorsal bundle into limbic and neocortical areas.

Groups A1 and 2 provide *local* brainstem inputs, particularly to the dorsal vagal nucleus and the nucleus of the solitary tract.

Finally, Groups A1, 2, 5 and 7 provide *descending* fibres to the spinal cord; these have been described (Dahlström and Fuxe 1965) as constituting an *anterior noradrenergic bulbospinal tract* with terminals in the anterior grey column of the spinal cord, and a *dorsolateral noradrenergic bulbospinal tract* with terminals in the intermediolateral grey column and also in the substantia gelatinosa.

THE DOPAMINERGIC NEURONAL GROUPS

No dopaminergic cell aggregations have been identified in the hindbrain; of the eight groups recognized so far (classified as groups A8–15) three (A8, 9 and 10) are mesencephalic, four (A11, 12, 13 and 14) are diencephalic, and a single group (A15) has been found in the telencephalon.

The three mesencephalic groups are interconnected plates or strands of dopamine-positive cells and their limits are therefore difficult to define. Group A8, generally accepted as part of the mesencephalic reticular formation is also known as the *substantia nigra pars lateralis* (but *see* p. 936), whilst A9 constitutes the whole of the *substantia nigra pars compacta*. Group A10 is a median group or complex that abuts ventrally on the nucleus interpeduncularis (the group receives the following terminologies—*nucleus linearis*, *nucleus parabrachialis pigmentosus*, *interstitial nucleus of the ventral tegmental decussation*: how far these are synonymous in primates is obscure).

Of the diencephaplic aggregations, A11 is in the subependymal grey matter in the caudal part of the third ventricular wall, partially encompassing the fasciculus retroflexus. Group A12 includes the *infundibular (arcuate) nucleus*, and rostral extensions of the latter into the anterior periventricular grey matter are often classified as group A14. Some neurons of the zona incerta (p. 965) make up group A13.

The solitary telencephalic group (A15) is provided by the periglomerular cells of the olfactory bulb (p. 992).

Summarizing briefly the efferent projections of the dopaminergic neurons—those derived from groups A8 and 9 (subdivisions of the substantia nigra) ascend through the caudomedial subthalamus and lateral hypothalamus, the fibre bundles then diverging and, intersecting the internal capsular fibres (as part of the *comb* bundle—*see* p. 978), they join the ansal system and continue to radiate, finally terminating as a profuse input to the whole of the caudate nucleus and putamen of the corpus striatum. Collectively these fibre bundles form the *nigrostriatal dopaminergic system*. In contrast, the fibres derived from the midline third mesencephalic group A10 ascend more medially and traverse the medial forebrain bundle to terminate in a variety of further telencephalic structures. These include the nucleus accumbens, the bed nucleus of the stria terminalis, the olfactory tubercle, nuclei of the septal area, granular areas of frontal neocortex, anterior cingulate cortex, and also the entorhinal cortex. These bundles have been grouped as the *mesolimbic dopaminergic system*. The remaining dopaminergic neuron groups do not belong to the 'reticular formation' as defined by the classical neuroanatomists, but such terminological irrelevances shall not deter us from summarizing them here.

Groups A11, 13 and 14 are considered together since their axons are relatively short and remain within the confines of the diencephalon. Group A11 projects to medial hypothalamic nuclei, the nuclei of the midline of the dorsal thalamus, the habenular nuclei, and the pretectal area. Groups A13 and 14 have axons that ramify to terminate in nuclei of the caudal part of the dorsal thalamus, other parts of the zona incerta, and nuclei of the dorsal and oral parts of the hypothalamus. Collectively the latter fibre bundles have been termed the *incerto-hypothalamic dopaminergic system*.

Neurons forming group A12 with their somata in the infundibular nucleus have axons which pass to the rostroventral part of the median eminence and upper infundibulum; here, they may terminate directly in synaptic relation with, or merely in the neighbourhood of, the axons or terminals of parvocellular releasing-factor neurons, or in relation to specialized elongate ependymal cells (tanycytes) of the infundibular recess of the third ventricle (for further comments and illustration *see* pp. 981, 1447 and **8**.197 A, B). Thus this *tubero-infundibular dopaminergic system* may modulate the transport and/or exocytosis of releasing factors and their uptake by venous portal system capillaries, also secretory activity or transport to and from the third ventricular cerebrospinal fluid by the tanycytes.

Finally, dopaminergic cells of group A15 are the periglomerular cells of the olfactory bulb; some details of their cytology and connectivity in this exceedingly complex part of the brain are given on p. 992.

THE SEROTONERGIC RETICULAR FORMATION

The reticular neurons synthesizing and containing the putative transmitter serotonin (5-hydroxytryptamine) have been identified at medullary, pontine and midbrain levels; they all lie in or

near the median plane (thus, they are mainly parts of the rapheal nuclei—*see* above); nine relatively distinct groups have been located and classified as B1–9. Group B1 is formed by some neurons of the nucleus raphes pallidus and B2 by the nucleus raphes obscurus; both groups have extensions ventrolaterally to include neurons of the nucleus paramedianus. Extending cranially from B1, further neurons of the nucleus raphes pallidus, and those of the nucleus raphes magnus approach and reach the pontomedullary junction together constituting group B3. Thus, groups B1–3 are serotonergic groups, median and paramedian in position and largely confined to the medulla. Group B4 is located in the pontine periventricular grey matter of the cranial part of the fourth ventricle; B5 is a circumscribed group in the nucleus raphes pontis near the motor nucleus of the trigeminal nerve, whilst group B6 is found in the cranial part of the central pontine tegmental reticular grey matter and extending into the superior central nucleus of the pons. Aggregate B7, the largest of the serotonergic cell groups, occupies much of the mesencephalic nucleus raphes dorsalis with extensions into the periaqueductal grey matter; B8 is a cranial extension of B6 continuing within the confines of the nucleus centralis superior (of Bechterew); finally group B9 is a lamina of serotonergic neurons embracing the lateral aspect of the nucleus interpeduncularis.

The routes and fields of termination of projection fibres from the serotonergic cell groups have much in common with those of the noradrenergic groups, but of course, with some exceptions. Thus, they may be considered as (*a*) descending, (*b*) local brainstem, (*c*) cerebellar, and (*d*) profuse and widespread dorsal and ventral ascending pathways. Moreover, a single serotonergic reticular neuron may have an axon that diverges to many of these destinations, whilst others appear to have a strictly localized zone of termination.

The *descending bulbospinal serotonergic projections* are contributed by medullary groups B1–3, particularly those located in the nucleus raphes magnus; they form two bulbospinal tracts—one traverses the anterior white funiculus giving off re-entrant terminals to the neurons of the ventral grey columns (laminae VIII and IX), the other descends through the dorsal part of the lateral white funiculus largely lateral to the corticospinal projection, its terminals innervating the preganglionic autonomic neuron-containing intermediolateral cell column, and the remaining laminae of the dorsal horn including the substantia gelatinosa. It has been held that the latter are particularly concerned in modulating nociceptive inputs to the spinal cord grey matter.

The *intrinsic brainstem serotonergic projections* involve groups B3–8; those from B5–8 project to the nucleus ceruleus, tegmental nuclei, and descending fibres to other (probably both aminergic and non-aminergic) zones of the pontine and medullary reticular formation. Groups B3–5 also project to neighbouring reticular nuclei and questionably to the inferior olivary complex. It is noteworthy that the largest aggregate of serotonergic neurons (group B7) sends the most massive bundle of axons yet identified to terminate in the largest aggregation of noradrenergic neurons which form the core of the nucleus ceruleus (group A6).

The *cerebellar serotonergic pathway* consists of axons that emerge from groups B5 and 6, then having entered the cerebellum through the homolateral middle cerebellar peduncle, branch to have terminal fields in the intracerebellar nuclei and then diverge to wide areas of the cerebellar cortex (cf. the noradrenergic cerebellar pathway through the inferior cerebellar peduncle).

The *dorsal ascending serotonergic bundle*, much smaller and with more restricted destinations than the ventral, arises from neurons with their somata in cell groups B3–6. These axons converge dorsocranially and become constituents of the dorsal longitudinal fasciculus (of Schütz) in which they ascend giving off side branches to the mesencephalic reticular nuclei, periaqueductal grey matter, and, entering the diencephalon, diverge to their fields of termination in the caudal zone nuclei of the hypothalamus.

The *ventral ascending serotonergic bundle* is relatively massive and stems from neuron groups B6–8 (rapheal nuclei of the upper pons and midbrain); curving ventrorostrally it traverses the ventral midbrain tegmentum as a constituent of the central tegmental fasciculus, then entering the diencephalon, courses through the hypothalamus in its lateral part as yet another constituent of the complex of fascicles forming the medial forebrain bundle; numerous side branches and a wide terminal radiation reach a great diversity of destinations. Mesencephalic bundles pass to many parts of the substantia nigra; others enter the interpeduncular nucleus—some terminate in this nucleus and the remainder of this side branch continues in the habenulo-interpeduncular tract to reach the epithalamus and dorsal thalamus, where they terminate in the habenular nuclei, the medial and midline nuclear groups and parafascicular nucleus of the thalamus.

Coursing through the diencephalon as part of the medial forebrain bundle, side branches are given to the mamillary and lateral hypothalamic nuclei; other fibres penetrate the hypothalamic region obliquely and reach the caudate nucleus and putamen of the corpus striatum, whilst some continue to reach parts of the lateral neocortex; a small bundle also enters the postcomissural column of the fornix and then recurves through its body, crus, and fimbria to distribute terminals to the dentate gyrus and cornu ammonis. At the rostral end of the hypothalamus the ventral serotonergic bundle diverges into numerous radicles. Some pass ventrolaterally as constituents of the ansa peduncularis and reach the nucleus of the diagonal band of Broca, the prepiriform and entorhinal cortex, and parts of the amygdaloid complex. Further bundles splay out to reach the nuclei of the preoptic and septal areas, the olfactory tubercle and adjacent grey matter, and some continue rostrally to reach the medial frontal neocortex and along the olfactory tract to end in the olfactory bulb. A third contingent of fibres radiate to the accumbens nucleus and then furnish a second (rostral) input to the anterior zones of the caudate nucleus and putamen of the corpus striatum. Ultimately, what remains of the ventral ascending bundle is still, however, a substantial fascicle, and this passes first rostrally, then dorsally to join the cingulum within which it arches over the corpus callosum and then curves downwards and forwards to run the length of the temporal lobe. Throughout its course it provides side branches and terminals to the cingulate, retrosplenial and entorhinal (parahippocampal) cortices, and from their ventrolateral aspects, sequential side branches to the cornu ammonis and subiculum, thus completing a *dual input* to the hippocampal formation (*vide supra*).

Thus, *in summary*, the serotonergic 'system' of neuron groups in the reticular formation of the brainstem possess axonal bundles that project to (*a*) other brainstem reticular nuclei, (*b*) many hypothalamic nuclei, (*c*) all the major limbic structures, (*d*) some 'limbic' and 'non-specific' nuclei of the dorsal thalamus, and the epithalamic nuclei, (*e*) much of the spinal cord grey matter.

THE MAPPING OF OTHER PUTATIVE NEUROTRANSMITTERS

There is now strong evidence that gamma-amino-butyric acid (GABA) and glycine act as inhibitory central neurotransmitters; data are also being accumulated concerning the transmitter status and possible excitatory roles of the amino acid taurine, and also glutamic and aspartic acids. However, their spatial location is limited to high resolution autoradiography after administration of radio-isotope labelled derivatives, with its restriction to relatively minute pieces of tissue. A further obstruction to progress is that these substances (other than GABA) form part of the metabolic pool of virtually all cells, neural or not, and they are therefore quite ubiquitous in their distribution, whatever their specifically neural functional roles, if any, may turn out to be. Thus, apart from gross biochemical assays, the effects of agonists and antagonists, and severely limited ultrastructural studies, there are no specific histochemical methods yet available for their identification. Accordingly, there has been virtually no progress in the 'mapping' of their sites of production, transport, release and postsynaptic action; whether such maps will become feasible, and if produced, how far they will assist an understanding of the operation of the whole, and parts of, the central nervous system remains quite speculative and must await future researches.

However, the mapping of the distribution of certain other

possible neurotransmitter substances which have recently come into prominence has made, and doubtless will continue to make, rapid and substantial progress (*see*, for example, Hughes and Kosterlitz 1977). These include the peptides substance P, the enkephalins, endorphins, and also the spatial distribution of opiate *receptor* sites are under intensive investigation (for detailed reviews *see* Guillemin 1978; and particularly Chan-Pham 1978).

As pointed out by Webster (1978) 'the distribution of enkephalin-containing fibres and terminals in the forebrain shows remarkable similarity to that of the monoamines'—(the basal nuclei, septal area, hypothalamus, amygdala, and areas of the cerebral neocortex all contain enkephalins—*see* Simantov *et al.* 1977); at the time of writing the siting of their parent cell somata was, in most cases, not established Nevertheless, Hökfelt *et al.* (1977) held that the somata of met-enkephalin-containing cells occur in zones of the mesencephalic periaqueductal grey matter, in the nuclei raphes magnus et pallidus of the medulla (cf. serotonergic groups B1–3), in the nucleus caudalis segment of the spinal nucleus of the trigeminal nerve, and throughout the spinal cord dorsal grey column laminae I, II, and V. There is additionally a close similarity in the distribution of substance P; it has been proposed, therefore, that these met-enkephalin-, endorphin-, substance P-, and serotonin-containing cells and fibres may form an integrative complex that modulates the mechanisms underlying pain perception (Basbaum *et al.* 1976; Nathan 1977; *see* also review and bibliography by Snyder, in: Reichlin *et al.* 1978).

FUNCTIONAL ASSOCIATIONS OF THE RETICULAR FORMATION

It will be clear from the preceding paragraphs that the reticular formation receives convergent information channels from *all* the principal parts of the nervous system and, in turn, it projects directly or indirectly back to all these regions, modulating their activities through complex and ill understood mechanisms that involve synaptic neurotransmission, and local neuroparacrine as well as neuroendocrine effects. Thus, the comments of some earlier neuro-anatomists and physiologists, and some current elementary texts, that the formation can be dismissed as merely that phylogenetically ancient neural network that remains 'filling in' those crevices that persist when all the well-defined 'specific' nuclei and tracts have been described, should be ignored. It is equally unsatisfactory, and a reflexion of our lack of comprehension of intimate mechanisms, that two completely contrasting and extreme views have been advanced. On the one hand some observers have found it sufficient to feed into the formation a channel from another neural complex, for example, the corpus striatum, and describe effects elsewhere as *mediated* by the formation without any attempt to analyse structural organization within the formation: this treats the latter as a 'black box'; analogous approaches are those that invoke the 'activity of the reticular formation' as sufficient explanation for almost *any* behavioural phenomenon which, as yet, cannot be explained by reference to what is known of the spatially more ordered 'specific systems'. On the other hand, with our present knowledge it is similarly facile to attempt to attach a *simple unitary functional label* to individual neurons, named nuclei, or small neuronal groups (whatever criteria are currently employed for their classification). The methods available for structural/functional evaluation have been outlined elsewhere (pp. 815, 817–820): the various cytoarchitectonic, impregnation, histochemical, histofluorescence, immunofluorescence, degeneration, autoradiographic and other modern tracer techniques having been used to form a picture of structural organization and connectivity patterns, albeit incomplete; this provides (as with other neural complexes) the reference framework for functional probing. The latter entails microelectrode recording under experimental conditions, analysing the behavioural changes or deficits that accompany or follow focal or zonal microstimulation or ablation, pharmacological enhancement or depression of neurotransmitter action, a wide range of neuropathological states, genetic/developmental deviations and studies of psychoses. All such methods have severe limitations, particularly when applied to neural complexes such as the reticular formation, hypothalamus, dorsal thalamus, limbic 'system' and cerebral neocortex. In the present context any approach towards a satisfactory understanding of the reticular formation would necessitate a knowledge of the form and significance of the flow of information along the numerous channels that converge upon it, including any pre-processing and convergent/divergent interaction that has already occurred; the transformations occurring within the formation itself, and the manner in which the outflow channels modulate the activities of their multiple destinations, and through the latter modify simple to complex behavioural patterns. We are far from such an understanding, and currently it seems appropriate to assume that if one or more of the foregoing techniques (although often highly artificial) produces a clear cut set of behavioural changes, the locus, zone, cell aggregate, or whole 'system' is in some unspecified way, *functionally associated* with the behaviour under study. Some of the more prominent fields currently engaging functional neurobiologists are noted below: they may all, of course, as has been a persistent theme throughout this volume, be allocated more or less obviously to some aspect of long, intermediate, or short term homeostasis.

(*a*) **Somatomotor control:** The reticular formation forms part of the complex of subregions of the nervous system exerting controlling influences on activity patterns of skeletal (striated) muscle ranging from relatively simple reflex loops, coarse to fine postural re-adjustments, positioning and scanning of distance receptors, manipulative skills, locomotion, to complicated patterns associated with intergroup and interpersonal communication and emotional expression involving the complexities of speech, gestures and fluctuations of facial expression. The degree and temporal sequence of involvement of the multiplicity of parts of the central nervous system that may be considered as fairly intimately concerned with influencing the activity levels of alpha and gamma motor neuron pools and their attendant neighbouring interneurons, varies greatly with the speed, force, finesse and complexity of the movement pattern in question. Reticular formation involvement may be direct or indirect through other major neural complexes. Thus, *direct* spinal influences are mediated through the reticulospinal tracts, stemming from the medial two thirds of the pontomedullary reticular formation; that from the pons descends in the ventral white funiculus and is largely ipsilateral; that from the medulla is bilateral and occupies a wide area of the lateral white funiculus. Stimulation and ablation experiments led to the concept of an *inhibitory motor* '*centre*' or '*zone*' located in the medulla, and a *pontine facilitatory* '*centre*'. It should be appreciated that such names are somewhat misleading—thus, in the case of medullary reticulospinal fibres inhibition results from an *increased* flux of impulses and therefore an increased release of quanta of transmitter from their terminals influencing the complex array of interneurons, alpha and gamma efferents in the spinal cord grey matter with varieties of receptor sites, and involving pre- and postsynaptic mechanisms. However, it is equally clear that, *on balance*, a *reduced* flux of impulses from the medullary origin would have the converse, i.e. a facilitatory effect, and that during normal activities there are *continual fluctuations* of activity making the terminological choice quite arbitrary. The descending fibres involved stem from some multipolar neurons of the medullary and pontine gigantocellular nuclei, the central medullary reticular nucleus and the nucleus reticularis pontis caudalis, and include cell aggregations A6 and 7 and the aggregations B1–2 in the nuclei of the raphe. Thus there are non-aminergic fibres intermixed with inhibitory noradrenergic and serotonergic fibres. It is noteworthy, also, that the nucleus-cerulean origin of bulbospinal fibres receives a serotonergic input from the caudal nuclei of the raphe, and the serotonergic bulbospinal fibres from the latter have been held as mediating the general relaxation of body musculature that characterizes rapid eye-movement (REM) sleep. Similar direct influences are directed to the motor neuron pools of the cranial nerves; also groups of the foregoing reticular neurons controlling the motor neuron pools innervating the diaphragm and intercostal musculature have been said to constitute the hierarchy of respiratory 'centres' described by neurophysiologists.

Indirect influences of the reticular formation on somatomotor control are too numerous to be pursued *in extenso* here, and the relevant sections of this volume should be consulted. Listing them briefly, they include, in virtually all instances, non-aminergic (presumably many of which are cholinergic) and aminergic fibres (*see* individual sections devoted to the noradrenergic, serotonergic and dopaminergic 'systems'), but their relative numbers, precise sites of termination and roles in functional integration remain to be discovered. Thus, the *cerebellum* receives reticular inputs through both the inferior and middle cerebellar peduncles that distribute to the intracerebellar nuclei and the cerebellar cortex; other brainstem complexes including the olivary nuclei, colliculi, red nucleus and substantia nigra; the corpus striatum—in particular the caudate nucleus and putamen through the comb bundle and central tegmental fasciculus; the nuclei ventralis anterior and lateralis of the dorsal thalamus, the zona incerta and other subthalamic nuclei, and finally the somatomotor cortex, either directly from reticular nuclei or indirectly from many of the regions just mentioned.

(*b*) **Somatosensory control:** All the subregions of the nervous system involved in the processing of somatosensory information are subject to influences from the reticular formation. Thus, the spinal and brainstem terminals of primary afferent fibres, their nuclear destinations and attendant interneurons, and the dendrites and somata of neurons projecting long axons to supraspinal centres are all subject to reticular control. (These include the dorsal spinal grey column, dorsal column nuclei gracilis et cuneatus, trigeminal sensory nuclei, nucleus of the solitary tract, amongst others.) In different situations the effects may be pre- or postsynaptic, and facilitatory or inhibitory. Currently, much interest persists in relation to the possible relevance of such controls to theories of sensory 'gating' mechanisms (p. 890); as noted previously, it has been proposed that descending bulbospinal and local bulbar reticular fibres that are serotonergic may cooperate with others that are noradrenergic, and yet others that contain met-enkephalins or substance P in an integrated mechanism that modulates pain perception (p. 962). (In this regard, compare also the diencephalic and limbic distribution of monoaminergic and enkephalin-containing reticular fibre terminals with the distribution of opiate receptors—*see* Guillemin 1978; Chan-Pham 1978.) More cranially sited centres receiving and processing somatosensory information, and also in receipt of a reticular input are the sensory relay nuclei of the dorsal thalamus and the somatosensory cortices.

Similar considerations apply to the special senses, reticular inputs being received by the cochlear and vestibular nuclei, tectal and pretectal laminae or nuclei, the nuclei of the geniculate bodies, pulvinar and other dorsal thalamic nuclei, and finally the visual, auditory and olfactory cortices (*see* appropriate sections).

In addition to influences controlling the activities of the more spatially ordered 'specific' sensory systems, spinoreticular and bulboreticular connexions are, in themselves, held by many to provide bilateral, polysynaptic, ascending, 'slow pain' pathways that discharge into multiple diencephalic nuclei; these convey both somatosensory and viscerosensory information.

(*c*) **Visceromotor control:** Cardiovascular readjustments and the activity of non-striated muscle and many glandular cells in the thoracico-abdominal viscera are, of course, in most cases under controlling influences of postganglionic autonomic neurons. Their preganglionic neuronal somata and dendrites are either directly, or through the intermediary of local interneurons, partially controlled by reticulobulbar and descending reticulospinal fibres. Thus, mainly on the basis of focal stimulation and ablation, or brainstem transection experiments, and also pharmacological manipulation, the concept of, for example, cardiovascular controlling 'centres' has gained popularity in general physiological texts. However (as in the case of the respiratory 'centres'), while the sites of the sympathetic and parasympathetic preganglionic somata are now fairly well established, it has not yet proved possible to locate with precision the functionally related groups of reticular neurons.

Forebrain control of autonomic activities involves areas of the orbitofrontal, cingulate and entorhinal cortices, the major limbic structures (*see* pp. 968, 990), the medial and anterior groups of dorsal thalamic nuclei, the hypothalamic nuclei, and descending fascicles of the various tegmental bundles with destinations in the reticular formation, and thence via the reticulobulbar and reticulospinal tracts mentioned above and elsewhere in this section.

(*d*) **Neuroendocrine transduction:** Through the complex of ascending bundles accompanying the central and dorsal tegmental fasciculi, cholinergic and all varieties of monoaminergic fibres pass in side channels to reach and terminate in most, if not all, hypothalamic nuclei including the infundibular nuclei of the median eminence, and the habenular nuclei. Thus, either directly, through the intermediary of other hypothalamic nuclei, or via the dopaminergic infundibular cells (*vide supra*), the reticular neurons are one source of modification of the synthesis and probably transport and exocytosis of 'releasing' or 'release-inhibiting' factors by the parvocellular neurons of the mediobasal hypothalamus (p. 966), thereby controlling adenohypophysial activity; similar mechanisms probably operate with respect to the neurohypophysis. The neural input to the pineal gland involves the sympathetic nervous system via the upper thoracic spinal cord outflow of preganglionic fibres, the superior cervical ganglion and nervus conarii; there is in addition a strong neural connexion via the habenulopineal tracts. The role of the suprachiasmatic nucleus has been mentioned elsewhere (*see* pp. 966, 1446 for further details). Thus, both main neuroendocrine transduction centres are, in part, under reticular control.

(*e*) **Biological rhythms:** The notion of the existence of '*biological clocks*' has, of recent years, permeated all branches of biological science and only a few of the more obvious ones can be listed here. A time-base is imposed on all living systems by the intrinsic turnover rates of biological macromolecules, including the genetic apparatus of the cell (pp. 23, 27), the annual seasonal variations, and daily environmental fluctuations. Thus biological rhythms attend, for example, the reproductive cycles, developmental horizons, cell division, death and replacement, and so forth, the list being endless. As stated elsewhere (p. 971) many rhythms are dependent upon an intact hypothalamus with its multiple input and output channels including those involving the reticular formation. As mentioned above the latter is also involved in the neural control of the pineal gland and much interest is currently centred upon the neuroendocrine role of the latter in relation to circadian rhythms (pp. 972, 1445).

(*f*) **Sleep, arousal, states of consciousness, perception:** Much philosophical, psychological, neurophysiological, neuropharmacological and neuroanatomical thought, effort and research has been directed, first to attain satisfactory definitions of the varying states of consciousness and their neural substrates, ranging from stuporose unresponsive conditions, through varieties of sleep, arousal and awakening, attention, perception, and the preparation for, and enactment of, active responses. Vigorous researches are being pursued on all these fronts and a vast literature has accumulated; this is beyond the scope of this or any volume (*see*, for example, Jouvet 1969, 1972: and for a concise summary and an extensive bibliography, Ingram 1976). Extremely briefly, it is important to distinguish between different *behavioural* states of unconsciousness, sleep and awakening, and the *electroencephalographic* records that usually, but not invariably, accompany these states. The terminology associated with the latter is widely employed by investigators in this field. Thus, there are two principal forms of sleep: *deep* or *slow wave* (*recuperative*) *sleep* (SWS) in which the person is deeply but reversibly unconscious, random limb and postural changes occur sporadically, there is an elevation of sensory thresholds, and the electroencephalogram records *synchronized*, high-voltage, slow waves; interspersed are periods of *paradoxical* (PS) or *rapid eye movement* (REM) sleep. In the latter dreaming normally occurs, there is relaxation of the general body musculature, but as the name implies, rapid oscillatory movements of the eyeballs. The latter are accompanied by corresponding bursts of electrical activity, similar waveforms being recordable from the pontine reticular formation, the dorsal lateral geniculate nucleus and the occipital visual cortex (PGO activity). Behavioural arousal and awakening is accompanied in the intact animal by a rapid, low

amplitude, *desynchronized* waveform. Mention has already been made of the early proposal of an '*ascending activating reticular system*', polysynaptic in nature, with multiple inputs from the principal sensory pathways, and following diencephalic synaptic complexes, bilateral widespread radiations, pass to most regions of the neocortex and limbic structures. Recent investigations indicate that both cholinergic and monoaminergic reticular groups in the upper pons and midbrain are, when stimulated, the most powerful instigators of cortical desynchronization. It is widely assumed that the latter state is a necessary prerequisite for maintaining wakefulness, for selective attention to particular features of the environment, for effective perceptual and cognitive utilization of inflowing information, and preparation for comparator and cooperative responses. The varieties of sleep are currently thought to be the result of activity of a hierarchy of hypnogenic neuron aggregates (balanced against the activating 'system' just mentioned), the majority being monoaminergic in nature. Slow wave sleep is dependent upon serotonin production by the rapheal nuclei, whereas paradoxical sleep after priming by serotonin follows intermittent activity on the part of both cholinergic and noradrenergic cells in the cranial part of the nucleus ceruleus, whilst its medial cells appear to function as a '*pontine pacemaker*', which together with the former cooperate in generating PGO responses. The descending serotonergic bulbospinal fibres from the rapheal nuclei and noradrenergic fibres from the caudal part of the nucleus ceruleus are held responsible for the relaxation of limb and trunk musculature during paradoxical sleep.

(*g*) **Spatio-temporal discrimination, cognitive mapping and exploration, reward, learning and memory, emotional content, long term homeostasis:** All the foregoing complex neural activities are intimately dependent upon an intact hypothalamo-limbic 'system' and will be discussed briefly in the appropriate parts of the present section. However, as indicated in previous paragraphs, in addition to numerous other inputs, all the hypothalamic nuclei and limbic structures receive widespread inputs from both aminergic and non-aminergic elements of the reticular formation, and surgical or pharmacological manipulation of these brainstem reticular elements cause profound alterations in these diverse aspects of complex behaviour.

As stated at the outset, therefore, the reticular core of the brainstem and its attendant cell aggregations, have reciprocal connexions with *all* the major parts of the central nervous system, and in accord with this, influences behavioural activities ranging from the most elementary to the most complex.

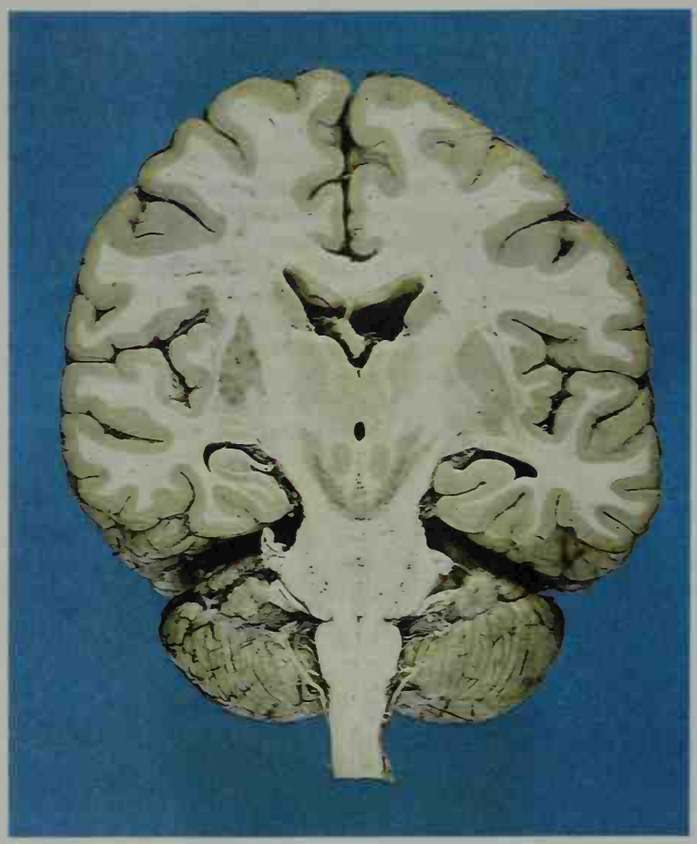
THE PROSENCEPHALON OR FOREBRAIN

The prosencephalon or forebrain develops from the most cranial of the three midline primary cerebral vesicles (p. 163). This *forebrain vesicle* and its contained cavity, the future *third ventricle*, is soon divisible into a caudal *diencephalon* and a cranial *telencephalon*. From the side walls of the latter, right and left diverticula form and develop into the cerebral hemispheres. Each hemisphere contains a lateral ventricle, and the sites of evagination are marked by the interventricular foramina, through which the lateral ventricles communicate with each other and with the cavity of the third ventricle. (Survey photographs of the cerebrum in sagittal and coronal section are shown in 7.95, 96, 110.)

Thus, the *diencephalon* corresponds in large measure to the third ventricle and the structures which bound it, whilst the telencephalon consists of a midline *telencephalon medium* or *impar* containing the cranial extension of the third ventricle, and the massive *bilateral telencephalic cerebral hemispheres* each containing a lateral ventricle. (For the development of these regions *see* p. 169.)

THE DIENCEPHALON OR 'INTERBRAIN'

As stated, the cavity of the diencephalon forms the greater part of the median slit-like third ventricle, which narrows caudally to continue into the aqueduct of the midbrain, while cranially it extends into the telencephalon medium (*vide supra* and p. 966).



More precise topographic limits for the diencephalon are: caudally—a plane which includes the posterior commissure and the caudal margins of the mamillary bodies; cranially—a plane which passes from the interventricular foramina through the posterosuperior border of the midline part of the optic chiasma. Cranial to the latter plane are the structures comprising the telencephalon medium. It should be emphasized, however, that while the boundaries just described have some measure of developmental and phylogenetic significance, in terms of the functional anatomy of the brain they are merely arbitrary descriptive aids, since many systems cross the boundaries into adjacent areas.

Thus, the diencephalon is a midline structure with symmetrical right and left halves. Traversing each lateral wall of the third ventricle is a *hypothalamic sulcus* of variable prominence, which extends from the cerebral aqueduct to the interventricular foramen (p. 981). The line of the sulcus is used to divide each lateral half of the diencephalon into a *pars dorsalis* and a *pars ventralis diencephali*.

The pars dorsalis diencephali consists on each side of: (1) the dorsal thalamus, (2) the metathalamus, and (3) the epithalamus; whilst the pars ventralis diencephali includes (1) the hypothalamus, and (2) the ventral thalamus.

Briefly, above the hypothalamic sulcus most of each side wall of the third ventricle is formed by a large egg-shaped mass of grey matter and associated laminae of white matter which together constitute the *dorsal thalamus*. The unqualified term *thalamus* is used by the majority of neuroanatomists as synonymous with dorsal thalamus and will frequently be used in this manner in the following account. As described in greater detail below, the thalamus can be divided into a series of major *parts*, and each of these can be subdivided into several *nuclei*. Inferior to the caudal end of the thalamus, and partly continuous with it, are two further swellings—the *medial* and *lateral geniculate bodies*—which overlie nuclei of the same names, and which together constitute the *metathalamus*. The roof of the diencephalon is largely formed by a layer of ependyma which is continuous with that lining the remainder of the third ventricle. Throughout most of its extent this ependyma is in close apposition with the overlying vascular pia mater, with no nervous tissue intervening. However, in the caudal part of the roof and in the adjoining lateral walls of the diencephalon, are the habenular nuclei and their commissure, the epiphysis cerebri or pineal gland, and the posterior commissure. Together these constitute the *epithalamus*.

Some neuroanatomists include the whole of the pars ventralis diencephali in an 'anatomical' definition of the hypothalamus, but this includes regions which are quite dissimilar functionally, and, accordingly, a more restricted definition is preferred in this account. The *hypothalamus* extends from the lamina terminalis to a vertical plane immediately caudal to the mamillary bodies, and dorsoventrally from the hypothalamic sulcus to include the structures in the side wall and floor of the third ventricle. The latter include the mamillary bodies themselves, the tuber cinereum and infundibulum, and nervous tissue adjacent to the

7.96A The dorsal half of a brain sectioned in an oblique coronal plane which passes through the cerebral hemispheres, diencephalon, midbrain, pons and medulla oblongata, to show the general disposition of main structures, many of which are labelled on 7.98. Note: (1) the complex folding of the cerebral cortical gyri and sulci of the frontoparietal, insular and temporal regions; (2) the sectioned surfaces of the corpus callosum, septum pellucidum, body of the fornix, the corona radiata, internal capsule, ventral pons and medulla oblongata; in the latter, part of the decussation of the corticospinal tracts is visible. Note also: (3) the body and inferior horn of the lateral ventricle; (4) the lentiform and caudate nuclei, and the dorsal thalami which are fused across the midline. This illustration includes features referred to at many points in the text which are too numerous to include in a caption; these should be studied as appropriate. (Dissection by Dr. E. L. Rees, Dept. of Anatomy, Guy's Hospital Medical School.)

optic chiasma (7.104). Rostrally, the preoptic region, which lies adjacent to the lamina terminalis and is therefore strictly a telencephalic structure, is for functional reasons usually included in descriptions of the hypothalamus.

The remaining zones of the pars ventralis diencephali are situated in part lateral to the hypothalamus, as a thin sheet immediately ventral to the dorsal thalamus, and as a thick zone which merges caudally with the tegmentum of the midbrain. Collectively these zones constitute the *ventral thalamus* or *subthalamus*. The region includes the rostral extensions of the red nucleus and substantia nigra, the prominent subthalamic nucleus, the prerubral field, the zona incerta, and their associated complexes of nuclei and fibre tracts.

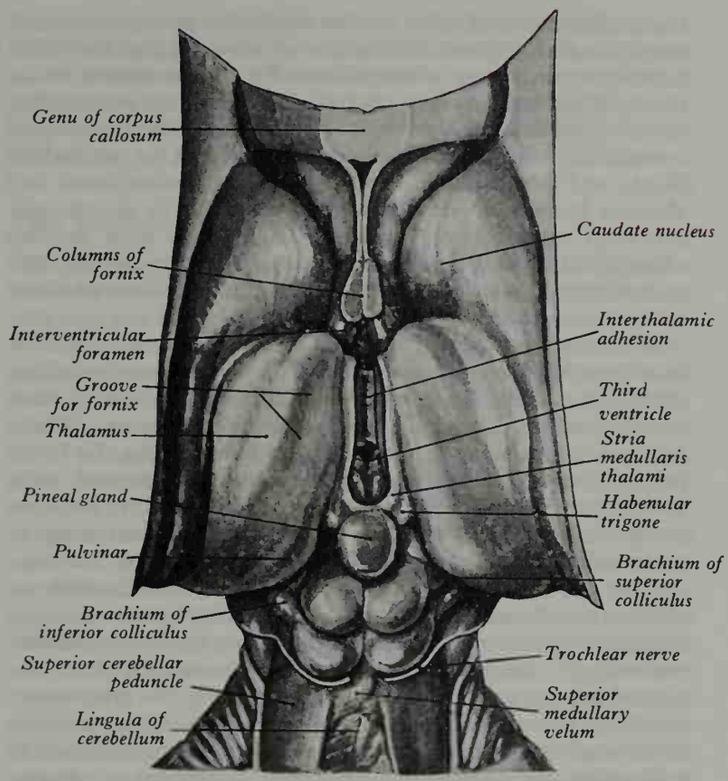
The Thalamus

The thalami (7.96A, B, 97, 98) are two large ovoid masses of grey matter, situated one on each side of the third ventricle and reaching for some distance caudal to that cavity. Each thalamus is about 4 cm long, and has two ends and four surfaces.

The *anterior end* is narrow; it lies near the median plane forming the posterior boundary of the interventricular foramen.

The expanded *posterior end*, the *pulvinar*, is directed dorsally and laterally and overhangs the superior colliculus and its brachium. On the inferior aspect of its lateral part the lateral geniculate body (p. 977) forms a small, oval elevation. Inferiorly, the pulvinar is separated from the medial geniculate body (p. 977) by the brachium of the superior colliculus.

The *superior surface* (7.97) is free, slightly convex, and covered by a layer of white matter, termed the *stratum zonale*. It is separated laterally from the ventricular surface of the caudate nucleus by a white band, termed the *stria terminalis*, and by the thalamostriate vein (p. 744). It is separated medially from the medial surface by the reflexion of the ependyma of the third ventricle to form its roof. This reflexion is termed the *taenia thalami*. The superior surface is divided into a lateral and a medial part. The lateral part forms a portion of the floor of the lateral ventricle. It is covered with the epithelium of that cavity, and is partly hidden by the vascular fringe of the choroid plexus (7.98). The medial part of this surface is covered with the tela choroidea of the third ventricle, by which it is separated from the body of the fornix which grooves the surface. Between the lateral edge of the fornix and the upper surface of the thalamus the lateral margin of the tela choroidea with its contained plexus is invaginated into the ventricle through the choroidal fissue (7.157). In front, the



7.96B The central area of the ventral part of the oblique coronal section of the brain shown in 7.95, photographed at higher magnification to show some structural features in greater detail; compare with 7.98 for appropriate labelling. Note in particular: (1) the anterior, medial and lateral parts of the dorsal thalamus; separated by the internal medullary laminae; (2) the relation of the caudate nucleus to the anterior and inferior horns of the lateral ventricle; (3) the lentiform nucleus, divided into an external putamen and an internal globus pallidus, the latter again divided into internal and external parts; (4) the internal capsule, external capsule, claustrum, extreme capsule and insular cortex; (5) the profiles of the sectioned subthalamic and red nuclei and substantia nigra; (6) the hippocampus projecting into the floor of the inferior horn of the lateral ventricle. Other structural features on this section are referred to at many points throughout the text. Compare also with 7.152. (Dissection by Dr. E. L. Rees, Dept. of Anatomy, Guy's Hospital Medical School.)

superior surface is separated from the medial surface by a narrow, raised ridge from which the epithelial lining of the third ventricle is reflected to the under surface of the tela choroidea. This ridge covers a small bundle of white fibres, named the *stria medullaris thalami* (p. 968). Posteriorly it turns medially to form the anterior boundary of the *trigonum habenulae* (7.97), from which the superior surface of the thalamus is separated by the *sulcus habenulae*.

The *inferior surface* rests upon and is continuous with the cranial prolongation of the tegmentum (*subthalamus*). In front of this it rests on that part of the hypothalamus lying in the lateral wall of the third ventricle.

The *medial surface* (8.195) is the superior part of the lateral wall of the third ventricle; it is usually connected to the corresponding surface of the opposite thalamus by a flattened grey band, named the *interthalamic adhesion* (*connexus interthalamicus*). This band is posterior to the interventricular foramen, and averages about 1 cm in its anteroposterior diameter; it sometimes consists of two or even three parts, and occasionally is absent. It contains nerve cells and nerve fibres; some of the latter cross the median plane, but many of them pass towards the median plane and then curve laterally on the same side. This surface of the thalamus is limited below by a curved groove, often ill-defined, termed the *hypothalamic sulcus*. It curves anterosuperiorly from the rostral end of the cerebral aqueduct to the floor of the interventricular foramen and is usually regarded as the cranial continuation of the sulcus limitans of the spinal cord and brainstem, but this view has been strongly challenged (Christ 1969).

On the *lateral surface* there is a thick band of white substance consisting of projection fibres, which form the posterior limb of the internal capsule and separate the thalamus from the lentiform nucleus of the corpus striatum (7.98).

7.97 Dorsal aspect of the caudate nuclei, thalami, pineal gland and tectum, revealed by removal of most of the corpus callosum, the body of the fornix, and of the tela choroidea.

The Gross Structure and Parts of the Thalamus

The thalamus is chiefly grey matter but its superior surface is covered by a layer of white matter, the *stratum zonale* and its lateral surface by a similar layer, the *external medullary lamina*. Internally, the thalamic grey matter is incompletely divided by a vertical sheet of white matter, the *internal medullary lamina* which splits anterosuperiorly in a Y-shaped manner. Accordingly, the main mass of the thalamus is divided into three major *parts*—anterior, medial and lateral; the lateral part is further divided into dorsolateral and ventromedial *parts*. Each of these major parts of the thalamus contains a *group of thalamic nuclei* and, further, these large groups are separated by more restricted groups of nuclei which occur within the internal medullary lamina, and also flank the medial and lateral surfaces of the thalamus.

The main nuclear groups of the thalamus are therefore:

(1) The *anterior group*, which constitutes the anterior part of the thalamus.

(2) The *medial group*, which lies between the internal medullary lamina laterally, and approaches but does not reach, the ependymal lining of the third ventricle medially.

(3) The *lateral group*, which constitutes the dorsolateral moiety of the lateral part of the thalamus, and which expands posteriorly to form the pulvinar.

(4) The *ventral group*, which occupies the ventromedial moiety of the lateral part of the thalamus.

(5) The *intralaminar group*, embedded in the substance of the internal medullary lamina.

(6) The *nuclei of the midline*, which are small, interlaced with a periventricular system of fine nerve fibres and which constitute part of the periventricular grey matter separating the medial part of the thalamus from the ependyma of the third ventricle and in part forming the variable interthalamic adhesion (p. 981).

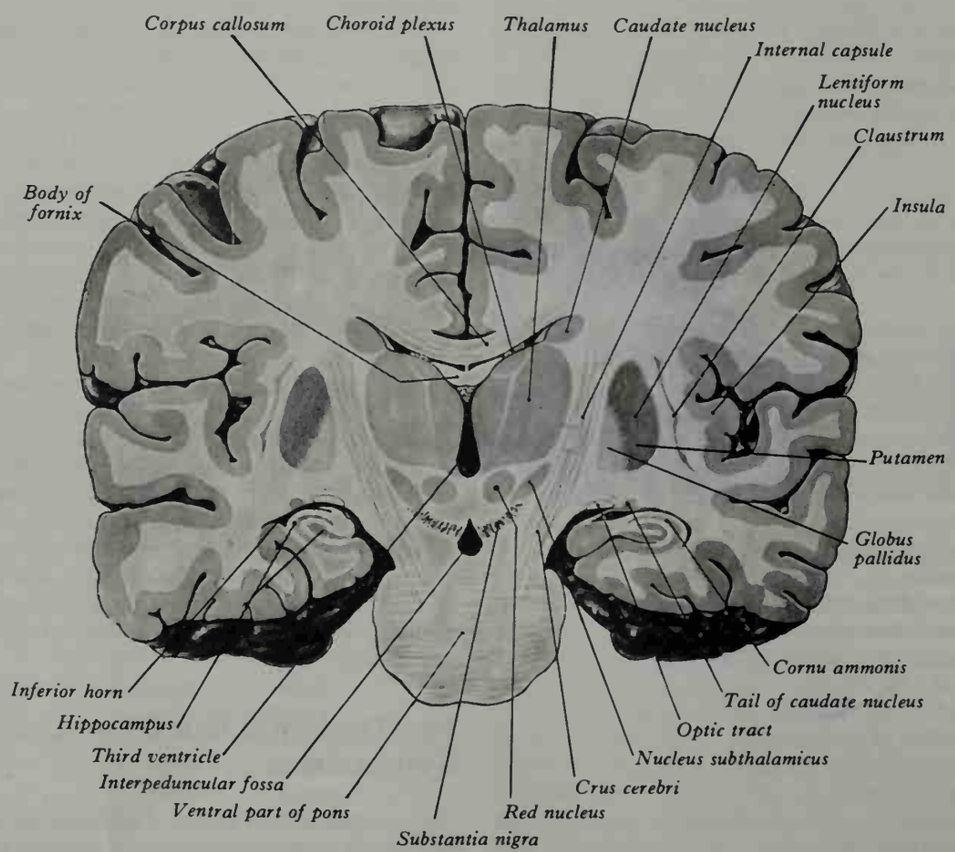
(7) The *reticular nucleus of the thalamus*, which is a long, thin, curved lamina of cells separating the external medullary lamina from the white matter of the posterior limb of the internal capsule.

The anterior and medial parts of the thalamus, together with some of the smaller groups of nuclei, are often regarded as phylogenetically the older regions, and designated *paleothalamus* in contrast with the lateral part or *neothalamus*, which reaches its greatest development in anthropoid apes and man. However, such modifications have occurred in the 'older' parts of the thalamus during the course of evolution, and the structural and functional relationships of the various regions of the primate thalamus are so intermingled, that some authorities regard such a division as little more than a convenient aid to elementary teaching.

As we shall detail further below, many parts of the thalamus are connected via relatively well-defined fibre bundles with all the main subcortical parts of the nervous system—the brainstem and spinal cord, cerebellum, hypothalamus and corpus striatum. Further, many parts of the thalamus establish reciprocal connexions with many parts of the cerebral cortex, and classically these two-way radiations of fibres between thalamus and cortex are grouped into four **peduncles** or **stalks of the thalamus**. Taken together, however, these peduncles form an almost continuous fan-like radiation from the ventral, superior, posterior and inferolateral margins of the thalamus to most regions of the cortex, and they form a substantial part of the internal capsule and corona radiata (7.99, 150B, and p. 1030). The *anterior* or *frontal thalamic peduncle* interconnects the anterior and medial parts of the thalamus with much of the cortex of the frontal lobe of the cerebrum. The *superior peduncle* interconnects the ventral and lateral thalamic regions with the pre- and postcentral gyri and the neighbouring parts of the frontal and parietal lobes. The *posterior peduncle* joins the occipital and posterior parietal cortex with the posterior parts of the lateral thalamus including the pulvinar and lateral geniculate body. Finally, the *inferior thalamic peduncle*, smaller than the others, interconnects the posterior thalamus and medial geniculate body with restricted regions of the temporal lobe cortex.

The Thalamic Nuclei and their Connexions

The nuclear groups of the thalamus outlined above have been intensively studied since the close of the nineteenth century in man and a number of other mammalian and submammalian



forms. A number of these studies have been purely structural, concerning the cytoarchitectonics as revealed by the Nissl technique, or the general disposition of the white matter, whilst the Golgi method has given much information on the morphology of individual neurons and their processes. Many investigations of connectivity patterns have been carried out with the methods of Nauta and Marchi; the effects of selective stimulation and ablation have been recorded; more recently, in as yet only restricted regions of the thalamus, there have been detailed ultrastructural studies of its synaptology, unit recording with microelectrodes, and analysis of the distribution of accepted and putative neurotransmitters.

What emerges from these studies, which are far too numerous to review here, is that the thalamus is a region of immense structural complexity, composed of a large number of often interdependent, but functionally distinctive zones. Whilst substantial agreement has been reached concerning the broad parcellation of the thalamus into nuclear groups, and often individual nuclei, it is still premature to assume that we possess a comprehensive picture of the structural and functional design of the organ. Difficulties of investigation result from the large number of nuclear groups, some of them very small, which are closely packed together, their afferent and efferent fibre systems often passing through or near neighbouring nuclear territories. Accordingly, stereotactic lesions almost invariably affect unwanted regions in addition to the target area of the experiment. Similarly, retrograde degenerative changes are difficult to assess in the smaller thalamic neurons, and these are equally difficult to study with microelectrode techniques. Nevertheless, despite these problems of technique, a large volume of data has accumulated and the main nuclei of the thalamus and their best substantiated connexions will be summarized here (7.100, 101). For details and an introduction to extensive bibliographies the reader should consult Le Gros Clark (1932, 1933 *a* and *b*, 1936, 1937, 1949); Walker (1938); Toncray and Kreig (1946); Sheps (1945); Dekaban (1953); Kuhlenbeck (1954); Hassler (1959); Schaltenbrand and Bailey (1959); Ajmone-Marsan (1965); Purpura and Yahr (1966); Scheibel and Scheibel (1966, 1967); Van Buren and Borke (1972).

In general terms a thalamic nucleus may establish connexions with: (1) other thalamic nuclei; (2) neighbouring subcortical masses of grey matter; (3) long ascending pathways from the brainstem and spinal cord; and (4) the cerebral cortex. The intrinsic connexions with other thalamic nuclei are the most difficult to analyse and thus are the least well understood both structurally and functionally. The general anatomy and thalamic termination of the more prominent long ascending pathways and those from neighbouring centres have been well established for a considerable period, but the finer details of their sites and modes of termination, and those of less substantial pathways are often uncertain and the source of much disagreement. Many thalamic nuclei show marked degenerative changes after experimental resection of regions of the cerebral cortex—hence the term *cortically dependent thalamic nuclei* for such centres. Again, some nuclei, whilst having local and intrinsic connexions, are predominantly in receipt of a discrete, often somatotopically organized input tract, and give rise to an equally well-organized projection to the cortex. These are often termed *relay nuclei* in contrast to *association nuclei* in which multiple subcortical connexions predominate. However, the former are not to be regarded as 'simple' relays since complex transformations of the flow of information are the rule in such centres. Further, based upon focal stimulation of the thalamus, together with recording from the cerebral cortex, thalamic nuclei have often been termed either *specific* or *non-specific*. In the former, a rapid, sharply localized, ipsilateral response is recorded, whilst with the latter the response is widespread, bilateral and occurs after a greater latency. With increasingly refined methods of investigation, however, many nuclei previously thought to have no connexion with the cerebral cortex are now shown to be 'cortically dependent', and the distinction between specific and non-specific nuclei is becoming less clear cut as a considerable measure of interaction between the two is becoming apparent.

SYNAPTIC ORGANIZATION OF THALAMIC RELAY NUCLEI

Studies with the electron microscope have shown that the ultrastructural organization of the principal sensory 'relay' nuclei is extremely complex, and attempts to analyse synaptic

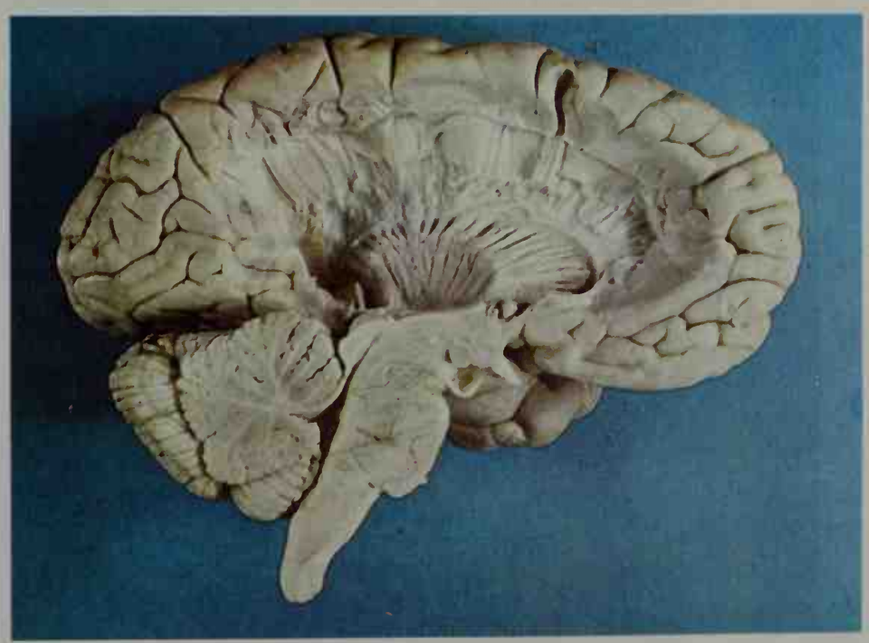
956 7.98 Coronal section of the brain through the ventral part of the pons.

relationships are in their infancy. A striking feature of all such nuclei so far studied is the *synaptic glomerulus*, a spherical, ovoid or more irregularly shaped tissue unit from 2 or 3 μm to 20 μm or more along one axis, consisting of closely packed axons and dendrites of different types, establishing with each other a large number and usually a considerable variety of synaptic relationships (Szentágothai 1970; *see* also p. 829 and 7.21). These neural components, which include dendrites or dendritic appendages of the thalamic neurons together with axon terminals of different types, are encapsulated, and separated from the surrounding and generally more simply organized neuropil, by thin, sheet-like astrocyte processes. It is principally within synaptic glomeruli that the specific afferents terminate (for example, the axons of the optic nerve and tract in the lateral geniculate nucleus, and those of the medial lemniscus in the nucleus ventralis posterior lateralis). Because of the synaptic interactions occurring within the environment of the glomeruli, each probably functions to some extent as an independent integrative unit whose output (to the cortically projecting thalamic neuron), following the arrival of an impulse in the specific afferent, is modified according to other variable factors, such as activity in the cortico-thalamic and other afferent systems and the extent of activity in neighbouring specific afferents and synaptic glomeruli.

One of the most interesting recent findings has been the discovery (Morest 1971) in thalamic nuclei of *presynaptic dendrites* morphologically similar to conventional dendrites but containing, in addition to the usual organelles, clusters of synaptic vesicles and establishing synaptic contacts with other dendrites. Some cells with presynaptic dendrites may also have conventional axons; others may resemble the amacrine cells of the retina and olfactory bulb and bear only one type of 'dual-purpose' neurite. More recent ultrastructural analyses (Lieberman and Webster 1972) have shown that the presynaptic dendrites eventually give rise to boutons, packed with distinctive disc-like synaptic vesicles. These dendritic boutons are very similar to axonal boutons, and constitute one of the principal classes of synaptic endings in the thalamic glomeruli. The significance of presynaptic dendrites in the information processing activities of thalamic nuclei, and elsewhere in the nervous system are discussed by Shepherd (1974, 1978); Schmitt *et al.* (1976); Rakic (1975).

THE ANTERIOR GROUP OF NUCLEI

This group is divisible into three nuclei: *anterior dorsalis* (AD), *anterior medialis* (AM) and *anterior ventralis* (AV), the first being the least prominent. The anterior group of nuclei is interconnected with both the medial and lateral groups of thalamic nuclei, and possibly with the contralateral anterior group. It receives some fibres directly from the postcommissural fornix, and the substantial mamillothalamic tract from the mamillary nuclei of the same side, a few fascicles stemming from the opposite side, and it also sends a small contingent of thalamomamillary fibres back to these nuclei. The main radiation from the anterior group are thalamocortical fibres to many parts of the gyrus cinguli (cortical areas 23, 24 and 32), and the anterior group also receives corticothalamic fibres from the same areas. Some authors contend that the anterior nuclei also have reciprocal connexions with the retrosplenial gyrus (areas 29 and 30).



The anterior thalamic nuclei are thus a principal centre linking the activities of the hippocampus and hypothalamus with other thalamic nuclei and with extensive cortical areas which belong to the *limbic system* (p. 990). Stimulation or ablation of the mamillothalamic tract causes alterations in autonomic control and is presumably involved in complex homeostatic cycles involving visceral responses. A normally functioning hippocampus-fornix-mamillary-body/thalamus/limbic-cortex system is now widely considered necessary for the establishment of a *recent memory trace*. In Korsakow's syndrome, characterized by a memory loss for recent events, lesions in the mamillothalamic system are common (Talland 1965; Barbizet 1963). However, experiments in rats (Krieckhaus 1967; Krieckhaus and Randall 1968) failed to show disturbances of recent memory following such lesions, and the interesting suggestion was made that the system is important in determining the balance between repetitive stereotyped behavioural responses and the initiation of 'novel' exploratory responses under different conditions of environmental stimulation.

THE MEDIAL GROUP OF NUCLEI

This consists of the large *nucleus medialis dorsalis* (MD) and a series of smaller nuclei (*parafascicularis, submedius, paracentralis* and *centralis lateralis*)—the connexions and significance of the latter are uncertain in man and will not be pursued further here.

The *nucleus medialis dorsalis* presents a rostral *pars magnocellularis* and a caudolateral *pars parvocellularis* and is considered to make intrinsic intrathalamic connexions with virtually all the other groups of thalamic nuclei. It receives, in certain regions, fibre connexions from the amygdaloid complex of nuclei (p. 996) and the piriform cortex, and establishes two-way connexions, thalamostriate and striatothalamic, with parts of the corpus striatum (p. 1035), but the precise regions of the latter involved are still rather uncertain.

The most widely described connexions of the nucleus medialis dorsalis of the thalamus are with the hypothalamic nuclei and with the cerebral cortex of the frontal lobe (*vide infra*). The two-way connexions with the hypothalamic nuclei are thought to run in the *periventricular system* of fibres, which are fine myelinated or nonmyelinated fibres and which pursue vertical or oblique courses immediately deep to the ependymal side wall of the third ventricle, where they are intermingled with patches of periventricular grey matter. Some of the periventricular pathways may be polysynaptic, and the system is often described as consisting of a rostrocaudal series of fascicles which connect different parts of the medial thalamus with the preoptic, tuberoinfundibular and mamillary parts of the hypothalamus respectively (p. 966). The most caudal fascicles continue as part of the *dorsal longitudinal fasciculus* (of Schütz) in the periaqueductal grey matter of the midbrain through which they reach numerous brainstem reticular nuclei. It should be noted, however, that not all investigators regard the existence of thalamohypothalamic

7.99 After median hemisection of the cerebrum, the left cerebral hemisphere has been dissected from its *medial* aspect to display the fibre bundles of the corona radiata and internal capsule. This entailed the removal of the cingulate gyrus and subjacent white matter, much of the paramedian corpus callosum and fornix, the dorsal thalamus, and the head and body of the caudate nucleus. The oval depression previously occupied by the dorsal thalamus can clearly be seen within the curved depression left after removal of the caudate nucleus. (Dissection by Dr. Andrew Seal, Dept. of Anatomy, Guy's Hospital Medical School.)

connexions in the periventricular system as proven (Raisman 1966; Szentágothai *et al.* 1968).

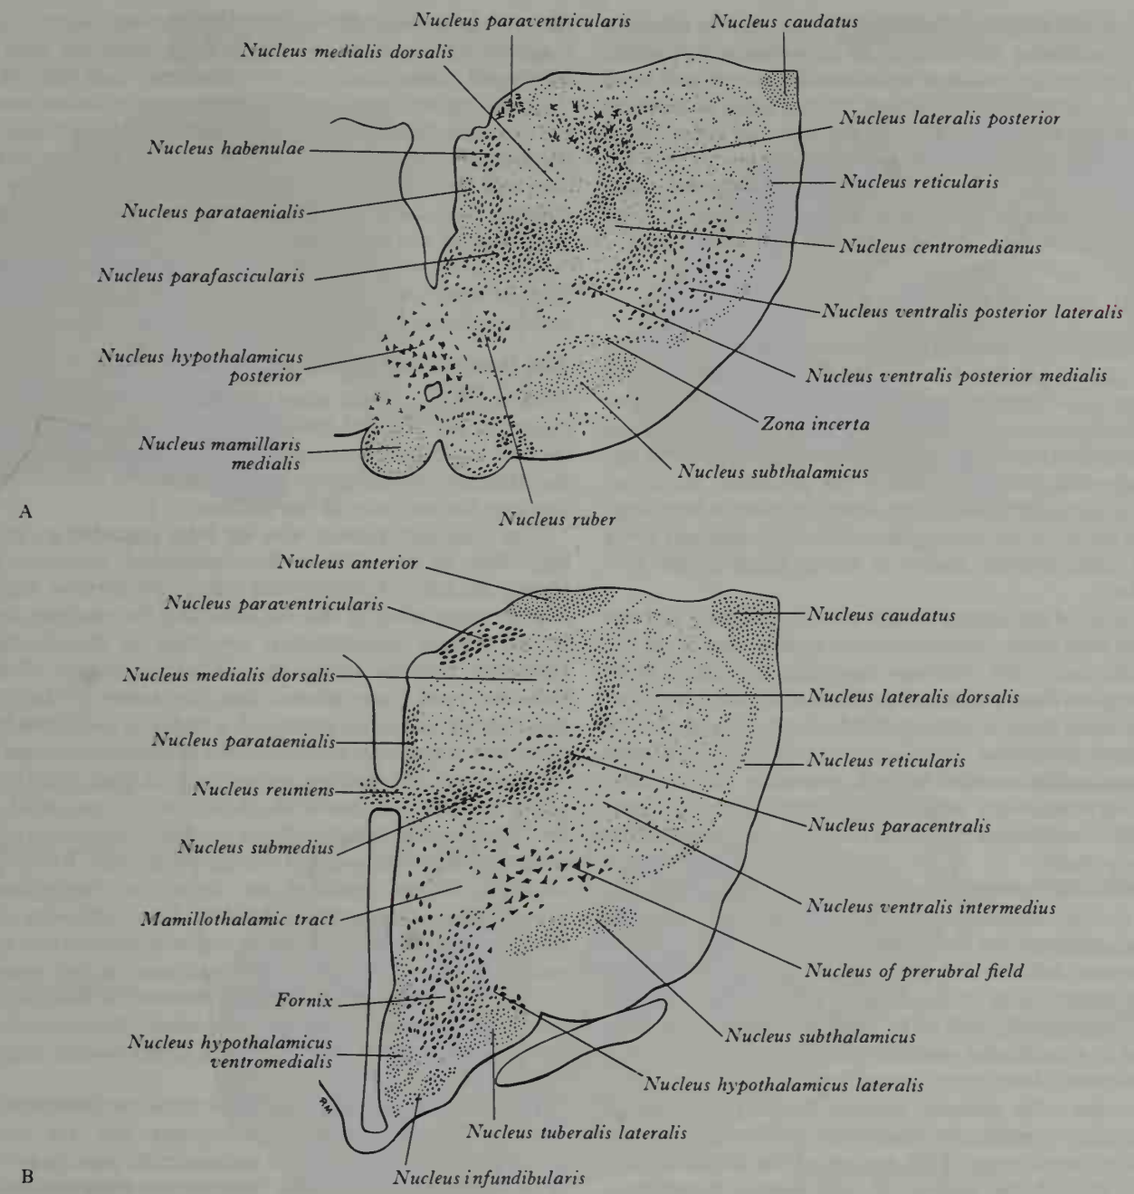
Profuse reciprocal thalamocortical and corticothalamic connexions exist between the nucleus dorsalis medialis and almost the whole of the prefrontal cortex of the frontal lobe of the cerebral hemisphere which lies cranial to cortical areas 6 and 32 (p. 1003). These radiations show an orderly topographic arrangement, specific regions of the nucleus connecting with specific cortical areas.

Clearly the medial part of the thalamus is a region of great functional significance, as evidenced by the wealth and complexity of its interconnexions; but equally it is impossible to attach simple functional labels to such a region of the nervous system. It probably provides mechanisms for the integration of a great variety of information channels, olfactory, visceral and somatic, by the convergence of multiple paths via the hypothalamus, amygdaloid complex, piriform cortex, corpus striatum and prefrontal cortex, and in turn has an output which can affect these and many other regions of the nervous system.

Stimulation of the dorsomedial thalamic nucleus in monkeys elicits movement patterns even after ablation of cortical motor areas, but the patterns disappear on ablation of the corpus striatum. Stimulation, disease or surgical ablation of the nucleus in man results in complex changes in motivational drive, the ability to solve problems and in the consciousness level, general 'personality' and subjective feeling states or 'affective tone' of the individual. The effects of ablation parallel in many ways the results of prefrontal lobotomy

THE VENTRAL GROUP OF NUCLEI

The ventral thalamic group form a rostrocaudal sequence of three main nuclei: *ventralis anterior* (VA), *ventralis intermedius* (VI) and *ventralis posterior* (VP). (Many workers use the term ventralis lateralis (VL) rather than the official term ventralis intermedius.) The *nucleus ventralis posterior* can be further subdivided into the important nuclei *ventralis posterior lateralis* (VPL) and *ventralis posterior medialis* (VPM), together with smaller and less well-understood nuclei which are inferior and oral in position.



The connexions of the main nuclei in this group include some intrinsic ones with adjacent thalamic nuclei such as the centrum medianum and pulvinar (*vide infra*), and also with neighbouring centres in the subthalamus and corpus striatum. However, by far the most prominent connexions of these nuclei are with the large ascending sensory systems, the medial, spinal and trigeminal lemnisci, and gustatory pathways, and also two-way links with the cerebral cortex. The origin, course and constitution of these ascending systems has already been described. The VPL receives the terminals of the medial and spinal lemnisci, whilst the VPM receives the trigeminal and gustatory pathways. (The cells receiving trigeminal terminals are sometimes called the *arcuate* or *semilunar nucleus*, whilst the gustatory fibres are sometimes held to end in an *accessory arcuate nucleus*.) Much research has been directed towards an understanding of the structural and functional localization and the types of interaction which occur during impulse transmission through these thalamic nuclei.

Briefly, there is an overall somatotopic pattern in the ascending pathways, in the nuclei themselves and in their connexions with the cerebral cortex. Both medial lemniscal and spinothalamic fibres from caudal body segments (i.e. from the nucleus gracilis in the case of medial lemniscal fibres) end in the lateral zone of the VPL, while fibres from successively more cranial body segments end in more medially placed zones in the nucleus. Still more medially placed is the VPM, which receives the trigeminothalamic fibres conducting information from the face and head, whilst most medial are the solitariothalamic gustatory fibres from the nucleus of the solitary tract. Other authors have emphasized that whilst such a lateromedial localization undoubtedly exists, the various tracts are not simply superimposed but end in different rostrocaudal regions. The lateral spinothalamic tract has been described as ending in the caudal nuclear regions followed by the medial lemniscal and anterior spinothalamic fibres, while the trigeminothalamic fibres end in a craniomedial position.

The terminations of medial lemniscal and spinothalamic tract fibres show further contrasting features. The lemniscal fibres are wholly crossed, originating exclusively in the gracile and cuneate nuclei of the opposite side and their terminals are confined to the VPL. Whilst the majority of the spinothalamic fibres are also crossed, an appreciable number ascend on the same side and terminate in the ipsilateral thalamus. Further, although many spinothalamic terminals occur in the VPL, others proceed to a number of alternative destinations, including restricted parts of the medial geniculate nucleus, a small supragenicular nucleus and various 'non-specific' thalamic nuclei—these are sometimes called the *posterior* (PO) *group* of terminals (Poggio and Mountcastle 1960, 1963). The latter may receive the terminals of high threshold spinal cord neurons which transmit nociceptive information (p. 890). The PO group of nuclei may have reciprocal connexions with the secondary sensory area SmII (p. 1015). Studies of the fine morphology of ascending tract terminals in the VPL have been carried out with the Golgi technique Scheibel and Scheibel (1966). Spinothalamic and reticulothalamic terminals form diffuse interweaving networks, medial lemniscal fibres end as small cone-shaped bushy terminals arranged in regular laminae, whilst corticothalamic fibres have terminal arborizations confined to narrow disc-shaped 'sheets' of tissue which encompass the territories of many lemniscal fibres. Ultrastructural studies have demonstrated the presence of small local interneurons within the VPL (Tomböl 1967), whilst others have started to explore the detailed synaptology of the nucleus (Andersen *et al.* 1964 *a* and *b*; Lieberman and Webster 1972; Shepherd 1974; Rakic 1975). Unit recordings have been taken with microelectrodes inserted into cells of the VPL during medial lemniscal and spinothalamic tract activity in the monkey, by a number of investigators, and also in man, before the placing of stereotactic lesions in the thalamus for various types of locomotor disease. In the monkey, units responding to lemniscal activity retained many of the features described previously for the cells of the gracile and cuneate nuclei. The VPL cells were in this case highly specific for both the type of stimulus and the bodily site of origin. Units responded to contralateral stimulation which consisted of either mechanical distortion of the skin or hairs, or joint movement, or static joint position, or sinusoidal tissue vibration, but never to two of these varieties. Their receptive fields were small and sharply localized, the smallest being recorded by stimulation of the terminal segments of the limbs. Units responding to spinothalamic tract activity in general showed rather larger receptive fields, and whilst some were 'modality specific' others showed interaction due to convergence of impulses from different types of stimulus pattern (p. 891). Impulse transmission in the VPL is now shown to be a most complicated series of events. Many of the units show the phenomenon of lateral inhibition of 'inhibitory surround' discussed previously (p. 808) which greatly enhances their discriminative value. Furthermore, transmission in the nucleus may be modulated by activity in descending corticothalamic fibres and in those which converge on the nucleus from other thalamic and extrathalamic sources. In this regard physiological studies have demonstrated that both presynaptic and postsynaptic inhibitory and facilitatory effects occur in the nucleus.

The recordings made in the nucleus ventralis posterior lateralis of the *human* thalamus, although necessarily more restricted in scope, substantially support the findings concerning somatotopic localization and modal specificity of units demonstrated in the monkey. Furthermore, localized stimulation of the nucleus in conscious subjects evoked sharply circumscribed sensations described as 'tingling', 'numbness', etc. on the opposite side of the body.

The main thalamocortical radiations from the VPL and VPM proceed through the posterior limb of the internal capsule to the primary somatic sensory areas of the cerebral cortex—the postcentral gyrus which includes cortical areas 1, 2 and 3 (p. 1003). Throughout this radiation the precise somatotopic organization of the nuclei of origin is preserved. The same cortical areas project reciprocal corticothalamic fibres back to the nuclei. Unfortunately, the thalamic projections to the secondary somatic sensory areas cannot yet be regarded as settled, although possibly some stem from the PO group (p. 962).

7.100A and B Drawings of coronal sections through the diencephalon, stained with the method of Nissl to show the main nuclear aggregations of nerve cell somata. A at the level of the mamillary bodies; B at the level of the tuber cinereum. Note the variations in cell size, shape and packing density, which characterize the nuclear masses of the dorsal thalamus, subthalamus and hypothalamus at these levels.

The *nucleus ventralis intermedius* (VI, which includes the nucleus ventralis lateralis, VL, of many authors) has been less extensively investigated. It establishes connexions with adjacent thalamic nuclei but its main sources of input are from the contralateral nucleus dentatus of the cerebellum via the dentatothalamic tract and rubrothalamic fibres of the ipsilateral red nucleus (pp. 918, 939). It also receives some fascicles from the globose and emboliform nuclei of the cerebellum and from the globus pallidus. A nigrothalamic projection has been described in monkeys (Carpenter *et al.* 1976). These various afferents are constituents of the *thalamic fasciculus* (*see* p. 965).

The main projection from the VI is somatotopically arranged and passes through the internal capsule to reach the motor and premotor regions of the cerebral cortex (areas 4 and 6). The caudal part of the nucleus has often been selected for neurosurgical ablation in cases of severe Parkinsonism.

The *nucleus ventralis anterior* (VA) has a complex organization and has come into greater prominence in recent research, together with the nucleus ventralis intermedius, because of the therapeutic placing of destructive lesions in or near these nuclei in various types of locomotor disorder.

The nucleus ventralis anterior has numerous interconnexions with other thalamic nuclei, but in particular with the *nucleus centromedianus* (*vide infra*), the other *intralaminar nuclei*, the nuclei of the midline, and the *reticular thalamic nucleus*, i.e. all the so-called 'non-specific' thalamic nuclei. In addition the VA receives an input from the brainstem reticular formation and profuse connexions from the globus pallidus through the *thalamic fasciculus* (*see* p. 965), together with the most rostral of the dentatothalamic fibres of the superior cerebellar peduncle. Carpenter *et al.* (1976) have adduced corroborative evidence for a nigrothalamic projection to VA in monkeys. Thalamocortical fibres radiate from the VA to the premotor cortex (area 6), to a lesser extent to the motor cortex (area 4), and fibres to restricted regions of the insular cortex have also been described. In turn corticothalamic fibres leave areas 6 and 4 and converge upon the VA. (For a detailed Golgi study of the nucleus see Scheibel and Scheibel 1966.)

Thus, the VA is an important focal centre through which the corpus striatum, the ascending reticular formation and non-specific thalamic nuclei, and to a lesser degree the cerebellum, are able to exert a powerful effect on the activities of the motor and premotor cortices and probably on many other regions of the cortex as well. To what degree the information flowing in the various channels which converge on the VA is integrated, before onward transmission to the cortex, is not clear.

Views concerning the possible functional significance of the VA are rapidly changing. Some relationship to the motor control systems is evident—stimulation of the nucleus increases Parkinsonian rigidity and tremor, whilst ablation of the nucleus

(often with, however, some surrounding tissue) may be effective in reducing or abolishing the tremor. In experimental animals, stimulation of the caudate nucleus is followed by a reduced level of activity in both VL and VA and their related areas of cerebral cortex, and this is accompanied by a loss of learned behavioural responses. It should also be noted that stimulation of the VA causes *desynchronization* of the electroencephalogram, and increasingly the nucleus is regarded as an important link in the final stages of the '*ascending activating system*' (see also p. 953).

THE LATERAL GROUP OF NUCLEI

This group is commonly divided rostrocaudally into three—the *nuclei lateralis dorsalis* (LD), *lateralis posterior* (LP), and most caudally the greatly expanded *pulvinar*, which occupies almost the whole of the caudal quarter of the thalamus. The pulvinar is a late phylogenetic development, only becoming prominent in the higher mammals and increasingly so in the primates, including mankind. It is sometimes divided into three or more subregions. The separation between the subregions of the pulvinar and LP is imprecise and some authors prefer to group them as the *LP-pulvinar complex*.

The three nuclei of the lateral group are all presumed to have interconnexions with other thalamic nuclei, but the details are not yet clear. Additionally, the *pulvinar* has been described as in receipt of connexions from the lateral geniculate nucleus, possibly the medial geniculate nucleus and amygdaloid complex, and some investigators have described direct projections from the optic tract constituting a direct *retinothalamic projection* (*see* p. 976). Whilst numerous connexions with such subcortical centres seem probable, further evidences must be awaited before definite conclusions are possible.

The best established connexions of the lateral group are two-way links with specific regions of the cerebral cortex, the LD with inferior parietal and posterior cingulate regions, LP with much of the parietal cortex behind the postcentral gyrus, whilst the pulvinar interconnects with wide areas of the parietal, occipital and temporal lobe cortices, each of its subnuclei projecting in an orderly fashion to a particular cortical area; it probably receives reciprocal connexions from these areas, but it should be noted that its connexions with *primary* sensory areas are sparse or absent. The pulvinar in particular establishes profuse connexions with Wernicke's speech area. This region of the thalamus has been implicated by different authors in such diverse activities as perception of chronic pain, oculomotor control, speech pattern control, and as a *polysensory data processor* involved in general '*gnosis*' (Ingram 1976).

THE 'NON-SPECIFIC' GROUPS OF THALAMIC NUCLEI

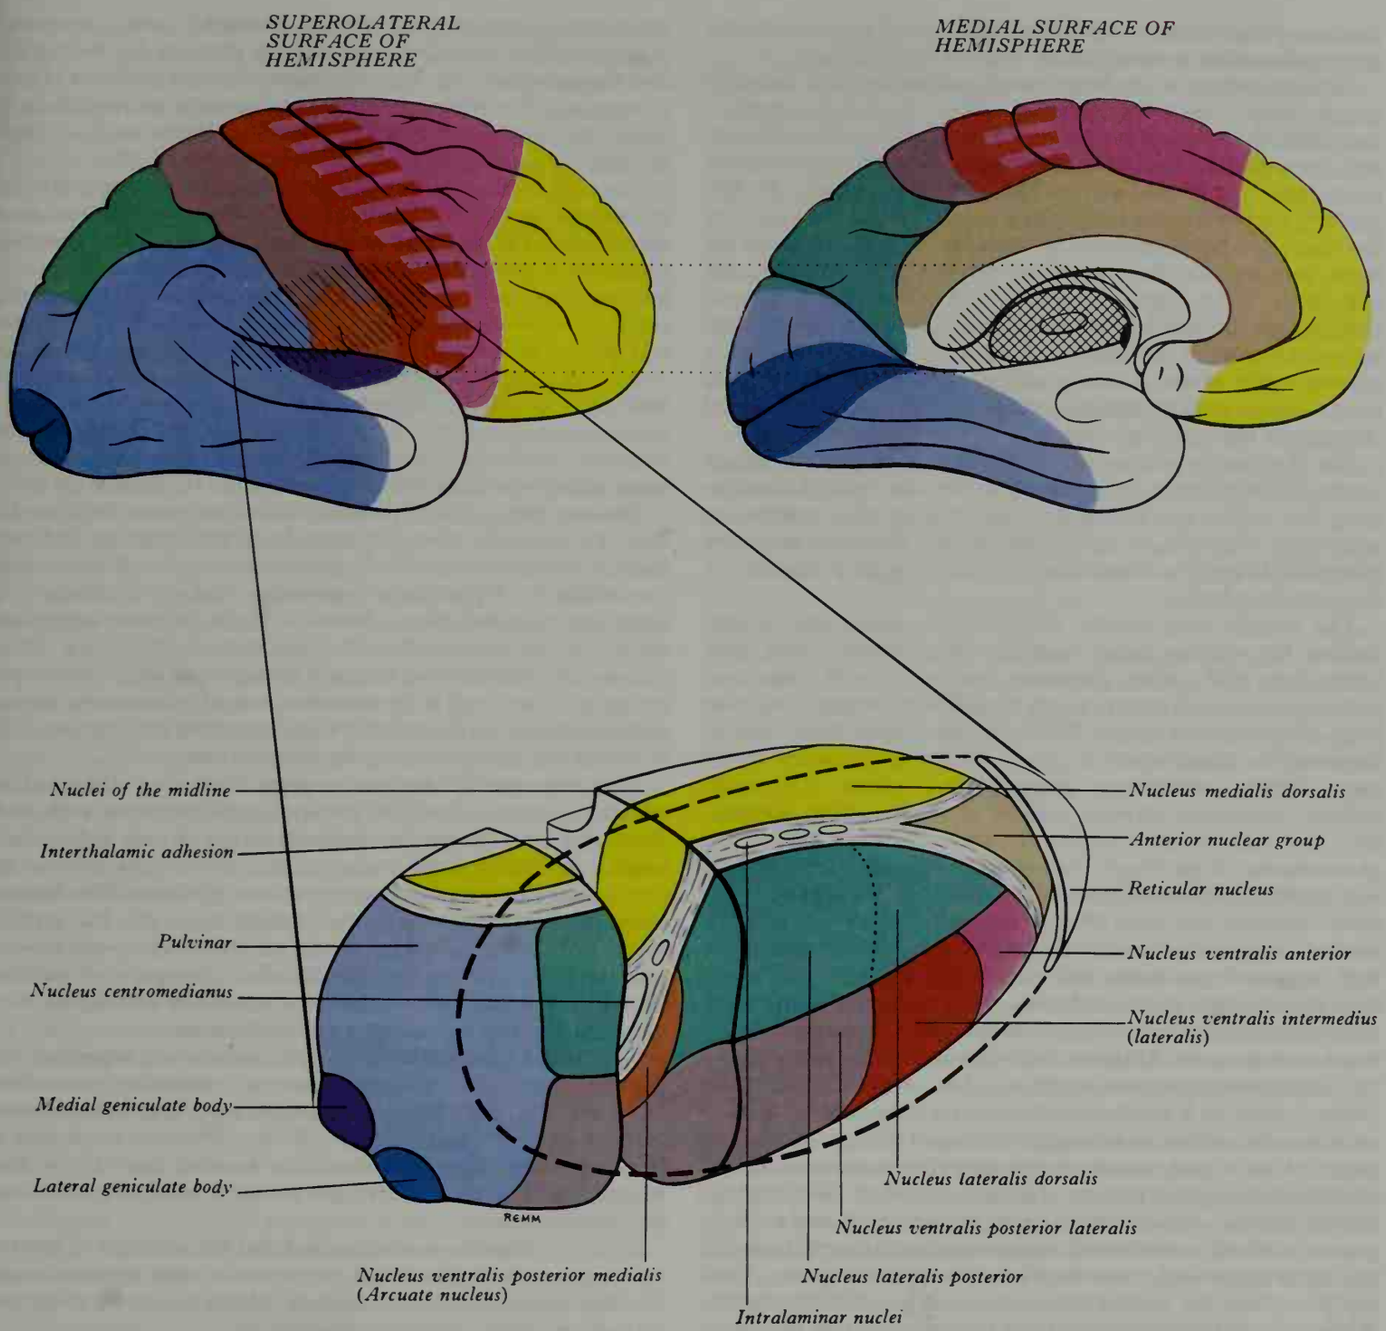
Since the recognition over a quarter of a century ago (Moruzzi and Magoun 1949) that stimulation or ablation of different regions of the brainstem reticular formation was followed by widespread changes in the state of synchronization or de-synchronization of electroencephalograms, attention has been focused upon possible cranially directed pathways from the reticular formation to the cerebral cortex. The suggestion soon followed that the brainstem reticular centres established profuse connexions with a series of thalamic nuclei from which proceeded a widespread *diffuse thalamocortical radiation* to virtually all parts of the cerebral cortex. Further, since stimulation of a number of these nuclei caused extensive, *bilateral* changes in cortical electrical activity, which were characterized by a slow onset and then a progressive build-up to a maximum, followed by fluctuations in level (recruitment)—the responses, and the nuclei themselves were called *non-specific*. It was widely assumed that the latter effects provided a background level of preparedness of the cortex which is necessary for the effective reception of the rapid, sharply localized ipsilateral, impulse patterns stemming from the larger *specific relay nuclei*, which have precise somatotopically organized thalamocortical and corticothalamic connexions. A large research literature has accumulated around this subject and, whilst many of the general concepts remain valid today, it is increasingly evident that the *reticulocortical pathways* involved are *multiple* and much more complex than originally envisaged, some involving extrathalamic pathways through the ventral diencephalon. Further, there is such extensive interaction between specific and non-specific parts of the thalamus that whilst the terms retain a general usefulness, and are so widely used that they will be retained here, it must not be assumed that they imply a sharp, separable distinction between two aspects of thalamic organization and function.

The non-specific nuclear groups are usually considered to include the intralaminar nuclei, the nuclei of the midline, and the reticular nucleus of the thalamus.

The Reticular Nucleus of the Thalamus

This is a thin curved sheet of cells situated between the white matter of the external medullary lamina and that of the posterior limb of the internal capsule. Accordingly, all the corticothalamic and thalamocortical fibres which run in the internal capsule pass through the territory of the nucleus.

The reticular nucleus was for long regarded as an important final link in the diffuse thalamocortical radiation mentioned above, because of widespread effects on cortical activity which follow stimulation of the nucleus, and the nuclear degeneration which follows experimental resection of the cerebral cortex. However, studies using the Golgi technique (Scheibel and Scheibel 1966) have shown that the axons of the cells in this nucleus run *caudally*, giving off a series of collateral branches to many of the thalamic nuclei and the midbrain reticular formation. The whole of the cerebral cortex projects in an orderly manner on to the reticular nucleus of the thalamus (Carman *et al.* 1964), and the degeneration which follows cortical resection is now thought to be transneuronal and not retrograde in type (Rose 1952). Other afferents to the nucleus are from the brainstem reticular formation, and the globus pallidus. Thus, afferents converge on the reticular nucleus from these various sources and its output is mainly to other thalamic nuclei both specific and non-specific.



The intralaminar nuclei include a number of small aggregations of grey matter (the *nuclei paracentralis, centralis lateralis* and *limitans*) and the much larger *nucleus centromedianus* (*vide infra*).

The nuclei of the midline form a complex and well-developed series in many mammals but are often poorly developed in man. Small but recognizable groups are sometimes to be found near the taenia thalami, the interthalamic adhesion when present, and others scattered in the periventricular wall. They will not be named and described individually here.

Because of their topography the non-specific nuclei are extremely difficult to investigate both anatomically and physiologically. In general, they are thought to receive the terminals of ascending fibres from the brainstem reticular formation, while some establish connexions with the corpus striatum, cerebellum, spinothalamic tracts, the hypothalamus, and many intrathalamic connexions with specific and non-specific nuclei on both sides of the midline. The most cranial of the non-specific nuclei project to the cerebral cortex including the phylogenetically older prepiriform and entorhinal cortices, together with the parieto-occipital and frontal regions of the neocortex. Clearly, much remains to be learned about the arrangement, connexions and significance of these nuclei.

The nucleus centromedianus, which is embedded in the white matter of the internal medullary lamina, only becomes a prominent structure in primates, and it is an easily recognized landmark in the human thalamus. Despite intensive investigation there has been much disagreement concerning its status and connexions.

However, the majority of investigators are now agreed that it is not connected with the cerebral cortex. A variety of ascending pathways have been described as ending partly in this nucleus; these include collaterals or terminals from a small proportion of the fibres of the spinal, medial and trigeminal lemnisci, ascending reticulothalamic fibres, and a contribution from the superior cerebellar peduncle. However, its main connexions are with parts of the corpus striatum, some of which are topically organized, and other profuse interconnexions are with the remaining non-

7.101 The main nuclear masses of the dorsal thalamus (below) have been labelled and colour coded, and the same colours have been used to indicate the areas of cerebral neocortex interconnected with these nuclei. The lack of colour in the centromedian, intralaminar and reticular nuclei, and in restricted areas of the frontal and temporal lobes are *not* related to the colour code. The boundaries of the coloured cortical zones may well need revision in the future as experimental and pathological data accumulate.

specific nuclei on both sides of the midline, and also with some 'specific' nuclei, particularly the nucleus ventralis anterior.

Further connexions of the dorsal thalamus. All the connexions of the dorsal thalamus mentioned in the previous pages were established by the older neuroanatomical and neurophysiological techniques. However, data are now accumulating rapidly in a variety of mammals with the advent of the newer tracing techniques (p. 819) and in particular, the methods for locating the somata and neurites of cholinergic and monoaminergic neurons. These were treated in some detail in the section devoted to 'The Reticular Formation' (pp. 943–953) and will merely be mentioned here. The *dorsal tegmental ascending cholinergic bundle* provides terminals for the nuclei of the geniculate bodies, the dorsally and anteriorly situated nuclear groups of the dorsal thalamus, and additionally, terminals are found in the midline and intralaminar nuclei, especially the nucleus centromedianus. The *ventral tegmental ascending cholinergic bundle* also provides terminals for the ventrally and anteriorly situated nuclear groups. The *dorsal ascending noradrenergic bundle* provides an afferent innervation to many, perhaps all, the nuclei of the dorsal thalamus. *Dopaminergic neuron cell aggregate* A11 sends fine axons that weave through, and terminate in, the nuclei of the midline, whilst aggregates A13 and 14 similarly innervate the caudal nuclei of the dorsal thalamus. The *ventral ascending serotonergic bundle*, in addition to many other destinations, provides axons that innervate the medial nuclear group, the nuclei of the midline, and the parafascicular nucleus. For brief comments on fibres containing met-enkephalins, endorphins, substance P, and the distribution of opiate receptor sites, *see* pp. 833, 951, 962. The functional roles of these multiple varieties of fibre converging on the dorsal thalamus are not clear at present, and progress in this field will be awaited with great interest.

SUMMARY

Clearly, the dorsal thalamus is a region of immense structural complexity and of outstanding functional significance, but

despite a voluminous research literature we still possess only the most rudimentary concepts of its mode of functioning.

Most prominent is the large number of information channels which *converge* upon the thalamus where, through the profuse intrathalamic connexions, many are *integrated*, i.e. they interact, and the resulting information patterns, now of much greater range and complexity, *diverge* to many destinations. In this manner, the thalamus is essentially involved in the activities of *all* the major subregions of the central nervous system. Thus, all the main sensory systems (with the exception of the olfactory pathways), most regions of the cerebral cortex, the corpus striatum, cerebellum, hypothalamus, subthalamus and brainstem reticular formation all send fibre systems which converge on various nuclei of the thalamus and metathalamus, and in turn, most of these cortical and subcortical centres receive reciprocal connexions from the thalamus.

The thalamus is not essential for olfactory perception, which occurs in the primary and secondary olfactory cortical areas (p. 995), but higher order olfactory information, after integration with other channels, is transmitted to the thalamus from the amygdaloid complex, the piriform lobe, and the hippocampus via the mamillary body.

The specific relay nuclei, including the geniculate bodies, receive the various major sensory tracts where, often after interaction with other channels, somatotopically organized thalamocortical radiations pass to the different sensory receiving areas of the cerebral cortex. Reference has already been made to the complex transformations in the flow of information which occur during transmission through these nuclei. The latter include interaction between parallel and converging channels, pre- and post-synaptic facilitatory and inhibitory effects, the phenomenon of inhibitory 'surround' with neural sharpening, and the modulation of transmission which follows activity in the corticothalamic and other fibre systems which converge upon the nucleus in question. Some of the thalamocortical fibres preserve a high degree of specificity with respect to single modalities and their site of origin in the periphery, whilst others transmit more complex orders of information derived from the convergence of a number of channels. Ablation of the thalamocortical radiations to the somatosensory cortex results in a loss or diminution of the ability to localize a tactile stimulus, and an impairment of two-point discrimination, and the appreciation of texture, weight and shape of an object (*astereognosis*) and the assessment of the position or movement pattern of a bodily segment. Nevertheless, knowledge that contact with an object has occurred, and a rough, poorly localized awareness of pain-evoking and thermal stimuli, still occurs, provided the thalamic mechanisms are intact. (For a general review on somaesthetic pathways *see* Webster 1976.) Whilst it is clear that some form of pain appreciation can occur after loss of the cerebral cortex, the degree to which the cortex is involved in an intact nervous system has still not been solved (Albe-Fessard and Delacour 1968). Disease in the lateral or central thalamus is sometimes followed by sudden apparently 'spontaneous' attacks of an unexplained type of *thalamic pain*. Paradoxically, in addition to spinal, medullary, or mesencephalic tractotomy as surgical measures for the relief of pain, selective thalamotomy with ablation of either the nucleus ventralis posterior and surrounding regions, or of the intralaminar nuclei including the nucleus centromedianus, has sometimes been effective in pain relief. In summary, therefore, it appears that the VPL and VPM, the so-called PO group (including areas of the medial geniculate, suprageniculate and intralaminar nuclei), the nucleus centromedianus, probably the nucleus dorsalis medialis and pulvinar, together with many hypothalamic nuclei, the globus pallidus and caudate nucleus of the corpus striatum, and limbic structures such as certain amygdaloid nuclei and the bed nucleus of the stria terminalis, are all involved in pain appreciation, but how they cooperate in this activity remains obscure. It may be recalled that many of these regions (including laminae I, II, and V of the spinal cord grey matter, the lateral reticular nucleus, the nucleus ambiguus, and nucleus of the solitary tract in the medulla, areas of the mesencephalic periaqueductal grey and of the pars compacta of the substantia nigra) are all in receipt of monoaminergic (particularly serotonergic), and met-enkephalin, endorphin, and substance P containing fibres and terminals, and the proposal has been made that these cooperate in the modulation of the mechanisms of pain perception. (For reviews on spinal mechanisms *see* Nathan 1977, 1978; Wall 1978; and for general reviews, Basbaum *et al.* 1976; Webster 1976, 1978; Snyder, in: Reichlin *et al.* 1978.)

The rich interconnexions of the nucleus dorsalis medialis with the frontal cortex, hypothalamus, and other specific and non-specific thalamic nuclei has already been described. It is generally regarded as the principal centre for the complex *integration of visceral and somatic functions*. Through its hypothalamic connexions it is importantly involved in a wide array of autonomic and endocrine activities. It appears to be concerned with the emotional content, subjective feeling states, and identification of 'self'; as mentioned, ablation or disease in the nucleus causes changes in personality, drive, intellectual performance, emotional level etc., and indifference to pain, changes which are similar in some respects to those following ablation of the frontal cortex.

The anterior group of thalamic nuclei integrates the complex flow of information along the mamillothalamic tract derived from many visceral pathways, the hypothalamus, and limbic structures (including the hippocampus, amygdala and septal areas), with that from other thalamic nuclei and from the cingulate cortex, and the group has reciprocal connexions with these centres. These circuits are important in complex homeostatic mechanisms and are possibly involved in the establishment of recent memory, and in determining the balance between 'repetitive and stereotyped', or 'novel and exploratory' forms of behaviour.

The non-specific nuclear groups (including the nucleus ventralis anterior) establish profuse interconnexions with each other and with the specific thalamic nuclei of both sides. They receive an input from many of the sensory pathways, the cerebellum and corpus striatum, and through their diffuse cortical projections they exert a powerful effect upon the background activity levels in wide areas of the cerebral cortex—the *arousal reactions*. The latter particularly affect the parietal, orbital, cingulate and occipital association areas of the cortex, the most marked responses being in the prefrontal areas.

The nuclei ventralis anterior and lateralis are important cell stations where outflows from the corpus striatum and cerebellum interact with those from other thalamic nuclei, and then project on to the motor and premotor cortices. They are important in locomotor control, and it should be recalled that the nucleus ventralis anterior shows features common to both specific and non-specific nuclei.

Finally, it must be re-emphasized that the activities of most of the major regions of cerebral cortex are in some measure under thalamic influence, whilst information from the cortex converges on to the majority of the thalamic nuclei.

The Epithalamus—Pineal Gland and Habenula

The epithalamic structures, as stated previously, occupy the caudal roof of the diencephalon together with adjacent areas on the side walls of the third ventricle (7.95). They include the right and left *habenular nuclei*, each situated deep to the floor of a *habenular trigone*, and each receives the termination of a complex fibre bundle, the *stria medullaris thalami*. The epithalamus also includes the midline *pineal gland* or epiphysis cerebri, and the *habenular* and *posterior commissures*, which cross the midline in the cranial and caudal laminae of the pineal stalk. The development of the pineal gland is briefly mentioned on p. 169, and its structure and possible neuroendocrine roles on p. 1445, together with some proposals concerning its nerve supply.

The *trigonum habenulae* is, as its name suggests, a small triangular surface depression on each side, situated cranial to the superior colliculus and medial to the pulvinar of the thalamus from which it is separated by the *sulcus habenulae*. The trigone is bounded rostromedially by the caudal end of the ridge occupied by the stria medullaris thalami and by the pineal stalk.

The habenular nucleus, sometimes regarded as consisting of medial and lateral parts, is a station on some of the olfactory reflex

pathways, and is probably closely concerned with one of the sources of innervation of the pineal gland. A number of connexions have been described but their complete pattern is still uncertain. Many *afferents to the nucleus* run in the *stria medullaris thalami* which is formed near the anterior pole of the thalamus. These include connexions from the amygdaloid complex of nuclei via the stria terminalis (p. 996), and from the hippocampal formation via the fornix (p. 1001). Other components of the stria are from the olfactory tubercle, anterior perforated substance, the preoptic and septal areas and various hypothalamic nuclei. Direct tectohabenular fibres from the superior colliculi have been described.

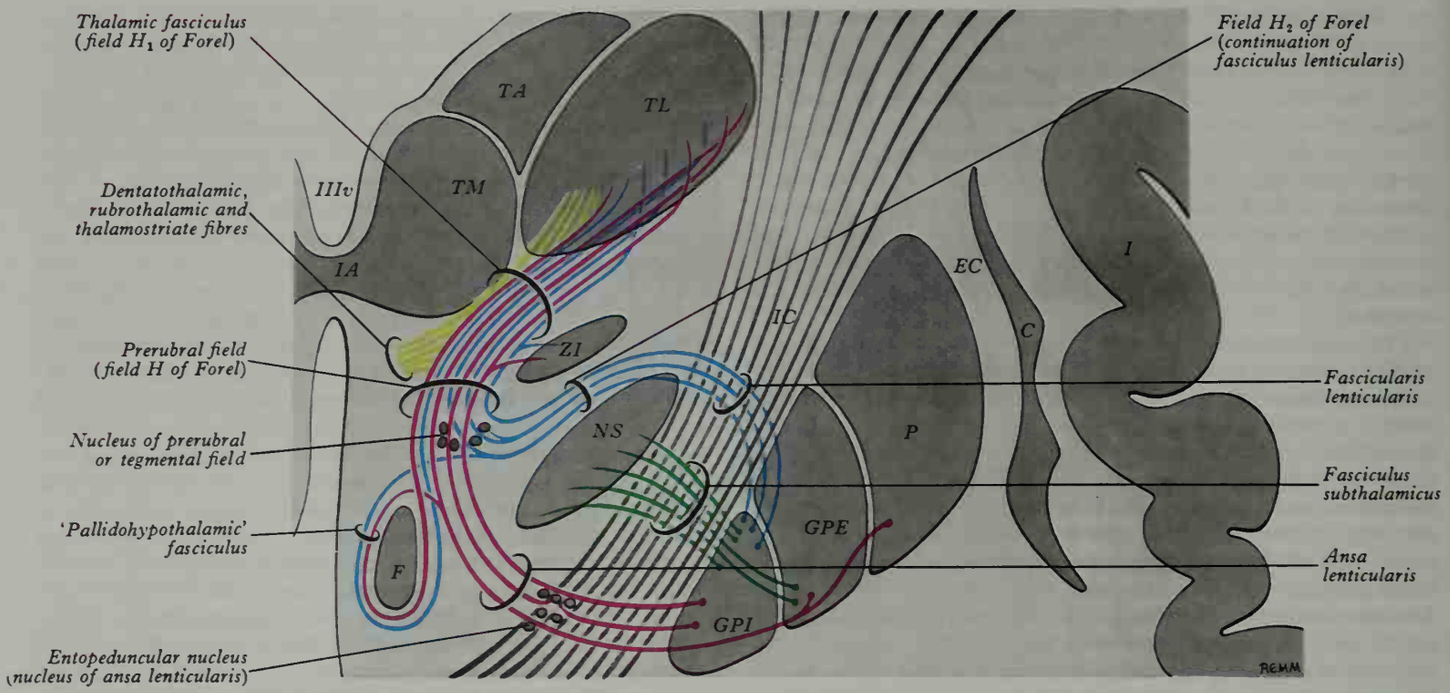
The stria medullaris courses across the superior part of the medial surface of the thalamus, skirts the medial margin of the trigonum habenulae, and many of the fibres end in the ipsilateral nucleus habenulae. Others, however, cross the midline in the cranial leaflet of the pineal stalk, interlacing with their fellows to form the *habenular commissure*, so reaching the contralateral habenular nucleus. Some of the fibres which also follow this route are truly commissural and interconnect the amygdaloid complexes and the hippocampal cortices of the two sides; crossed tectohabenular fibres accompany them in the commissure. Additional afferent axons that provide terminals for the habenular nuclei are 5-hydroxytryptamine-containing fibres derived from the *ventral ascending tegmental serotonergic bundle* that join the habenulopeduncular tract (*vide infra*) and pass, in the opposite direction to its main contingent of fibres, to reach the nuclei. Thus, these fibres may be involved in exerting some control over the habenular neurons that give origin to the *habenulopineal tract*, thereby influencing the activity of the innervation of the pinealocytes (*see* p. 1445). Similar remarks apply to habenular nuclear innervation by fine fascicles from the *dorsal ascending tegmental noradrenergic bundle* (pp. 940, 949).

Thus, although the habenulae are relatively small in man, they provide a nodal point for the integration of a considerable variety of olfactory, visceral and somatic afferent pathways.

The main outflow paths from the habenular nuclei pass to the interpeduncular nucleus, the nucleus medialis dorsalis of the thalamus, the tectum, and to the reticular formation of the midbrain tegmentum. The largest of these paths constitutes the *habenulopeduncular tract*—often known as the *fasciculus retroflexus* (of Meynert) (7.103). The latter courses rostroventrally, skirts the caudal zone of the nucleus medialis dorsalis of the thalamus, and then passes through the rostromedial part of the red nucleus to reach the interpeduncular nucleus from which nerve fibres relay to the midbrain reticular formation. From these centres, descending fibres such as the tectotegmentospinal tracts and the dorsal longitudinal fasciculi ultimately connect with the autonomic preganglionic centres through which control of salivation, gastric and intestinal secretory activity and motility are effected, and others pass to the motor centres for the muscles concerned in mastication and swallowing. It should also be noted that ablation of the habenular complexes in experimental animals leads to extensive changes in metabolism, endocrine regulation and thermo-regulation (Szentágothai *et al.* 1962).

The posterior commissure is a complex fibre bundle which crosses the midline in the caudal lamina of the pineal stalk. Its size is relatively reduced in primates and its fibre constitution is imperfectly known in man. It acquires its myelin sheaths early, and some estimates of the number of fibres in different specimens of the commissure have been made (Tomasch and Malpass 1958). Various nuclei are associated with the commissure—small groups scattered along its length and sometimes called the *interstitial nuclei of the posterior commissure*, accumulations in the periventricular grey matter which constitute *dorsal nuclei of the posterior commissure*, the *nucleus of Darkschewitsch* in the cranial part of the periaqueductal grey matter, and the *interstitial nucleus* (of Cajal) situated near the rostral end of the oculomotor nucleus and closely linked with the medial longitudinal fasciculus (p. 939). Fibres from all these nuclei, and continuations from the medial longitudinal fasciculus all cross the midline in the posterior commissure. Other centres which contribute fibres to the commissure include the posterior thalamic nuclei, the pretectal nuclei, the superior colliculi, and connexions between the tectum and habenular nuclei. The precise destinations and functional significances of many of these bundles in the human brain are incompletely understood and will not be discussed further here.

Caudal and ventral to the commissure (i.e. in close relation to the caudal wall of the pineal recess), the ependymal cells lining the dorsal aspect of the cerebral aqueduct are specialized, being tall, columnar and ciliated, with a granular basophilic cytoplasm and characteristic histochemical reactions. This patch of cells, which are possibly secretory, with their products passing into the cerebrospinal fluid, is sometimes termed the *subcommissural organ* (Keene and Hewer 1935; Wislocki and Leduc 1953; Møllgård *et al.* 1973). They may also be involved in the transport of materials, gained from neighbouring nerve terminals or blood capillaries, to the cerebrospinal fluid. Alternatively, substances taken up from the cerebrospinal fluid may be transported to more deeply placed nerve cell somata, blood vessels or pinealocytes (*see* p. 969, and cf. the infundibular recess of the third ventricle—pp. 966, 1445). For a review of the possible neuroendocrine role of specialized ependymal cells (tanycytes) *see* Knowles (1974); a number of references throughout Reichlin *et al.* (1978) and especially, Joseph and Knigge (1978). It may also be noted here that in addition to the specialized ependyma of the median eminence and infundibular recess, and that of the subcommissural organ, another patch of similarly specialized ependyma projects towards the cavity of the third ventricle from its anterior wall between the diverging columns of the fornix; it is called the *subfornical organ*, or the *intercolumnar tubercle*. These (and in some vertebrates, other) various specialized regions of the lining of the third ventricle are sometimes collectively termed the **circumventricular organs**.



The Ventral Thalamus or Subthalamus

As mentioned previously, the pars ventralis diencephali, which lies caudoventral to the hypothalamic sulcus, may be divided on phylogenetic, ontogenetic and functional grounds into a *hypothalamus* and a *ventral thalamus* or *subthalamus*. The hypothalamus, which includes the structures forming the floor of the third ventricle as far caudally and including the mamillary bodies, together with the structures embedded in the rostroventral side wall of the ventricle, will be described in a later section. The remainder of the pars ventralis diencephali constitutes the subthalamus. It merges caudally with the tegmentum of the midbrain, and the rostral extensions of the substantia nigra and red nucleus project into the caudal subthalamus, whilst important fibre tracts ascend and descend between the two regions (7.103). Dorsally, the subthalamus adjoins the ventral nuclei of the dorsal thalamus, whilst rostromedially it is bounded by the various subdivisions of the hypothalamus (7.100). Ventrolaterally and directly laterally, the subthalamus is in contact with the expanding and rotating junctional zone where the cerebral peduncle merges into the internal capsule; and the latter separates the subthalamus from the medial aspect of the globus pallidus of the lentiform nucleus.

The main aggregations of nerve cells in the subthalamus are: (1) the rostral end of the red nucleus; (2) the rostral end of the substantia nigra; (3) the nucleus subthalamicus; (4) the zona incerta; (5) the nucleus of the prerubral or tegmental field; and (6) the entopeduncular nucleus or nucleus of the ansa lenticularis.

The main tracts of nerve fibres in the subthalamus are: (1) the rostral ends of the medial, spinal and trigeminal lemnisci and the solitariothalamic tract, as they approach their terminations in the thalamic nuclei; (2) the dentatothalamic tract from the opposite superior cerebellar peduncle accompanied by ipsilateral rubrothalamic fibres; (3) the fasciculus retroflexus; (4) the fasciculus lenticularis; (5) the fasciculus subthalamicus; (6) the ansa lenticularis; (7) the fibre aggregates of the prerubral field (the H field of Forel); (8) the continuation of the fasciculus lenticularis (in the H_2 field of Forel); and (9) the fasciculus thalamicus (the H_1 field of Forel).

The topographical neuroanatomy of the subthalamus is rather complex and is best understood by reference to *three-dimensional* models and closely graded series of coronal and sagittal sections in

7.102 A diagram of the nuclear masses of grey matter and fibre tract systems associated with, or closely related topographically to, parts of the dorsal thalamus, subthalamus and globus pallidus. The information presented is compounded from a series of closely spaced coronal sections through this region, attempts being made to include what are essentially three-dimensional structures in a two-dimensional diagram; it must be emphasized that all the structures shown would not appear on the same single coronal section. The significance of the letters is as follows: IIIv—third ventricle; M—medial nuclear group of thalamus; TA—anterior nuclear group of thalamus; TL—lateral nuclear group of thalamus; IA—interthalamic adhesion; ZI—zona incerta; F—column of fornix; NS—nucleus subthalamicus; IC—internal capsule; GPI and GPE—internal and external parts of globus pallidus; P—putamen; EC—external capsule; C—claustrum; I—cortex of insula.

the practical laboratory; a parallel study of the corpus striatum (p. 1032) from which a number of the prominent subthalamic tracts are derived is also helpful. Illustration 7.102 may assist with the complicated terminology of the region, but the topography can only be appreciated in part from such a *two-dimensional* diagram.

As the rostral ends of the red nucleus and the substantia nigra pass into the caudal part of the subthalamus they gradually diminish in cross-sectional area to terminate a little caudal to the mamillary bodies. The changing relationship of the lemnisci to the red nucleus and substantia nigra as they ascend through the midbrain has already been described. The lemniscal fibres enter the subthalamus largely lateral to the red nucleus, and as they continue to ascend they pass on to the dorsal aspect of the nucleus to reach the inferior surface of the nucleus ventralis posterior of the thalamus, in which the majority of their fibres terminate. Dentatothalamic and rubrothalamic fibres run in company with pallidothalamic fibres and form part of the thalamic fasciculus, which passes cranial to the termination of the lemnisci noted above to distribute largely to the nuclei ventralis intermedius and anterior of the thalamus (*see* pp. 959, 962, and below for further description).

The nucleus subthalamicus does not occur in sub-mammalian forms, is small in most mammalian groups, and is prominent only in primates. In man the nucleus is an aggregation of medium to large multipolar neurons and classically described as of the general shape of a biconvex lens when seen in coronal sections. It lies in the caudal subthalamus, but extends into the junctional zone of subthalamus and midbrain tegmentum, where it lies dorsolateral to the cranial end of the substantia nigra and lateral to the cranial margin of the red nucleus. The subthalamic nucleus is closely related to the medial aspect of the internal capsule, which separates it from the globus pallidus of the corpus striatum. Medially, the subthalamic nucleus abuts upon the hypothalamic region, whilst dorsally it is separated from the ventral nuclei of the thalamus by a thin strip of grey matter, the zona incerta, which is interposed between complex fibre bundles, the continuation of the fasciculus lenticularis, and the thalamic fasciculus (7.102, and *vide infra*).

The connexions of the nucleus subthalamicus are numerous, some being well-established, whilst considerable uncertainty attaches to the remainder. The principal connexions are with the corpus striatum; two-way fibre systems pass by a number of routes between the globus pallidus and the subthalamic nucleus. Interconnexions with the putamen and caudate nucleus have also been described but are less well documented. The other connexions reported include ones with the opposite subthalamic nucleus and globus pallidus, and with the ipsilateral red nucleus, substantia nigra, the reticular formation of the midbrain tegmentum, the zona incerta and other small nuclei in the subthalamus, various hypothalamic and thalamic nuclei, and possibly with regions of the cerebral cortex. Recently, it has been demonstrated that some of the afferent fibres to the nucleus subthalamicus are derived from the *ventral ascending tegmental cholinergic pathway*, and probably from the *incerto-hypothalamic dopaminergic system*; their specific functional roles remain enigmatic.

The subthalamic nucleus is clearly an important site for the integration of a number of motor control centres, but particularly through its connexions with the corpus striatum and midbrain tegmentum. Relatively discrete lesions of one subthalamic nucleus in man result in the condition of *hemiballismus*, with uncontrollable, violent, torsional movements, choreiform in type, affecting the contralateral side of the body. The movements, which often continue for long periods, usually affect the proximal musculature of one or both limbs and may mimic throwing or kicking; but facial and trunk muscles may also be involved, though with a much lower incidence. Interestingly, unlike most of the other *dyskinesias*, hemiballismus can be reproduced in the experimental animal; in the monkey the condition follows surgical ablation of at least one-quarter of the subthalamic nucleus, provided the surrounding fibre systems associated with the globus pallidus are preserved intact. The hemiballismus so generated is unaffected by ablation of the rubrospinal, vestibulospinal and reticulospinal tracts, or area 6 of the cerebral cortex, but the condition *is* abolished by ablation of the globus pallidus or its outflow tracts, the nucleus ventralis anterior of the thalamus, Area 4 of the cerebral cortex or the corticospinal tract. It is assumed, therefore, that the subthalamic nucleus exerts an inhibitory form of control on the globus pallidus, and therefore on its main outflow pathway via the thalamus to the motor cortex, the

principal origin of the crossed corticospinal tract (Whittier and Mettler 1949; Carpenter 1950; Carpenter *et al.* 1950, 1951, 1958, 1960).

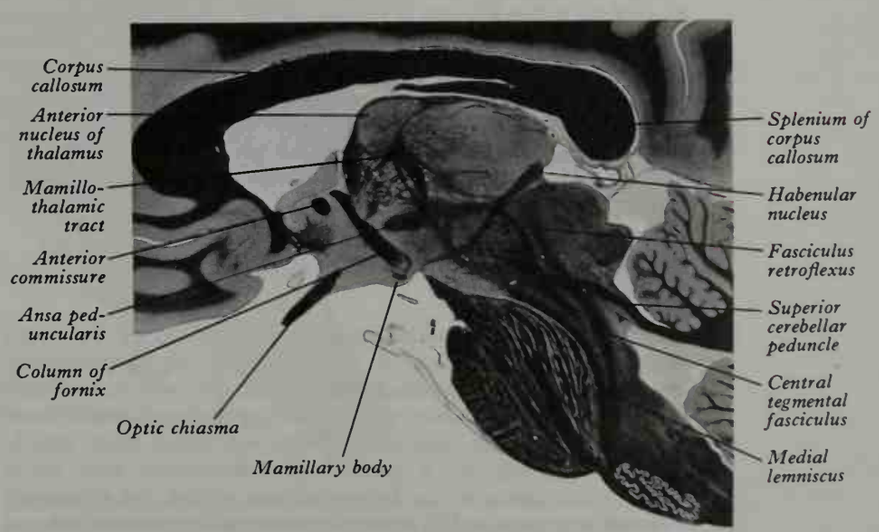
The zona incerta is a thin lamina of grey matter interspersed with fine fibre bundles which extends throughout most of the diencephalon a little ventral to the thalamus but separated from it by the fibres of the thalamic fasciculus (*vide infra*). Laterally the zone is continuous with the reticular nucleus of the thalamus, whilst ventrally it is in apposition with fibres of the fasciculus lenticularis (*vide infra*). Functionally associated with the zona incerta are scattered groups of neurons along its caudomedial border which constitute the *nucleus of the prerubral* or *tegmental field*, and other groups interspersed between the fibre bundles of the ansa lenticularis (*vide infra*), which some authorities regard as 'detached' parts of the globus pallidus and which constitute the *entopeduncular nucleus*. These various cell groups are to be regarded in the main as stations on discharge pathways from the globus pallidus to the reticular formation in the tegmentum of the midbrain, some of the descending fibres running with the central tegmental fasciculus as far as the inferior olivary complex of nuclei (p. 904); numerous side-fascicles leave these descending bundles to innervate many of the 'reticular' and 'non-reticular' brainstem nuclei. Additionally, fibres descending from the cerebral cortex to terminate in the zona incerta have been described, and these various subthalamic nuclear masses probably also interconnect with the main subthalamic nucleus, the intralaminar and ventral nuclei of the thalamus, and with the red nucleus. The zona incerta has recently been shown to receive terminals from the *ventral tegmental ascending cholinergic pathway*, and to be involved in the *incerto-hypothalamic dopaminergic system* (pp. 948, 949). Much remains to be learned concerning their functional significance.

In addition to the termination of the lemniscal systems and that of the dentatothalamic and rubrothalamic tracts (p. 959), the subthalamus is characterized by a series of bundles of white fibres, often interspersed with small groups of neurons. The fibre constitution of these bundles and their topography is complex, and a number of rather confusing and sometimes conflicting terminologies have been proposed. One approach, adopted here, is to consider the various bundles in relation to the main fibre systems which flow out of the corpus striatum (their relationships to that organ are further discussed on p. 978). The various fibre bundles derived in part from the putamen, but predominantly from the globus pallidus, appear at the surfaces of the latter, from which they diverge medially in a fan-shaped radiation. The dorsal and intermediate fibres of the fan intersect with the fibres of the internal capsule, whilst the ventral fibres curve around the caudoventral border of the capsule. Earlier investigators (von Monakow 1882) termed the whole radiation the ansa lenticularis and considered it to consist of dorsal, intermediate and ventral divisions. The term ansa lenticularis is, however, now restricted to the ventral division, the intermediate division is termed the fasciculus subthalamicus, whilst the dorsal division is termed the fasciculus lenticularis (*see* 7.102 for an outline of these relationships).

The fasciculus lenticularis consists of the dorsal bundle of pallidofugal fibres which pass through the internal capsule, intersecting with its fibres, from lateral to medial side. They then course medially, closely related to the medial aspect of the internal capsule, and partly intermingled with the dorsal aspect of the subthalamic nucleus and the ventral aspect of the zona incerta; in this part of its course the fasciculus traverses what is sometimes called the H_2 *field of Forel*. Having reached the medial border of the zona incerta, the fibres of the fasciculus lenticularis meet and intermingle with the fibres of the ansa lenticularis, with the scattered cell groups of the nucleus of the prerubal field, and also with bundles of dentatothalamic and rubrothalamic fibres. This zone of merging of diverse fibre pathways and associated cell groups, is variously called the *prerubral, tegmental,* or *H field of Forel*.

The ansa lenticularis has a complex origin from both parts of the globus pallidus, the putamen and possibly other neighbouring centres; its fibres partly relay in scattered cell groups along its course—the *entopeduncular nucleus*. The fibres of the ansa curve medially around the ventral border of the internal capsule and then continue to curve dorsomedially until they meet and become admixed with the other fibre systems mentioned above in the prerubral field. A number of the fibres in both the fasciculus and ansa lenticularis synapse with cells in the nucleus subthalamicus, the nucleus of the prerubral field and the zona incerta, whilst the remainder continue in company with the other fibre bundles, and then loop laterally and cranially to reach a number of thalamic nuclei, particularly nuclei ventralis anterior, intermedius and centromedianus.

The thalamic fasciculus is the complex bundle of fibres which extends from the prerubral field, passing dorsal to, but also partly traversing, the zona incerta, and related dorsally to the ventral nuclear groups of the thalamus. It contains the continuation of the fasciculus and ansa lenticularis just described, dentatothalamic and rubrothalamic fibres, and, running in the opposite direction, bundles of thalamostriate fibres. Another name often used for the territory occupied by the thalamic fasciculus is the H_1 *field of Forel*.



The 'pallidohypothalamic' fasciculus is the name commonly given to a bundle of fibres which leaves the main pallidofugal system in the prerubral field and then pursues a curious course, curving ventromedially around the column of the fornix to approach the hypothalamus (Bard and Rioch 1937; Vidal 1940; Ingram 1940), where it was for long widely assumed to terminate in its dorsomedial nucleus. However, there is no conclusive evidence for a hypothalamic termination, and more recent experiments in the monkey (Nauta and Mehler 1966) indicate that the bundle recurves yet again, passing laterally below the column of the fornix, and then dorsally to rejoin the main system of fibres in the H_1 field of Forel.

The fasciculus subthalamicus comprises the profuse two-way array of fibres which passes through the internal capsule, interdigitating at right angles with its main fibre systems, to interconnect the nucleus subthalamicus with the globus pallidus, and to a lesser extent with the putamen.

Some of these connexions will be mentioned again in the description of the basal ganglia (pp. 1033 *et seq.*).

The Hypothalamus

The general position and extent of the hypothalamus has been considered previously (p. 953). In the present account it will be assumed to extend from the lamina terminalis to a vertical plane caudal to the mamillary bodies, and from the hypothalamic sulcus, to include the structures in the ventral side-wall and floor of the third ventricle. Strictly, the most cranial part of this region,

7.103 Sagittal section of the right cerebral hemisphere through the mamillary body, viewed from the left. Myelin stain. The fasciculus retroflexus is seen crossing the medial side of the red nucleus, which is surrounded by a capsule of white fibres derived chiefly from the superior peduncle. (After C. Foix and J. Nicolesco, *Anatomie cérébrale*, Paris, 1925.)

the preoptic area, belongs to the telencephalon impar, but is included for functional reasons. *Lateral* to the hypothalamus lies the rostral part of the subthalamus, the internal capsule and the optic tract; *caudally* the hypothalamus abuts on the tegmental part of the subthalamus which is continuous caudally with the tegmentum of the midbrain; *dorsal* to the hypothalamus lie the various nuclei of the dorsal thalamus; *rostrally* the optic chiasma, lamina terminalis and the anterior commissure separate the preoptic area from the precommissural septum, i.e. the continuation of the diagonal band of Broca into the paraterminal gyrus (p. 995), anterior to which lies the parolfactory gyrus. As mentioned previously, however, these topographical 'boundaries' are arbitrary, and functionally continuous systems cross many of them.

The structures which form the floor of the third ventricle extend to the free surface of the brain in the **interpeduncular fossa** (7.104) and consist, rostrocaudally, of: (1) the optic chiasma; (2) the tuber cinereum with its eminences, and the stalk of the infundibulum; (3) the mamillary bodies; and (4) the posterior perforated substance which is not usually included in the hypothalamus, but is included here for convenience.

The posterior perforated substance is a small depressed area of grey matter which lies in the caudal part of the interval between the diverging crura cerebri. It is pierced by a number of small apertures which transmit the central branches of the posterior arteries. Deep to its floor lies the *interpeduncular nucleus*, a relatively small structure in man which is homologous with a much more extensive nuclear complex in submammalian forms. It receives the curiously looped terminals of the fibres of the fasciculus retroflexus (p. 963) of both sides, and establishes further connexions with the reticular formation of the midbrain tegmentum and with the mamillary bodies.

The mamillary bodies are a pair of smooth, hemispherical masses, each about the size of a small pea, placed side by side in the floor of the interpeduncular fossa just rostral to the posterior perforated substance. Each is enclosed by bundles of white fibres derived in large part from the column of the fornix; internally are a number of aggregations of grey matter; these and their connexions are described further below.

The tuber cinereum lies rostral to the mamillary bodies and caudal to the optic chiasma. It is, as its name suggests, a convex mass of grey matter when viewed from its inferior aspect, but it is not a completely smooth convexity, its surface presenting a series of eminences with intervening grooves which vary in their prominence. In the midline caudal to the optic chiasma, the hollow, conical **infundibulum** proceeds ventro-inferiorly to become continuous with the solid expanded posterior lobe of the hypophysis cerebri (p. 1438). The tuber cinereum around the base of the infundibulum is raised to form a **median eminence** which, however, is superficially marked by a shallow *tuberoinfundibular sulcus* along their lines of junction. The tuber cinereum, also presents a pair of **lateral eminences** and a midline **postinfundibular eminence**, whilst caudolaterally, on each side, a row of two or three minute *hillocks* project into the shallow groove between the tuber cinereum and the mamillary bodies.

7.104 The interpeduncular fossa and surrounding structures. Note from above downwards: (1) the gyri recti of the frontal lobes, and the olfactory tracts, trigones and anterior perforated substances; (2) the optic nerves, chiasma and diverging optic tracts which disappear beneath the medial borders of the unci hippocampi; (3) the tuber cinereum with the attached superior part of the infundibular stem; (4) the mamillary bodies; (5) the deep recess between the mamillary bodies, the diverging crura cerebri and the cranial border of the pons, the floor of which is the posterior perforated substance; (6) on each side the prominent oculomotor nerves, more laterally the slender trochlear nerves, and bordering the pons, the thick trigeminal nerves are visible. (Dissection by Dr. E. L. Rees. Dept. of Anatomy, Guy's Hospital Medical School.)

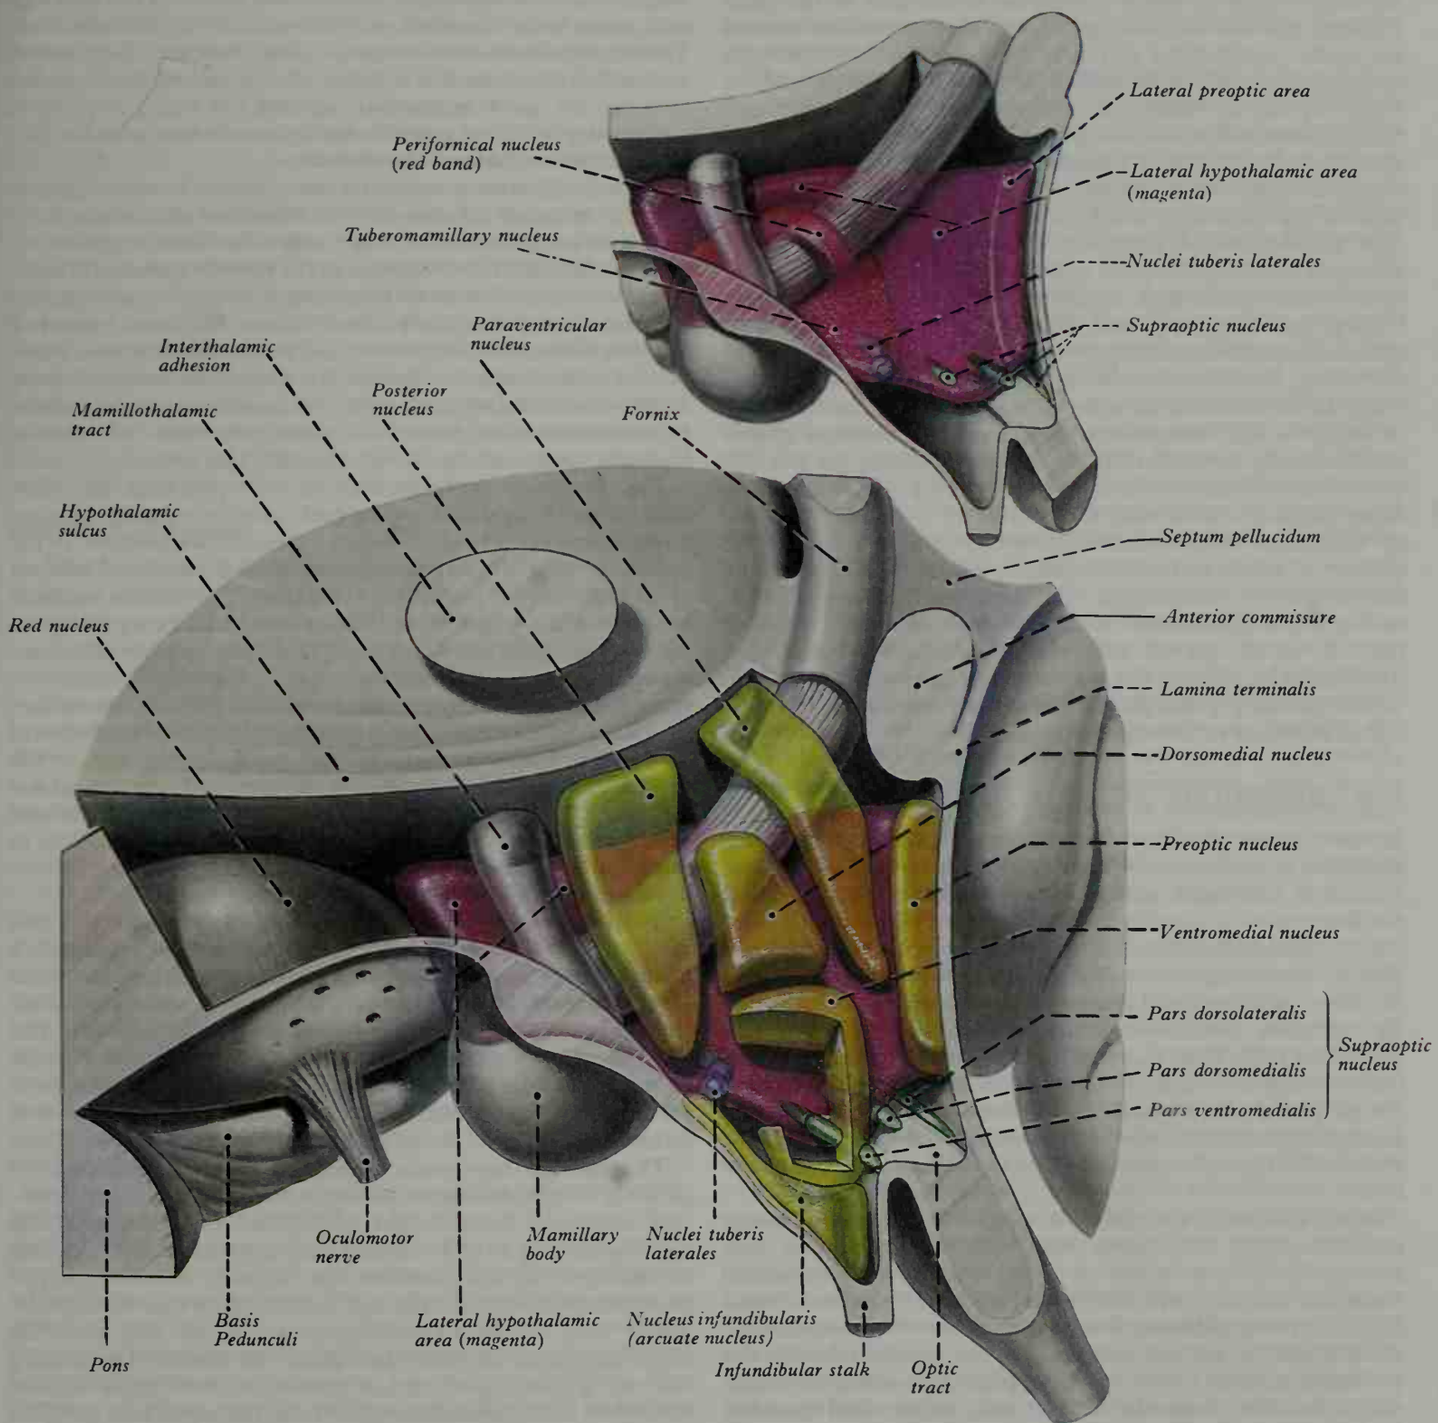
THE DIVISIONS AND NUCLEI OF THE HYPOTHALAMUS

Most regions of the hypothalamus contain populations of neurons which have been divided on the basis of phylogenetic, developmental, cytoarchitectonic, connectivity and histochemical studies into a number of nuclear aggregations, which have been given specific names, but some are much more clearly defined than others. A number of well-defined fibre tracts characterize parts of the hypothalamus, whilst the remaining regions are permeated by a complex series of interconnexions and more diffuse fibre arrays entering, leaving, passing through, or intrinsic to the region. Although the connexions of some of these fibres are fairly well-established, others are known only in outline. Further complications arise in the study of this small but immensely complex region of the brain; different authorities have, on occasion, used different criteria for its classification and their terminology does not always correspond. Only the major nuclear groups and principal connexions of the hypothalamus, followed by a brief outline of its main functional associations can be given here. For details, extended discussion and comprehensive bibliographies consult Le Gros Clark *et al.* (1938); Crosby and Woodburne (1940); Harris (1955); Haymaker *et al.* (1959); Szentágothai *et al.* (1962). For an excellent modern review *see* Reichlin, Baldessarini and Martin—editors (1978).

In general, the hypothalamus may be divided into a rostrocaudal sequence of three zones—*supraoptic, infundibulotuberal* and *mamillary*. Similarly, a longitudinal division has been proposed into *lateral* and *medial zones* on each side. These are separated by a paramedian plane, which includes on each side the prominent fibre bundles of the column of the fornix, the mamillothalamic tract, and the fasciculus retroflexus. Some authorities prefer to subdivide the medial zone into a thin subependymal *periventricular zone*, and a thicker *intermediate* (or medial) *zone*.

Some of the main nuclear groups of the hypothalamus are illustrated in 7.105 and a more complete list is given below for reference purposes. Many of the latter are small and poorly localized, but despite this, some authorities even subdivide these into still smaller aggregations. Each zone may be considered as a rough, rostrocaudal sequence of nuclei, but some overlap occurs dorsoventrally, and the preoptic grey matter is common to all three zones.

The periventricular zone consists of: (1) part of the *preoptic* nucleus; (2) a small *suprachiasmatic* nucleus—but *vide infra*; (3) the large *paraventricular* nucleus; (4) the *infundibular* nucleus;



and (5) the *posterior* nucleus of the hypothalamus. In general, these masses of grey matter are interspersed between the periventricular region of fibres (pp. 957, 968) with which some of them are functionally associated. The most prominent nucleus of this zone, and the best understood in functional terms, is the paraventricular nucleus, which is further discussed below.

The intermediate zone (the medial zone of many authors) consists of: (1) part of the *preoptic* nucleus; (2) the *anterior* nucleus; (3) the *dorsomedial* nucleus; (4) the *ventromedial* nucleus; and (5) small *premamillary* nuclei.

The lateral zone consists of: (1) part of the *preoptic* nucleus; (2) the well-known *supraoptic* nucleus; (3) the extensive *lateral* nucleus; (4) the *tuberomamillary* nucleus; and (5) the *lateral tuberal* nuclei.

Finally, the mamillary body, with its main *medial* and *lateral mamillary* nuclei and a number of smaller associated aggregations of grey matter, may be considered as lying between the intermediate and lateral zones of the hypothalamus, although in fact they overlap both these zones.

A detailed description of the shapes, sizes, architectonics, and what is known of the connexions of these individual nuclei cannot be given in this volume, and for this, the references quoted should

7.105 Schemata of the hypothalamic region of the left cerebral hemisphere from the medial aspect to display the major hypothalamic nuclei. In the upper diagram the medially placed nuclear groups have been removed, whilst in the lower diagram both lateral and medial groups are included. Lateral to the fornix and the mamillothalamic tract is the lateral hypothalamic region (magenta), in which the tuberomamillary nucleus is situated. Situated rostrally in this area is the lateral preoptic nucleus. Surrounding the fornix is the perifornical nucleus (red band), which joins the lateral hypothalamic area with the posterior hypothalamic nucleus. The medially situated nuclei (yellow) fill in much of the region between the mamillothalamic tract and the lamina terminalis, but also project caudal to the tract. The nuclei tuberis laterales (blue) are situated ventrally, largely in the lateral hypothalamic area. The supraoptic nucleus (green) consists of three parts. See text for further description. (From *The Hypothalamus*, by courtesy of the authors, W. J. H. Nauta and W. Haymaker, and the publishers, Charles C. Thomas, Springfield, Illinois, 1969.)

be consulted; but the following outstanding points may be noted. The preoptic, anterior, dorsomedial, and ventromedial nuclei and part of the posterior nucleus are mainly composed of small or medium-sized neurons and, in man, are rather poorly differentiated from their surroundings. Relatively large scattered neurons surrounded by small ones characterize the rest of the posterior nucleus and much of the lateral nucleus. The lateral tuberal nuclei, although small, are well defined, each being encapsulated by a dense meshwork of fine fibres, and each is located within one of the caudolateral surface hillocks between the tuber cinereum and mamillary body described above. The large size of the medial mamillary nucleus is characteristic of the human brain. The supraoptic nucleus, which covers the lateral part of the optic chiasma, and the large subependymal paraventricular nucleus are richly vascularized and they have certain distinguishing cytological features in common. They are composed in part of large, bipolar or multipolar neurons, which are sometimes multinucleate and which, using Nissl's method, stain much more densely than the cells of surrounding nuclei. Their cytoplasm contains characteristic granules or droplets of neurosecretory material (pp. 969, 1441, and **8**.197).

In addition to the foregoing, however, it should be noted here that the advent of the newer neurite tracing techniques (p. 819), the formaldehyde histofluorescence method of Falck and Hillarp (pp. 819, 948), and the refinement of the powerful immunofluorescence techniques (p. 819) has caused an explosive increase in the detailed research data related to neuroendocrinology. In the following paragraphs only the briefest mention can be made to this voluminous literature; the interested reader should consult the cross-references given, including the sections devoted to the neuro- and adenohypophysis (pp. 1438–1443), the recent proposals concerning the circulatory system of the latter (p. 1443), the 'diffuse neuroendocrine system' and the APUD concept (p. 1454), and the habenulopineal system as a 'model' of neuroendocrine transduction (pp. 963, 1445). Most apposite among recent publications is the collection of essays edited by Reichlin *et al.* (1978), particularly informative being that contributed by Hökfelt and his numerous co-workers (1978) on 'aminergic and peptidergic pathways in the nervous system with special reference to the hypothalamus'.

THE CONNEXIONS OF THE HYPOTHALAMUS

As mentioned previously, some hypothalamic connexions constitute fairly discrete fibre bundles, whilst others are diffuse, difficult to investigate, and hence often of uncertain origin and termination.

In broad outline, fibre systems *converging* on the hypothalamus include ascending visceral and somatic sensory pathways, olfactory pathways, and numerous tracts from the midbrain, diencephalon, 'limbic' structures, and from the neocortex. *Outflowing* paths from the hypothalamus return to many of these regions but, in particular, control paths reach lower loci from which the *peripheral autonomic nervous system* originates; and it also controls the secretory cycles of the *hypophysis cerebri* and *epiphysis cerebri*, and through these activities, the *endocrine system* of the body.

More precisely, the different parts of the hypothalamus establish direct connexions with: (1) the tegmentum and periaqueductal grey matter of the midbrain; (2) subthalamic nuclei and indirectly with the globus pallidus; (3) thalamic nuclei; (4) the hippocampal formation; (5) the anterior olfactory areas; (6) the amygdaloid nuclear complex; (7) the septal areas; (8) the prefrontal cerebral cortex; (9) the hypophysis cerebri; (10) some direct fascicles from the retina (*vide infra*); (11) possibly accessions from the superior cerebellar peduncle and the globus pallidus; and (12) numerous inputs from centres throughout the pontine and medullary reticular formation (*see* pp. 943–953). Some of the more important pathways will now be briefly detailed.

Afferent Connexions

The ascending sensory pathways to the hypothalamus include collateral branches of the lemniscal somatic afferent fibres, but in the main they are considered to be polysynaptic routes conveying visceral and gustatory information from the spinal cord and brainstem. They include the **mamillary peduncle** which is formed by the convergence of a number of fibre systems in the midbrain tegmentum to give a discrete bundle which ends in the mamillary body; ascending fibres run with the other components of the **dorsal longitudinal fasciculus** (*see* p. 840 and below) to reach the hypothalamus, and a number of **ascending pathways** from the **brainstem reticular formation** have also been described (for further details of the latter *see* pp. 943–953, and also below).

Direct projections reach the hypothalamus from the subthalamic nucleus and zona incerta of the same and the opposite side, the latter crossing in the supraoptic decussations. Thalamohypothalamic connexions pass from the dorsomedial nucleus of the thalamus to many of the hypothalamic nuclei through the **periventricular system** of fibres previously described (p. 967) and probably also by traversing the medial part of the **inferior thalamic peduncle**.

A group of forebrain structures, many of which were originally regarded as mainly olfactory in their functional associations, have now been recognized as of much wider functional significance, and are often described together as the **limbic system** (p. 990). These structures include the hippocampal formation, amygdaloid and septal complexes, the piriform lobe and adjacent regions of neocortex which will be detailed further in subsequent sections. For our present purposes, however, it is necessary to state that the limbic structures give rise to a series of prominent pathways to the hypothalamus—the *fornix*, the *stria terminalis*, the *medial forebrain bundle* and the *ventral amygdalofugal pathways*.

The fornix is complex both in its topography and fibre constitution (p. 1001), containing both commissural and projection fibres from a number of sources to a series of destinations. In the present context it is the main outflow from the neuronal laminae of the hippocampal formation, and as these fibres curve ventrally to approach the region of the anterior commissure they are joined by fascicles from the cingulate gyrus, possibly the indusium griseum, and many from the septal areas. As it continues ventrocaudally the fornix divides around the anterior commissure into pre- and postcommissural components. The *precommissural fornix* distributes in part to the preoptic regions of the hypothalamus, whilst during its descent the *postcommissural (column) of the fornix* gives offshoots to the dorsal, lateral and periventricular regions of the hypothalamus before continuing to its main termination in the mamillary nuclei. The fornix is further described on p. 1001.

The amygdaloid complex of nuclei project on to the preoptic area and most of the hypothalamic nuclei cranial to the mamillary bodies. These **amygdalohypothalamic fibres** are conducted along two pathways—the complex curved fibre bundle called the *stria terminalis*, and also by a *ventral amygdalofugal route*. The latter consists of a diffuse array of fibres passing inferior to the lentiform nucleus through the anterior perforated substance to reach the hypothalamus. The amygdaloid complex and stria terminalis are further described below (p. 996).

The medial forebrain bundle is another complex fibre pathway which, although relatively reduced in the human brain, still constitutes the principal longitudinal fibre system of the hypothalamus (**7**.123). It contains both ascending and descending components. It interconnects the anterior olfactory, hypothalamic and midbrain tegmental centres, and it runs through the lateral zone of the hypothalamus, giving off and receiving numerous small fascicles throughout its course. Descending afferents to the hypothalamus running in the bundle include numerous *septohypothalamic fibres* from the septal area (p. 997), *olfactohypothalamic fibres* from parts of the piriform cortex, and possibly *corticohypothalamic fibres* from the orbitofrontal cortex. Ascending visceral afferents reach the hypothalamus through the caudal part of the medial forebrain bundle. It should also be noted that descending fibres from the anterior terminations of the fornix and stria terminalis accompany the medial forebrain bundle and its branches. The details of some of these fibre systems have only been established in subprimate brains, but it is widely assumed that they also exist in the human brain.

The constituents and destinations of certain fascicles in the medial forebrain bundle have been somewhat clarified by the application of the newer fibre-tracing and fluorescence techniques (pp. 819, 820, 825). Some of the fascicles derived from the *ventral tegmental ascending cholinergic pathway* accompany or lie near the bundle and most, if not all, hypothalamic nuclei receive a cholinergic input from their side branches. The *ventral tegmental noradrenergic bundle* runs with the medial forebrain bundle, its hypothalamic distribution being to the dorsomedial, periventricular, paraventricular, supraoptic and lateral nuclei. The *mesolimbic dopaminergic fibre system* (p. 949) passes through the hypothalamus in the medial forebrain bundle. Dopaminergic cell aggregate A12, in the infundibular (arcuate) nucleus, provides terminals in the median eminence and infundibulum; group A11 innervates the medially placed hypothalamic nuclei; groups A13 and 14 distribute axons to the dorsal and rostral hypothalamic nuclei. (*See* p. 949 and **8**.197A.)

Corticohypothalamic fibres project to the hypothalamus from wide areas of the prefrontal cortex by direct and indirect routes, but there has been much debate concerning the relative importance of the two pathways. The indirect fibres converge on the nucleus medialis dorsalis of the thalamus where they relay, and are then continued to the hypothalamus in the periventricular fibre system. In different experimental animals direct corticohypothalamic fibres have been variously described as ending in the lateral, dorsomedial, mamillary and posterior nuclei of the hypothalamus, but these have been denied by some authors. For a detailed review of these and other hypothalamic connexions consult Nauta and Haymaker (1969); Reichlin *et al.* (1978). Finally, as mentioned previously, some hypothalamic nuclei may receive an input from the superior cerebellar peduncle.

Efferent Connexions

In broad outline, the connecting pathways from the hypothalamus include: (1) reciprocal paths to parts of the limbic system; (2) a series of descending polysynaptic paths to lower autonomic and motor centres; and (3) nervous and vascular links with the hypophysis cerebri.

The septal areas and the amygdaloid complex receive hypothalamic fibres which return along the pathways described above.

The prominent medial nucleus of the mamillary body gives rise to a large fibre bundle which ascends and, partly by branching of its individual fibres, diverges into two substantial tracts. The *mamillothalamic tract* (**7**.117) continues to ascend and terminates in all parts of the anterior nuclear group of the thalamus, where, after relay, massive projections radiate to the cingulate gyrus (pp. 960, 1023). The *mamillotegmental tract* curves caudally to enter the midbrain ventral to the medial longitudinal fasciculus and is distributed to tegmental nuclei of the reticular formation. Small bundles of *mamillosubthalamic fibres* pass to the prerubal field of the subthalamus, but their destination is uncertain. In addition to the mamillotegmental tract, descending fibres from the hypothalamus also reach the midbrain tegmentum in the *dorsal longitudinal fasciculus* and in the caudal extension of the *medial forebrain bundle*.

As mentioned above, the **connexions of the hypothalamus with the hypophysis cerebri** are by means of: (1) *nerve fibres* derived from various groups of hypothalamic neurons, which terminate at different levels throughout the median eminence, infundibulum, and *posterior lobe* of the hypophysis; and (2) a system of long and short *portal blood vessels* which interconnect plexuses of sinusoids in the median eminence and infundibulum with other plexuses in the *anterior lobe* of the hypophysis. The anatomy of these nervous and vascular channels is further considered with that of the hypophysis (p. 1438; **8**.197, 198), but certain points must be emphasized here. The main glandular mass of the anterior lobe of the hypophysis receives no nerve supply; and virtually the whole of its blood supply is from the hypothalamohypophysial portal vessels. Direct observation in the living experimental animal has established that the predominant direction of the blood flow in these vessels is from a series of complex sinusoidal tufts in the median eminence and infundibulum, through the portal vessels, to discharge into the blood sinusoids which run between the cords of glandular cells in the anterior lobe. However, as indicated on p. 1443, *flow reversal* may occur in certain parts of this vasculature, with consequently widespread neuroendocrinological implications.

It is now widely accepted that a process of *neurosecretion* is involved both in the production and release of the posterior lobe hormones *oxytocin* and *vasopressin*, their related transport proteins the *neurophysins*, and also in the neurovascular mechanism whereby secretory activity in the various types of glandular cell in the anterior lobe is controlled. The hypothalamic centres containing neurons whose axons terminate in the median eminence or upper infundibulum, or pass through the latter to terminate in the posterior lobe of the hypophysis, include the supraoptic, paraventricular, and infundibular nuclei, and part of the ventromedial nucleus.

The supraoptic nucleus, as mentioned above, is draped over the lateral part of the optic chiasma, and some authorities divide it into three or more subsidiary nuclei which are named according to their relationship to the chiasma. It is composed of a uniform population of large cells. **The paraventricular nucleus**, which causes a visible bulging of the ependyma into the third ventricle, extends from the hypothalamic sulcus and crosses the medial aspect of the column of the fornix, whilst its ventrolateral angle points towards the supraoptic nucleus. A number of its cells are large like those of the latter, but in addition there are many intermediate and small cells of varying shapes. **The infundibular nucleus** (often called **the arcuate nucleus**) occupies the median zone of the postinfundibular part of the tuber cinereum, and it extends into the median eminence and largely encircles the base of the infundibulum. However, it is deficient cranially where the infundibulum adjoins the midline part of the optic chiasma. No glial layer intervenes between the nucleus and the specialized ependymal (tanycyte) lining of the *infundibular recess* of the third ventricle. (For the possible neuroendocrine role of these tanycytes consult Knowles 1974; for a recent review and extensive bibliography *see* Joseph and Knigge 1978; also pp. 836, 1441.) In contrast to the other nuclei just described, it is composed exclusively of numerous small cells, which appear round in coronal section and oval or fusiform in sagittal section.

Thus, the neurons which project into or through the infundibulum may be considered in two groups: **magnocellular**, including the large and intermediate cells of the paraventricular nucleus, the large cells of the supraoptic nucleus and small groups or rows of internuclear cells between them, and **parvocellular**, which includes the small cells of the infundibular nucleus and some in neighbouring nuclei. Whilst the magnocellular group is characterized by the presence of neurosecretory material (*vide infra*), it must be emphasized that both groups consist of true neurons. Each cell possesses a soma, dendrites and an axon with collateral branches, and these contain the usual neuronal organelles (p. 825). Furthermore, they receive axodendritic and axosomatic synapses from unknown sources, and their axons conduct volleys of nerve impulses. Their axonal terminals expand into end-bulbs which contain mitochondria and clear synaptic vesicles about 40–60 nm in diameter, and many of them are closely applied to the basement membranes of capillaries with no intervening neuroglia, in either the infundibulum or the posterior lobe. Whilst it is clear that important neural connexions exist which may influence the activities of these various nuclei—probably stemming from other hypothalamic nuclei and also from a number of the channels which converge upon the hypothalamus from other centres—their precise connexions have not yet been established. Equally, the significance of volleys of nerve impulses in these neurons, and the functional meaning of the presynaptic vesicles is by no means clear: no direct relationship to the process of neurosecretion has been demonstrated. (For further details *see* p. 1441.)

The terminology used in connexion with the neural pathways from the hypothalamus to the hypophysis has undergone several changes with increasing knowledge. This has resulted in an array of terms, some of which lack precision, and often different meanings attach to the same term when used by different authorities.

The term *supraopticohypophysial tract* was often used to denote

all fibres which entered the infundibulum, whatever their origin or destination, but its use is now often restricted to those originating in the supraoptic and paraventricular nuclei. Since the nuclei are by no means equivalent in either their cytology or functional associations, some workers in the field prefer the more specific terms *supraopticohypophysial* and *paraventriculohypophysial tracts*. However, it must be realized that many of their fibres end in the infundibulum and do not reach the posterior lobe. The term *tuberohypophysial* or more precisely **tubero-infundibular tract** is used to denote the fibres of the small neurons of the infundibular and related nuclei of the mediobasal hypothalamus (*vide infra*) which end in the infundibulum.

The cells and axons of the **magnocellular neurosecretory** pathways from the supraoptic and paraventricular nuclei, scattered internuclear neurons, and some contend occasional neuron groups of the suprachiasmatic nucleus, contain what were originally termed colloid droplets. These vary in size, are sometimes found between the cells and fibres, and they stain selectively with the chrome-alum haematoxylin stain of Gomori, when the fine axons and their branches are seen to contain a row of stained masses, each of which distends the axon, the whole appearance resembling a 'string of beads'. Irregularly distended nerve terminals containing large masses of neurosecretory material are termed *Herring bodies*. Ultrastructurally, the material consists of membrane-bound aggregations of dense granules, the whole mass varying from 200 to 300 nm in diameter. Much intensive research has been directed towards an understanding of neurosecretion, and the methods used include: studies on the effects of transection of the infundibulum; transplantation of the hypophysis; culture of neurohypophysial explants; autoradiography following the administration of labelled cysteine; subcellular fractionation and extraction followed by biological assay or chemical analysis; studies on the effects of dehydration, hydration, various drugs and stressful situations; chemical or electrical stimulation and ablation of focal points in the hypothalamus.

Briefly, it is now accepted that neurosecretory material is synthesized in the large cell somata of the supraoptic, paraventricular, and neighbouring neurons in relation to the endoplasmic reticulum, further elaborated in the Golgi complex, and then transported along the axons and their branches, to be released at the axon terminals, and then to be taken up by the blood which is percolating through adjacent capillaries. Further, there is some evidence that, whilst *both* the supraoptic and paraventricular nuclei are associated with the production of both hormones vasopressin and oxytocin, vasopressin is *predominantly* a product of the supraoptic nucleus and oxytocin of the paraventricular nucleus. Suitable immunofluorescence techniques have allowed a precise three-dimensional analysis of the distribution of oxytocin and vasopressin cells in a number of mammals; marked regional and species differences exist. However, many questions remain unanswered (Donovan 1970; Knowles 1974). For example, the precise chemical constitution of the neurosecretory material remains to be determined, and it appears that the chemically related hormones oxytocin and vasopressin (both are nonapeptides) are transported in a relatively non-active form, each probably conjugated with a specific low molecular weight protein carrier which is termed a *neurophysin*. Secondly, the rate and mechanism of transport, presumably involving some form of fast axoplasmic flow, remains to be defined accurately. Finally, the detailed manner in which the hormones are released exocytotically at the axonal terminals is not understood, although suggestions have been made that both calcium ions and the local release of acetycholine by the synaptic terminals may be involved. The special vascular relationships of the supraoptic and paraventricular nuclei are discussed in some further detail below. (For a detailed review of the magnocellular neurosecretory system consult Defendini and Zimmerman 1978.)

In addition to the production of posterior lobe hormones oxytocin and vasopressin, and their respective neurophysins, neurosecretory pathways are also considered to play an important role in the control of secretory activity by the anterior lobe of the hypophysis. Much evidence supports the view that groups of hypothalamic cells produce a variety of *peptidergic releasing hormones* which are transported along their axons and then discharged into the upper radicles of the portal system of blood vessels, by which means they are carried to the vascular bed which permeates the anterior lobe, where they reach and influence the appropriate glandular cells. The term *releasing hormone* is not, however, entirely appropriate; some inhibit the release of hormone by anterior lobe cells, whilst others stimulate synthesis of the hormone, as well as promoting its release. They include *releasing hormones* for corticotropin, luteinizing hormone, follicle stimulating hormone; thyrotropin and somatotropin, and *release inhibiting hormones* for prolactin, melanocyte stimulating hormone, and somatostatin. The **parvocellular neurosecretory pathway** provided by the '*tubero-infundibular tract*' has been proposed as the main route for the synthesis and transmission of these releasing hormones to the portal blood flow. Immunofluorescence techniques have now allowed the localization of some of these peptides (*see* p. 1441, table on p. 1455, and Renaud 1978). For example, corticotropin releasing factor has been localized in the small cells of the paraventricular, anterior and posterior hypothalamic nuclei, thyrotropin releasing factor in the nuclei dorsomedialis and ventromedialis, luteinizing hormone releasing factor in some neurons of the nucleus infundibularis (arcuatus), somatotropin releasing factor in the anterior and posterior hypothalamic nuclei, and somatostatin in some of the nuclei periventriculares. In addition to releasing factors some fibres in the tract also have particularly high concentrations of acetylcholine, whilst others are rich in catecholamines, and this is paralleled by the ultrastructural appearances of their end-bulbs (p. 1441). Some contain small clear synaptic vesicles, whilst others contain larger dense-cored vesicles, and yet others contain a mixed population. There are no structural evidences of the typical large, electron-dense, membrane-bound granular masses which characterize the magnocellular pathway. Accordingly, it has been proposed that the fibres of the tubero-infundibular tract carry releasing hormones in a dispersed, active, form, and may also carry catecholamines or acetylcholine. It will have become clear to the reader that with such relatively widespread origins, the name tubero-infundibular may well be too restrictive. Mention has already been made (p. 969) of the possible role of the tubero-infundibular dopaminergic (and other monoaminergic) pathways in modulating the synthesis, transport and exocytosis of releasing or release-inhibiting factors, and also the activities of tancytes (see also p. 1441 and **8**.197A). According to Renaud (1978), it should also be noted that the tubero-infundibular neurosecretory parvocellular neurons are in receipt of neural inputs from the amygdala, preoptic nuclei and hippocampus: in turn their axons provide collaterals back to these regions, to the medial nuclei of the dorsal thalamus, and to other hypothalamic nuclei, in addition to their *infundibular* terminals.

Finally, it must be emphasized that many of the axonal terminals of the magnocellular pathway also end in the upper infundibulum and may also be involved in control of the anterior lobe of the hypophysis. For these reasons, the magnocellular and parvocellular pathways may not be as functionally independent as has been envisaged by some investigators.

FUNCTIONS OF THE HYPOTHALAMUS

Clinically it had long been recognized that lesions in the hypothalamus often lead to widespread and bizarre combinations of symptoms and signs, which stem from endocrine, metabolic, visceral and behavioural disturbances. However, it has been widely assumed that such combinations result from the interruption of control pathways for these various 'functions' which, although largely independent, are closely related topographically either in or near the hypothalamus. In particular, although the general significance of the hypophysis cerebri as an endocrine gland was gradually emerging in the closing decades of the last century and the opening ones of the twentieth (Cushing 1912), it is only in the last forty years that the interrelation of the hypophysis and nervous system has been firmly established (Harris 1955). Thus, the science of *neuroendocrinology* has emerged (Scharrer and Scharrer 1963; Heller and Clark 1962; Gabe 1966; Donovan 1970; Knowles 1974; Reichlin *et al.* 1978)

and has made increasingly rapid progress, complementing the widely accepted role of the hypothalamus as the 'head ganglion' of the autonomic nervous system (Sherrington 1947). More recently, intensive investigation has not only confirmed in greater detail the controls exerted by the hypothalamus on the *endocrine system* and the *lower autonomic centres*, but has also emphasized that hypothalamic action depends upon afferent information channels, both nervous and vascular, and that it is interlocked, both structurally and functionally, with higher regions of the nervous system. The latter include the complex of structures which many authors group as the *limbic lobe* or system (p. 990), and the pre-frontal regions of the cerebral cortex.

Reference has been made elsewhere (p. 802) to one possible approach to the study of nervous systems in general, namely, that they operate in more complex animals as controllers of the *homeostatic cycles* which tend to preserve the individual and the species within a fluctuating environment. In mammalia, the frontal cortex, limbic system, hypothalamus, and lower regions of the brainstem and spinal cord are conveniently regarded as forming a hierarchy of controls particularly directed towards those homeostatic cycles, which are mediated by the autonomic nervous system, the endocrine system, and the locomotor patterns associated with them. The concept of such a hierarchy is important because of the widespread use of the terms lower, intermediate and higher 'centres' for a variety of visceral (and locomotor) controls. The term centre is largely a product of the available methods of analysing central nervous activities—usually by the focal stimulation or destruction of more or less discrete patches of nervous tissue, usually by electrical or chemical means. Such experimental manœuvres are then combined with other forms of observation—biochemical or cytological analysis, changes in general metabolic status, growth or behaviour patterns, electrophysiological recording and so forth. Whilst it is undoubtedly true that focal stimulation or obliteration may cause dramatic changes in a particular group of responses, and that some regions exhibit apparently spontaneous and sometimes rhythmic electrical changes when isolated, great caution must be used before regarding such regions as independent autonomous, controlling centres of particular activities. The bulk of the available evidence indicates that such 'centres' are best regarded as *nodal regions* of nervous tissue which, by virtue of their chemical constitution, intrinsic geometry and connexions, and extrinsic connexions, nervous or vascular, are essential for the normal range of certain responses which follow particular patterns of inflowing information. It must be appreciated that the various other regions of the nervous system from which afferent information channels converge upon the 'centre', whilst often less dramatic in their effect upon the responses in question when individually modified, are nevertheless collectively as important as the so-called centre itself. Further, particularly within a confined region such as the hypothalamus, to and from which numerous pathways converge and diverge, and which is composed of many rather ill-defined neuron groups, some of which have diffuse patterns of connexions, it is found that many of the functional 'centres' of different investigators overlap or virtually coincide. For these reasons, many investigators prefer to discuss the effects of stimulation or ablation of general zones of the hypothalamus, e.g. lateral, posterior, preoptic, mamillary, etc., rather than attempting to ascribe particular functional roles to individual hypothalamic nuclei. Partial exceptions to this are the well-recognized neurosecretory nuclei with specific cell products which pass into the bloodstream in the infundibulum or posterior love of the hypophysis, but even in these cases their afferent neural and vascular connexions are incompletely understood.

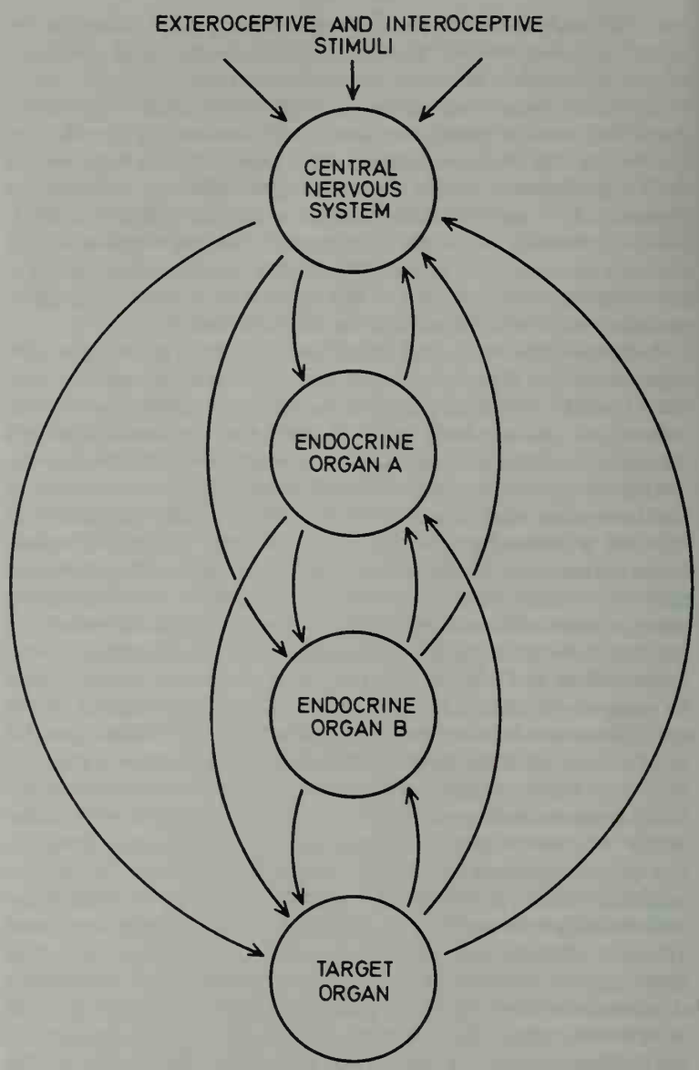
In general terms, experiments in animals involving transection of the nervous system at various levels demonstrate that as progressively higher levels are included below the plane of section, more complex and effective homeostatic readjustments can be carried out (Anand 1970). Decerebrate preparations with transection at upper midbrain levels can perform individual minor reflex readjustments of the cardiovascular, respiratory and alimentary systems, but these are not integrated and normal body temperature is not maintained. When transection is performed cranial to the hypothalamus, separating it from the limbic system, but retaining the connexions between the hypothalamus, hypophysis, brainstem and spinal cord, a completely different picture emerges. Quite effective homeostasis is maintained over a moderate range of environmental conditions. The various visceral and endocrine control systems are integrated into more ordered patterns of responses; furthermore, 'innate drives' and 'motivated behaviour patterns' make their appearance, including forms of feeding, drinking, apparent satiation, copulatory responses, and so forth. However, the homeostatic mechanisms break down if the environmental stresses involved exceed a certain range, e.g. persistent fairly high or low environmental temperatures. In addition, the motivated behaviour patterns become abnormal under stress, the animal may attack, attempt to eat, drink, or copulate with a bizarre range of objects. If, however, the connexions between the limbic system (p. 990) and hypothalamus are also preserved, and only neocortical regions are ablated, highly effective homeostatic responses occur under a wide range of adverse environmental conditions.

An enormous research literature has accumulated concerning the functional roles of the hypothalamus and the subject of neuroendocrinology, which cannot be reviewed in this volume; and the references quoted should be consulted for details and an introduction to extensive bibliographies. In summary, therefore, animal experimentation, usually involving focal stimulation or ablation of the hypothalamus, has emphasized its intimate relationship to the following activities.

(1) **Endocrine control** by the formation of releasing or release-inhibiting factors related to the production of thyrotropin, corticotropin, somatotropin, somatostatin, prolactin, luteinizing hormone, follicle stimulating hormone, and melanocyte stimulating hormone, by the cells of the *anterior pituitary*. Some of these affect target cells in the general body tissues directly, whilst others do so through the intermediary of a second endocrine organ, e.g. the thyroid gland, adrenal cortex, or the gonads. In the latter instances the sequence of control mechanisms is illustrated diagrammatically in 7.106. Neural pathways converge upon, and are integrated within, the hypothalamus, and modify its production of releasing or inhibiting factors (p. 970). In turn these modify the activities of endocrine glands A and B, and ultimately the target tissues. Each of the intermediate levels in the chain are also modified by the operation of negative or positive feed-back loops which depend upon the blood concentration of the secretory products of subsequent stages in the chain. (For further details consult Haymaker *et al.* 1969; Donovan 1970; Bargmann and Scharrer 1970; Knowles 1974; Reichlin *et al.* 1978.)

(2) **Neurosecretion** of oxytocin and vasopressin (antidiuretic hormone, ADH) directly into the bloodstream of the infundibulum and posterior lobe of the hypophysis. Despite its name, whether vasopressin exerts any significant effect on vascular non-striated muscle under physiological conditions remains uncertain. However, it has a powerful effect on the reabsorption of water by the kidney, whilst oxytocin causes contraction of uterine and mammary smooth muscle which may be of importance during suckling, coitus and parturition. Stimulation of neural pathways from the nipples and genitalia causes an increase in the rate of oxytocin release. The rate of release of vasopressin is determined, in part, by the tonicity and osmotic pressure of the blood perfusing *osmoreceptor sites* both within the hypothalamus (Verney 1947) and in the peripheral circulation—probably in the hepatic portal vein (Haberich 1968). From the latter, lengthy nervous pathways are involved before the impulse pattern generated reaches the hypothalamus. Similarly, a reduced blood volume is considered to stimulate *volume receptors* in the great veins and the walls of the atria of the heart, thus causing an increased release of vasopressin (Gauer 1968). Finally, pain, and a variety of emotional states and conditions of stress, greatly modify the rate of release of the hormone.

(3) **General autonomic effects.** It has long been held that rostral zones of the hypothalamus mediate general parasympathetic activity, whilst caudal zones mediate sympathetic activity. Whilst there is undoubtedly a preponderance of one or other effect in these zones, there is much interaction and overlap between the effects in different regions, and a rigid distinction between parasympathetic and sympathetic 'centres' cannot be



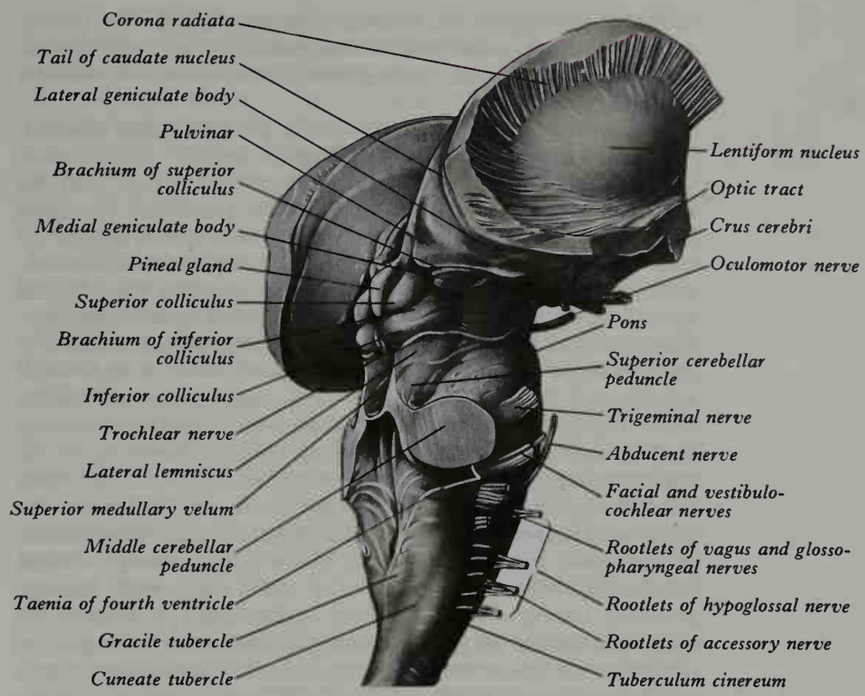
maintained. However, focal stimulation or ablation of the hypothalamus shows that it is intimately concerned with *cardiovascular*, *respiratory* and *alimentary* control. A detailed analysis cannot be given here, but such experiments are often accompanied by profound changes in heart rate, cardiac output, vasomotor tone and peripheral resistance, blood pressure, differential blood flow through different organs, and also in the frequency and depth of ventilatory excursions of the thorax, and in the motility and secretory activity of the stomach and intestines.

(4) **Temperature regulation.** In all warm blooded animals a critical balance is achieved between the overall heat production and loss of the body, and the hypothalamus provides a central regulating mechanism for this. A raised body temperature is depressed by vasodilatation, with an increased cutaneous blood flow, sweating, panting, and reduced heat production, whilst with a lowered body temperature the converse conditions apply, with shivering and, if prolonged, an increase in the activity of the thyroid gland. Information concerning body temperature reaches the hypothalamus via neural pathways from peripheral *thermodetectors* for cold and heat, and from thermodetector neurons within the hypothalamus itself. The latter monitor the prevailing temperature of the blood perfusing the hypothalamus, whilst other hypothalamic neurons are chemoreceptors which react specifically to the presence of blood-borne viruses, toxins, pyrogenic drugs, etc. These converging flows of information are passed to regions of the hypothalamus which then set in train the appropriate autonomic, endocrine and muscular responses. It has been proposed that an '*antirise*' region exists in the cranial hypothalamus which controls vasodilatation, sweating, panting and possibly reduction of heat production, whilst the caudal hypothalamus houses an '*antidrop*' region controlling vasoconstriction, shivering and other means of raising heat production. The topographical limits and degree of separation of this *dual hypothalamic thermostat* cannot yet be regarded as finally settled. Some investigators (Myers 1969) consider that a *dual chemical thermostat* is interposed between the inflow of information and the 'antirise' and 'antidrop' regions of the hypothalamus, consisting of groups of neurons containing 5-hydroxytryptamine, or noradrenalin (and possibly dopamine). Warmer blood, impulses from heat receptors, antipyretic substances or anaesthetics, are thought to cause the release of noradrenalin (or dopamine) which in turn stimulates the 'antirise' mechanisms. Cooler blood, impulses from cold receptors, or pyrogenic substances, stimulate a release of 5-hydroxytryptamine which causes activation of the 'antidrop' mechanisms.

(5) **Regulation of food and water intake.** Many investigations (*see* Anand and Brobeck 1951; Anand 1961) have demonstrated that there exist regions with opposing actions in the medial and lateral zones of the hypothalamus. Ablation of the medial zone leads to over-eating or *hyperphagia*, eventually leading to gross obesity, whilst ablation of the lateral zone leads to *hypophagia* or even complete *aphagia* with death from starvation. Conversely, stimulation of the medial zone causes the animal to eat less, whilst lateral stimulation initiates eating or increases and prolongs the food intake. Thus, a laterally placed *hunger* or *feeding* '*centre*' balanced against a medially placed *satiety* '*centre*' have been proposed. Neurons which are specifically sensitive to the concentration of glucose in the circulating blood have been demonstrated in the medial zone of the hypothalamus and are probably important in the operation of the satiety centre.

Water balance and the osmolality of the blood are in part controlled by the *osmoreceptor/volume receptor—vasopressin—renal system* described previously, which determines the rate of water loss in the urine. Coupled with this is a *thirst* or *drinking centre* in the lateral zone of the hypothalamus which regulates water intake. Experimental stimulation of this region causes immediate and copious drinking, and, if the stimulation persists, gross hyper-hydration results.

(6) **Sexual behaviour and reproduction.** Through its control of gonadotrophin production by the anterior pituitary, the hypothalamus controls many aspects of reproductive physiology, including gametogenesis, cyclic variations in the reproductive tracts, and the maturation and maintenance of secondary sexual characteristics. Furthermore, hypothalamic stimulation may induce receptivity of the male in the female, and simple copulatory movements in the male, and it has also been shown that some hypothalamic neurons are sensitive to the circulating level of oestrogen or testosterone.



7.106 A flow diagram showing a stimulus pattern impinging on the central nervous system, and the possible interactions of the latter with endocrine organs A and B and a target tissue. Note the different orders of feed-forward and feed-back pathways envisaged. (From *Neuroendocrinology* by E. Scharrer and B. Scharrer, Columbia University Press, 1963. By courtesy of the authors and publishers.)

It should be noted at this point that whilst the elementary *drives* associated with hunger, thirst and sex may be considered to stem in part from an intact hypothalamus, for their full integration into complex behaviour patterns, a two-way commerce between the hypothalamus and limbic system is necessary (p. 997). Such patterns include searching for and procuring a mate, food and drink, home-building, rearing of young, etc.

(7) **Biological clocks.** Many tissues, organs and systems in the body show a cyclic variation in some of their functional activities, the cycle having a periodicity of approximately twenty-four hours. Well-known examples of such *circadian rhythms* include regular fluctuations in the body temperature, the concentration levels of a number of plasma constituents, the eosinophil count, adrenocortical secretory activity, and renal secretory mechanisms. In some cases the rhythm is partly an intrinsic property of the organ or tissue itself, but in many cases an overall control is exerted by an intact hypothalamus. Widespread lesions in other parts of the nervous system leave the biological timing mechanism unaffected, but hypothalamic lesions alone cause serious disturbances of rhythm. The suprachiasmatic nucleus appears in many animals to be an *endogenous neural pacemaker*, a 'biological clock' whose rhythmic activity can respond to regulating cues

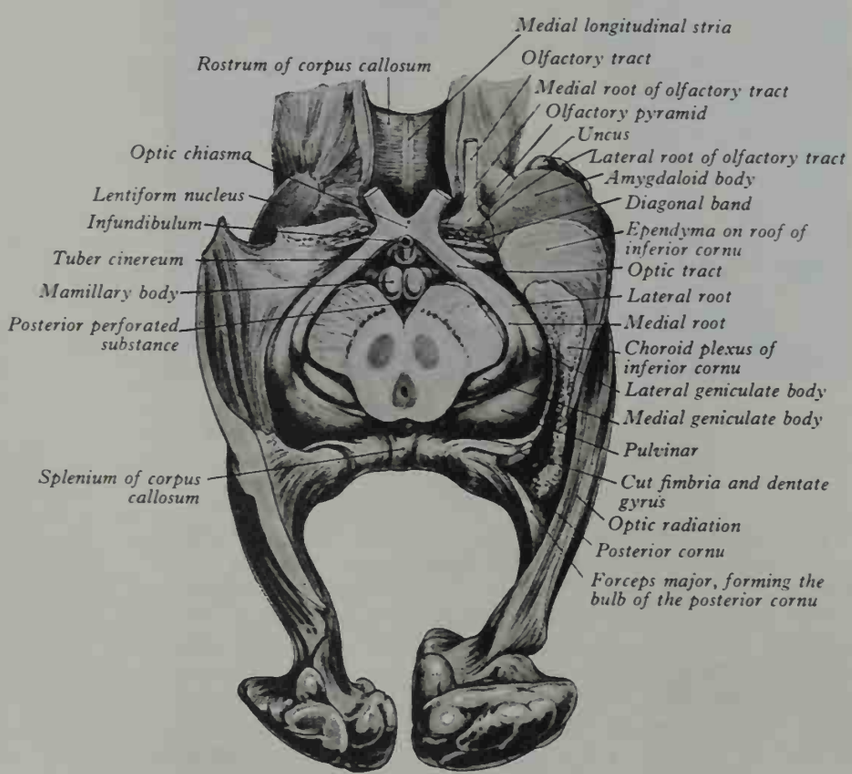
provided by changes in environmental lighting (p. 1448). Although of widespread occurrence throughout the vertebrates (Joseph and Knigge 1978) occasional doubts have been expressed concerning the prominence, or even the presence, of the suprachiasmatic nucleus in mankind (Defendini and Zimmerman 1978). Bilateral experimental destruction of this nucleus permanently interferes with the circadian rhythms of, for example, adrenocorticosterone secretion (Moore and Eichler 1972), drinking and locomotion (Stephan and Zucker 1972), sleeping and wakefulness (Ibuka and Kawamura 1975) and pineal N-acetyltransferase activity (Moore and Klein 1974). As far as pineal activity is concerned, it has been demonstrated by Nishino *et al.* (1976) that the neuronal activity of the suprachiasmatic nucleus is increased by visual stimulation, and that this increased activity inhibits the sympathetic neurons which supply the pinealocytes, an action which results in a decrease in their secretory activity (p. 1448). Although still a somewhat controversial proposal, there is now considerable experimental evidence supporting the existence of direct retino-suprachiasmatic connexions which may be involved in the photic regulation of circadian rhythms. Terminations of retinal fibres in the suprachiasmatic nucleus have been demonstrated by a variety of techniques, including autoradiography after intra-ocular injection of tritiated amino acids, in a range of mammals from the tree-shrew to the macaque (Moore 1973)—findings which support the nerve degeneration studies of other workers (Moore and Len 1972; Printz and Hall 1974). Further supporting evidence for the existence of *retino-suprachiasmatic* connexions has been provided by the cobalt precipitation techniques of Mason and Lincoln (1976), by electron microscopy (Wenisch 1976) and by electrophysiological investigation (Sawaki 1977). *Retinal projections* to the rostral part of the infundibular (arcuate) nucleus have also been demonstrated (Mason and Lincoln 1976). Efferent fibres have now been traced from the suprachiasmatic nucleus to the ventromedial, dorsomedial and arcuate nuclei of the hypothalamus, suggesting that the fine control of the endogenous circadian regulator is a mechanism of considerable delicacy and sensitivity.

The periodic conditions of sleeping and wakefulness are an outstanding example of a circadian rhythm. In recent years a large volume of investigation has been directed towards an understanding of the mechanisms of sleep (*see* Jouvet 1962, 1964, 1965; Rossi 1964; Koella 1969 for an introduction to the literature). Briefly, sleep is no longer regarded as a passive 'switching off' process whereby there is simply a reduction in the activity of a cerebral activating system. Two principal states of sleep are now recognized. During the waking state, the electroencephalogram is characterized by a low-amplitude wave pattern with a frequency of about 10 cycles per second, upon which background there are bursts of irregular 'random' activity. With the onset of sleep, the waveform changes to one which is *synchronized*, of a large amplitude and a slow frequency. This state of *deep* or *slow wave sleep* (SWS) is one from which the subject can however be aroused relatively easily; it is a dreamless condition. After some time the condition of slow sleep is interspersed with bouts of *paradoxical sleep* (PS). The electroencephalogram shows fast, low-amplitude, bursts of waves. Muscle tone is in general reduced, particularly in the neck musculature, but there occur characteristic rapid eye movements (so-called REM sleep), during which the subject is difficult to rouse, and experiences dreams. The electroencephalographic waveform corresponds to the pattern of ocular oscillation. Three or four sessions of REM sleep occur each full night. It is generally thought that the level and type of sleep depends upon the *balance* between two opposing systems, which are disposed throughout much of the brainstem and include parts of the thalamus, hypothalamus and limbic system. On the one hand there is the *reticular activating* or *arousal system*, with its cranial extensions to the cerebral cortex, stimulation of which leads to wakefulness and desynchronization of cerebral activity. On the other hand, there has been demonstrated a series of *hypnogenic zones* in the medulla, pons, midbrain, thalamus, hypothalamus and basal limbic structures, the stimulation of which leads to synchronization of cerebral cortical activity, and a *variety* of induced sleep-like states, which differ in their detailed

7.107A Posterolateral aspect of the hindbrain and midbrain, exposed by removal of the cerebellum and most of the cerebrum.

7.107B Right lateral view of the brainstem; compare with 7.107A. (Dissection by Dr. E. L. Rees, Dept. of Anatomy, Guy's Hospital Medical School.)

characteristics. The precise manner in which these opposing, hierarchical systems of sleep-controlling regions interact awaits further investigation, but in general the thalamohypothalamic centres seem dominant whilst those in the medulla, pons and midbrain are subordinate. It is of interest that intact centres in the nucleus ceruleus, rich in both noradrenergic and cholinergic neurons, seem to be important in the generation of paradoxical sleep. Furthermore, the overall circadian rhythm of sleeping and waking is seriously disturbed with lesions in the cranial hypothalamus, and the disturbances being paralleled by corresponding fluctuations of serotonin (5-hydroxytryptamine) concentration in the hypnogenic zones of the brainstem and diencephalon. Whether the serotonin functions as a humoral sleep-inducing and maintaining factor, or as a neural transmitter



in the hypnogenic system, remains to be determined. (For further comments on sleep rhythms, and the possible roles of cholinergic and monoaminergic cell aggregations in the brainstem reticular formation, *see* p. 951.)

(8) **Emotion, fear, rage, aversion, pleasure and reward.** The emotional content of an individual consists of two main elements: the *subjective feeling state* or *affective tone*, and the *objective physical accompaniments* which constitute *emotional expression*. For the full integration of both these aspects of emotion, with changes in the internal and external environment, and with other cerebral activities, the essential neurological structures are an intact hypothalamus, limbic system, and prefrontal cortex. With such a complex and interlocked system it is impossible to ascribe specific functional roles to individual subregions. Nevertheless, some elementary responses can be elicited by focal stimulation or ablation of the hypothalamus both in the intact animal (or human being during neurosurgery), or after the experimental removal of higher centres. The early classical experiments were carried out on decorticate dogs (Goltz 1892), and subsequently analysed in greater detail on decorticate cats (Cannon and Britton 1925). In the latter, mild peripheral stimulation evoked a condition of *sham rage*, with hissing, growling, baring of claws and fangs, piloerection, arching of the back, dilatation of the pupils, striking at objects and lashing of the tail. The term 'sham' was used because it was assumed that feeling states and directed behaviour could not occur in the decorticate animal. Later it was shown that the sham rage was abolished by obliteration of the caudal hypothalamus, but could be elicited by stimulation of the latter in intact animals.

Many subsequent studies have demonstrated that stimulation or ablation of different hypothalamic regions cause changes in the emotional accompaniment of the basic drives of sex, hunger and thirst, whilst other regions are related to the behavioural and (in man) the subjective aspects of rage, fear and pleasure. Particular emphasis has recently been placed upon the existence of centres which are broadly opposed in their actions—*positive* and *negative reward centres*. Stimulation of the former ('*pleasure centres*') leads to 'pleasurable sensations' or the gratification of an intense drive—with an appropriate experimental situation, an animal will repeatedly *self-stimulate* its hypothalamus until exhausted, even ignoring food and drink after prolonged periods of deprivation. The principal brain areas from which positive reward (experimental self-stimulation) can be elicited include parts of the catecholaminergic complex of pathways in the brainstem, the medial forebrain bundle of the hypothalamus, the septal areas, the orbitofrontal and parahippocampal (entorhinal) areas of the cerebral neocortex. The most effective region, in the earlier studies, proved to be the medial forebrain bundle (p. 968), in which both ascending and descending fascicles with multiple sources and destinations are intermixed. Furthermore, noradrenergic, dopaminergic, serotonergic and non-aminergic pathways are in close apposition. Readers interested in the history and methods employed in attempts to analyse the functional neuroanatomy of brain stimulation reward should consult Wanquier and Rolls (1976); Olds (1977); Routhenberg and Santos-Anderson (1977). In brief, the latter authors, after highly selective focal stimulation, ablation, and pharmacological manipulation came to the conclusion that intact dopaminergic pathways ascending from the pars compacta of the substantia nigra were essential for 'normal' patterns of self-stimulation. Stimulation in man often causes a general sensation of well-being, and on some occasions it has a strong erotic content. Such *positive reinforcement* may be used to expedite the responses of experimental animals in situations which demand *learning*. In this regard, the forward projection of the *mesolimbic dopaminergic pathways* to their multiple destinations in the limbic system (p. 992), with their possible relevance to the establishment of memory patterns, is perhaps noteworthy. Conversely, stimulation of the negative reward centres presumably causes pain or 'displeasure' and the experimental animal will go to considerable effort and complex patterns of behaviour to avoid repetitive stimulation.

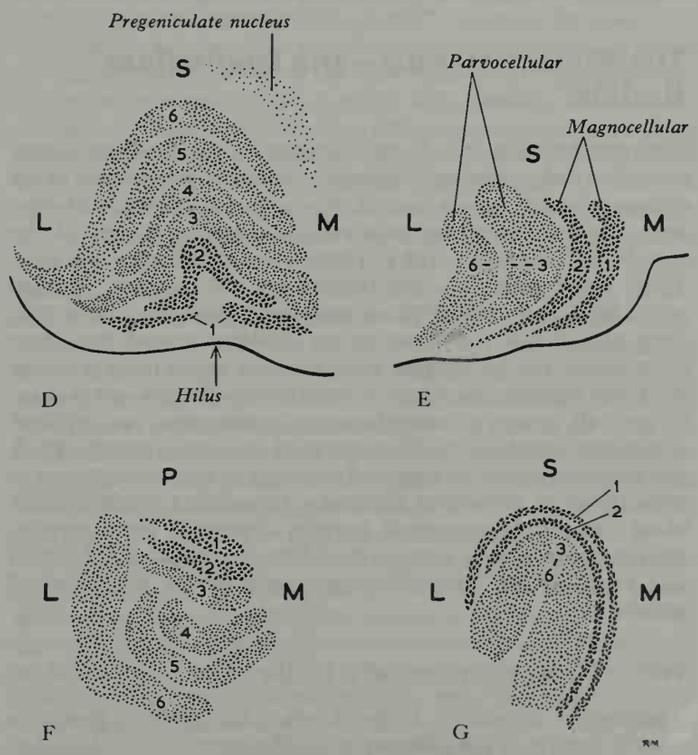
7.108B An oblique view of the dorsal aspect of the brainstem looking cranially. In the foreground is the floor of the rhomboid fossa, bounded laterally by the sectioned white matter of the cerebellum containing the dentate nuclei; the cranial recess of the fourth ventricle passes inferior to the superior medullary velum to continue into the aqueduct of the midbrain. More cranially, the emerging trochlear nerves, the colliculi, superior and inferior brachia, the medial and lateral geniculate bodies, and the pineal gland may be identified. Lateral to the pineal gland on each side is the rounded pulvinar of the dorsal thalamus, skirted laterally by the curving body and tail of the caudate nucleus, whilst most laterally is the cut surface of the corona radiata. (Dissection by Dr. E. L. Rees, Dept. of Anatomy, Guy's Hospital Medical School.)

7.108A A ventral dissection of the brain showing the metathalamus and the optic tracts. On the right side of the figure the inferior horn of the ventricle is exposed. The floor has been removed but the choroid plexus is *in situ* and obscures most of the roof.

The Metathalamus and Visual Pathway

The optic chiasma (7.108A) is a flattened, somewhat quadrilateral bundle of nerve fibres situated at the junction of the anterior wall of the third ventricle with its floor. Its anterolateral angles are continuous with the optic nerves, the posterolateral angles with the optic tracts. The lamina terminalis (p. 981) is continuous with its upper surface and is crossed, just above the chiasma, by the

anterior communicating artery. Inferiorly the chiasma usually rests on the diaphragma sellae a short distance posterosuperior to the 'optic' groove of the sphenoid bone. In about 10 per cent of subjects it is either more anterior and in the groove, or altogether more dorsal in position. It is always in close relation to the hypophysis (**8**.196). Posteriorly it is related to the tuber cinereum and the infundibulum below, and to the third ventricle above. Laterally it is related to the termination of the internal carotid artery and the anterior perforated substance. A small recess of the third ventricle, the *optic recess*, passes ventrocaudally over its superior surface as far as the lamina terminalis (**8**.196).



Most of the fibres of the optic chiasma start in the retina and reach the chiasma through the optic nerves. In the chiasma the fibres from the nasal half of each retina, including the nasal half of the macula, cross the median plane and enter the optic tract of the opposite side, while the fibres from the temporal half pass backwards in the optic tract of the same side. The crossed fibres loop for a short distance into the ipsilateral optic tract before crossing in the chiasma or into the contralateral optic nerve after crossing. The macular fibres, and those from the central area in the immediate vicinity of the macula, form a flattened band which occupies almost two-thirds of the central region of the chiasma. This bundle is superior to all peripheral decussating fibres. Inferior to this are the fibres from the extramacular parts of the nasal half of the retinae. Most inferior are the nasal fibres concerned with the monocular fringes of the binocular visual field. Dorsal to and within the optic chiasma are bundles of fibres which are not derived from the optic nerve and form no part of the visual pathway. Although these are termed, collectively, the *supraoptic commissures*, they are not really commissures but decussations. One of these is the *supraoptic commissure* (of Gudden), which was formerly, but incorrectly, believed to connect the medial geniculate bodies of the two sides. Its connexions are not fully known, but evidence, from work on mammals, suggests that its fibres arise in the brainstem and spinal cord; its existence, in man, is denied by some authorities. The so-called supraoptic commissure is only one of at least three dorsal connecting pathways described in the optic chiasma. They are reputed to terminate in various hypothalamic and subthalamic nuclei in some animals, such as the cat, but it appears improbable that they are in any way associated with vision. There is, however, convincing evidence of a retinal projection to the suprachiasmatic, the ventral part of the infundibular (arcuate), and perhaps the supraoptic nucleus in the rat; and whilst these connexions are not concerned with perceptual aspects of vision, they do, through projections to the pineal gland (p. 1448), mediate the influence of light and dark on hypothalamic, pineal and autonomic activity in circadian rhythms. Similarly, detached bands of nerve fibres have been noted as leaving the optic tract to pass dorsally across the cerebral peduncle inferior to the main tract. Such bundles as the *transverse peduncular tract* and various other *accessory optic tracts*, though present in some lower mammals and infra-mammalian forms, have been claimed to be absent in primates by some authorities (but *see* p. 936). According to this view all the myelinated fibres of the optic tracts in man pass either to the lateral geniculate body or to the superior colliculus and pretectal nucleus (Polyak 1957). However, as detailed above and elsewhere (p. 969) there is an impressive body of evidence that the suprachiasmatic and ventral part of the infundibular (arcuate) nuclei, and as indicated below, a thin lamina in the pulvinar, receive optic tract fibres, i.e. forming *retinohypothalamic* and *retinothalamic projections*.

The optic chiasma is supplied from the network of arteries in the investing pia mater. This network receives branches from the superior hypophysial, internal carotid, posterior communicating, anterior cerebral and anterior communicating arteries. The veins drain into the basal veins and the anterior cerebral vein above.

The optic tracts (7.108, 109) are continued dorsolaterally from the posterolateral angles of the chiasma. Each passes between the anterior perforated substance and the tuber cinereum, as the anterolateral boundary of the interpeduncular fossa. The tract becomes flattened and winds round the upper part of the cerebral peduncle, to which it adheres. In this part of its course it is hidden from view on the basal surface of the cerebrum by the uncus and parahippocampal gyrus. Reaching the lateral geniculate body the optic tract divides into medial and lateral 'roots'. The medial of these is believed to contain supraoptic commissural fibres; the lateral root or ramus consists

C

7.108C–G (C) The lateral geniculate body, shown in coronal section in the human brain to display its general position and orientation—it is the cap-shaped mass of grey and white matter near the centre of the field. Note its relationship to the inferior horn of the lateral ventricle, the structures visible on the sectioned surface of the midbrain tegmentum, and the dorsal thalamus. Even at this low magnification the lamination of the lateral geniculate body is visible. The four diagrams show the right lateral geniculate nucleus in section: (D) a mature human nucleus in coronal section near its central region and (E) near its posterior pole. Note the reduction in the number of discernible laminae in the latter. The lamination is also visible (F) in an approximately horizontal section at the time of birth. In some primates, for example *Tarsius* (G), the magnocellular layers (1 and 2) are curved externally around the parvocellular layers (3–6); the higher primate arrangement is almost the reverse of this when examined in the coronal plane. See text for further details, and consult Le Gros Clark (1932), Cooper (1945); Chacko (1955).

of afferent fibres which arise in the retina and undergo partial decussation in the optic chiasma, as already described, but it also contains a few fine efferent fibres which are passing forwards to terminate in the retina. Most of the fibres of the lateral ramus are found to end in the lateral geniculate body (p. 977); some sweep medially below the pulvinar and gain the superior colliculus and the pretectal nucleus (pp. 941, 942). The termination of some of these fibres in the pulvinar itself has suggested in various mammals, including primates (Campos-Ortega *et al.* 1972) and cats (Berman and Jones 1977) that they may provide part of a more direct route to cortical areas outside the striate cortex. The latter authors describe the pulvinar projection as ending in a thin zone which borders the lateral aspect of the lateral geniculate nucleus. The detailed arrangement of retinal fibres in the optic chiasma and tract has been worked out in the monkey (Polyak 1957) and clinical observations had already suggested a similar form of organization in human structures (Traquair 1948). Illustration 7.109 shows these details. A notable feature is that nerve fibres derived from the macula, which occupy a central position in the optic nerve and chiasma, assume an eccentric and dorsolateral location in the optic tract, where fibres from both retinae mingle. As will be detailed later, this rearrangement is a prelude to the mode of spatial representation in the lateral geniculate body (p. 941), the superior colliculus and visual cortex (p. 1018).

Further fibres arise from nerve cells in the lateral geniculate body, and pass through the posterior limb of the internal capsule. Emerging from the capsule as a broad bundle termed the *optic radiation*, the fibres of the second visual neurons curve backwards and medially to reach the cortex of the occipital lobe of the cerebrum, where the cortical visual apparatus is situated (p. 1018). On their way they are separated from the posterior horn of the lateral ventricle only by the tapetum of the corpus callosum.

Some of the fibres in the optic radiation take an opposite course, arising from the cells of the occipital cortex and passing to the superior colliculus, which therefore receives cortical in addition to retinal fibres. From the superior colliculus further fibres travel by the tectobulbar tracts to reach the nuclei of the third, fourth, sixth and eleventh cranial nerves, and the anterior grey column of the spinal cord. Recent studies suggest that such 'oculomotor' connexions are doubtful in primates, including man (p. 941).

The Metathalamus—the Geniculate Bodies

The metathalamus (7.108, 109) consists of the *medial* and *lateral geniculate bodies*, bilateral eminences on the inferior aspect of the thalamus lateral to each side of the midbrain. As this collective term suggests, they are relatively late specializations of the vertebrate thalamus in both phylogenetic and ontogenetic senses. Their basic roles as relay nuclei on the acoustic (medial geniculate) and visual (lateral geniculate) pathways have long been recognized; but more recent evidence shows that their connexions, and hence their functions, are much more complex than this. In particular, there exists in both pathways—as in most, if not all sensory projections—a *corticofugal* or efferent component, modulating the patterns of *centripetal* inputs, which can hence no longer be regarded as arrays of simple responses to stimulation of peripheral receptors, proceeding independently along completely separated parallel channels. For example, neuronal mechanisms exist, as elsewhere, for collateral inhibition and probably for interaction between different modalities of sensibility.

THE MEDIAL GENICULATE BODY

The medial geniculate body (7.108, 120) projects from the inferior surface of the pulvinar of the thalamus (7.108), lateral to the superior colliculus. Its contour is ovoid, with the long axis directed anterolaterally. The inferior brachium (p. 935) ascends with a ventrolateral inclination to reach the medial geniculate body, passing between it and the pulvinar; it contains nerve fibres from the ipsilateral lateral lemniscus (derived in part from the the opposite superior olive) and from both inferior colliculi.

In its **internal structure** the medial geniculate nucleus exhibits no clear-cut division into sub-nuclei; the entire mass presents a knee-shaped profile in section and hence its name. On the basis of size its cells are largely segregated into a *dorsal, pars parvocellularis*, or *principal division*, and a smaller *ventromedial division*, the *pars magnocellularis*, which in fact contains an admixture of the smaller cell type. Wedged between the pulvinar and the pretectal region, dorsomedial to the medial geniculate body, is a small mass of nerve cells, the *suprageniculate nucleus* of some forms; its connexions are uncertain, but it probably receives fibres from reticular elements in the lateral tegmental region of the midbrain and pons concerned in other modalities of sensation, including pain (p. 943). Closer study of the constituent nerve cells of the medial geniculate nucleus, particularly of their dendritic organization and their connexions in the cat, has prompted a more complex partition into regions and component nuclei (Morest 1964, 1965). In this animal the medial geniculate nucleus has been allotted *dorsal, ventral* and *medial divisions*, with further subdivisions, one of which—the '*ventral nucleus*' of the ventral division—has a laminar structure. This is a detail of special interest, because this part of the geniculate body receives most of the inferior collicular projection in the cat (Moore and Goldberg 1963); and, as will be described below, the lateral geniculate body is also laminated, this pattern being clearly associated with a spatial organization of sensory terminals. In the same feline schema, the medial division is regarded as the terminus of direct lateral lemniscal fibres, and evidence is growing that these are, in the cat and monkey, spinal afferents concerned in modalities of sensibility other than acoustic, ending in the magnocellular (ventromedial or medial) part of the medial geniculate body. It has hence been suggested that this, and perhaps the suprageniculate nucleus, may be involved in integrations between visual, auditory, general somatic and even visceral inputs.

The role of the medial geniculate body in the acoustic pathway is still in many details obscure, apart from its function as a relay nucleus. This is in large part due to its relative inaccessibility to the recording electrode or destructive probe, neither of which can be accurately placed without marked difficulties of approach. By analogy the laminar appearance of the ventral division, and the existence of a tonotopical organization at cortical level, both suggest similar arrangements in the medial geniculate body; and evidence both in favour of this and against it has been adduced in experimental animals. It is clearly not yet justifiable to suggest tonotopical representation in man. The efferent auditory projection is considered to be derived directly from the small-celled regions of the medial geniculate nucleus, terminating in the temporal lobe, in an area in monkeys corresponding to area 41 in man (p. 1021)—part of the superior temporal gyrus. Other acoustic areas have been delineated by animal experimentation, and they may also exist in man (p. 1021). A primary acoustic area (designated AI in the cat) is directly connected to the medial geniculate body; secondary acoustic area (AII and others) may also receive projections from the same parvocellular parts of the geniculate complex, or from its magnocellular part (Niimi and Naito 1974). All these areas may be concerned in various aspects of acoustic function (p. 1021), and there is abundant evidence of tonotopical representation of the spiral organ of the cochlea in area AI. The role of the medial geniculate body, however, in determination of frequencies of sounds remains *sub judice*, the evidence being largely negative (Whitfield 1967). Lesions of the medial geniculate body do not lead to pronounced deafness unless they are bilateral, since both cochlear organs are represented in each lateral lemniscus (p. 909). As in the case of the first somatosensory (p. 1016) and other receptive areas, the auditory cortex projects to lower centres. Cajal first suggested a cortico-geniculate projection, which was demonstrated in monkeys by Whitlock and Nauta (1956). Pontes *et al.* (1975) have described in detail projections from AI and adjoining areas upon the medial geniculate nuclei (dorsal and magnocellular) in the cat and have also summarized previous work in this field. Their results confirm the findings of Walther and Rasmussen (1960) and hence corroborate the concept of a *descending auditory pathway* (*see* Rasmussen 1967, and pp. 964, 1074).

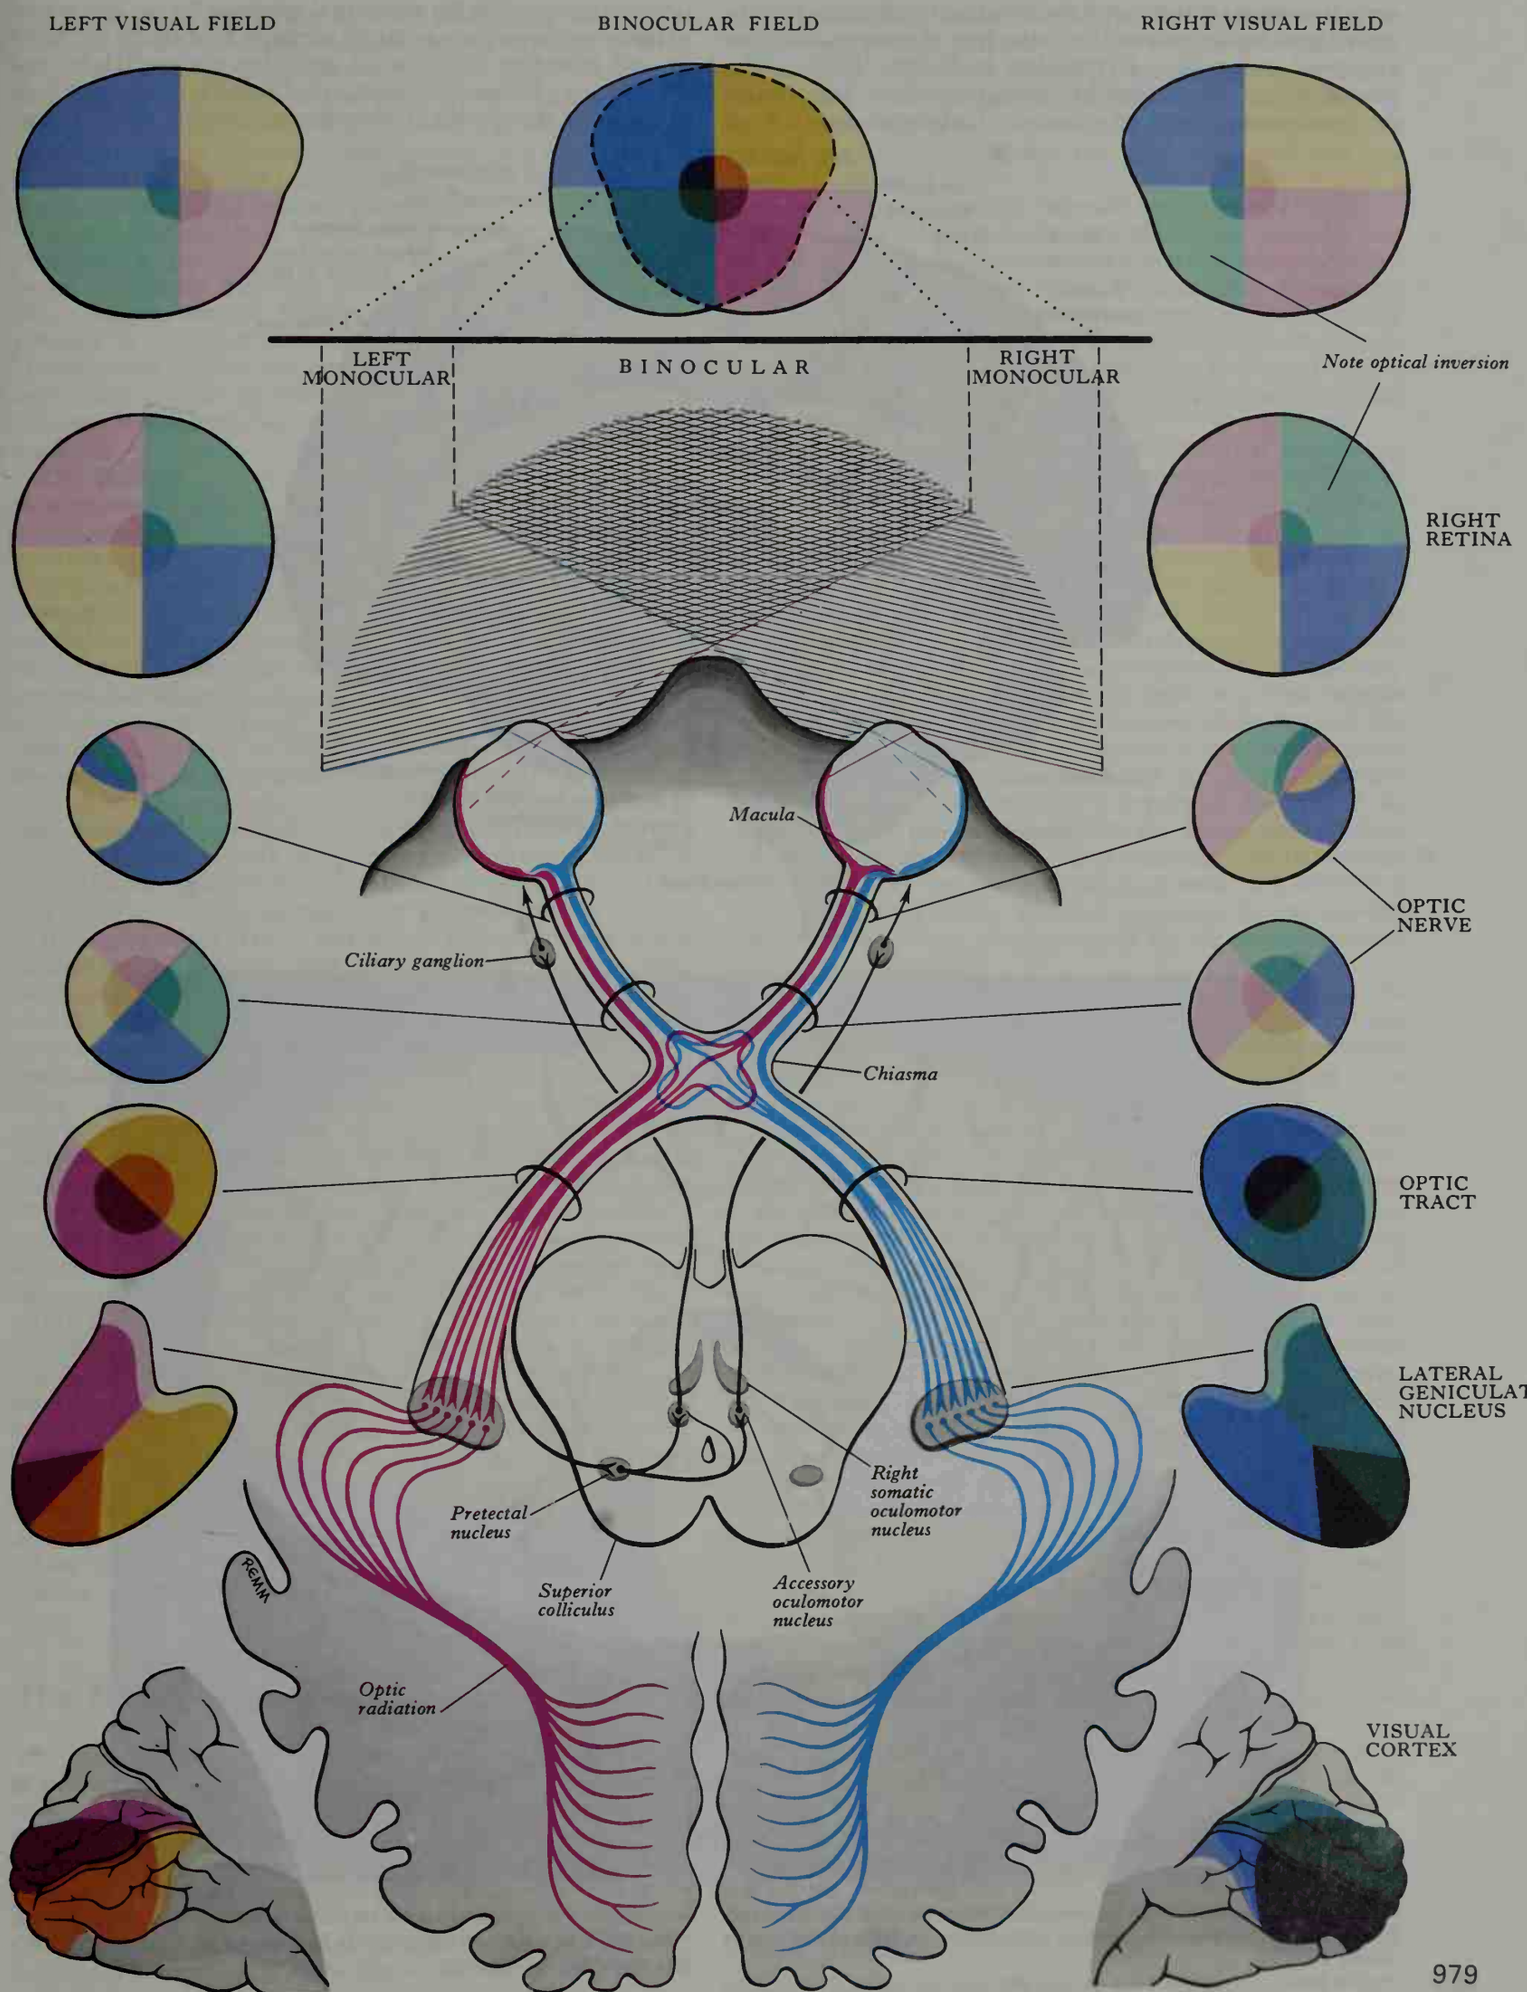
THE LATERAL GENICULATE BODY

The lateral geniculate body is a small nuclear complex distinguishable on the surface as a small ovoid projection from the inferior aspect of the posterior region of the thalamus (7.108, 120). Its long axis is approximately sagittal, and its anterior pole blends with the larger, lateral moiety of the optic tract, the medial 'root' or ramus of which separates the geniculate elevation from the lateral aspect of the crus cerebri. The medial geniculate body is, of course, medial to it, but in a more dorsal position. The inferior or superficial aspects of both geniculate bodies are obscured from view by the medial region of the temporal lobe, the parahippocampal gyrus being the immediate relation (p. 990). Proceeding dorsally from the posteromedial region of the lateral geniculate body, to reach the pretectal area and lateral side of the superior colliculus, is a narrow linear elevation, the *superior brachium* (7.107). This contains uninterrupted retinal nerve fibres which mediate optic reflexes through the pretectal and thence via the oculomotor nuclei and tectospinal tracts (p. 941). The superior brachium is between the medial geniculate body and the pulvinar in much of its extent. From comparison of the lateral ramus of the optic tract and superior brachium, whose relative sizes represent the balance between the forebrain and midbrain destinations, it is obvious that the phylogenetically older, mesencephalic termination is greatly reduced in man, as in other primates, but to a lesser degree in mammals in general. The emergence of the lateral geniculate body was during submammalian evolution, at a stage where the optic tract contains only contralateral nerve fibres from the eye. This decussation is basic in vertebrates, and while it is possible to formulate various explanatory hypotheses to account for it—like other central nervous decussations—these must remain speculative (Polyak 1957; Duke-Elder 1932). The advent of an element of uncrossed retinal connexions in mammals—especially developed in the primates and others with forward looking eyes and overlap of visual fields—can be associated with an increasing specialization of the *dorsal part* of the *primitive lateral geniculate body*, which forms by volume the main part of the structure in higher mammals, including man. It is in this region of the whole nuclear mass that a *laminar organization* appears, perhaps in direct association with the terminals of ipsilateral and contralateral retinal projections (*vide infra*). The *ventral part* of the mammalian lateral geniculate body is also known in many forms as the *pregeniculate nucleus*, which is in man represented by a small but not exiguous group of nerve cells (Le Gros Clark 1932) medial to the main laminar nucleus in its ventral third or so. Medially, the cells of the pregeniculate nucleus extend in a scattered array towards the subthalamic region, marking the evolutionary and embryonic origin of this part of the lateral geniculate complex. It receives a bilateral retinal projection (possibly as collaterals from fibres passing to the tectum and to the main nucleus); this projection is said to be limited to the central region of the retina and to form part of the light reflex pathways through a *pregeniculo-mesencephalic connexion* (Polyak 1957). Such an arrangement has a particular clinical interest to explanations of the Argyll-Robertson phenomenon (p. 1184). However, Pierson and Carpenter (1974) could find no evidence of involvement of this nucleus in the light reflex in monkeys subjected to various lesions of the eye, geniculate and pretectal regions. A cortical connexion with the pregeniculate nucleus has not been established, and it is to be emphasized that some workers deny that optic nerve fibres terminate in this nucleus in primates, in which it is nevertheless a definable entity, though in this order it is not so well developed as in some other mammalian groups, such as ungulates and carnivores (Niimi *et al.* 1963).

The dorsal (or main) lateral geniculate nucleus exhibits a well-known laminar structure, there being six (and perhaps seven) layers of nerve cells discernible in some part of the nucleus in higher primates, such as the rhesus macaque (the subject of much experimental study) and mankind. It should be noted at once, however—particularly in respect of proposals to equate this pattern with functional ideas, such as trichromatic theories of colour vision (Le Gros Clark 1940, 1949)—that the number and arrangement of laminae varies in different mammals, being three in the cat (another much used experimental animal). The laminar pattern also displays regional degrees of elaboration in the geniculate nucleus in most species, including man. Phylogenetically, an original division into two laminae has been suggested, concerned with separate terminations of ipsi- and contra-lateral retinal fibres (Polyak 1957). Nevertheless, all six layers appear together in human embryonic development (Cooper 1945). With the development of two major classes of neurons, large and small, a splitting of these primary layers may have occurred. In this connexion it is pertinent to note that interlaminar strata of larger cells occur between the three recognized laminae in the feline lateral geniculate nucleus (Thuma 1928).

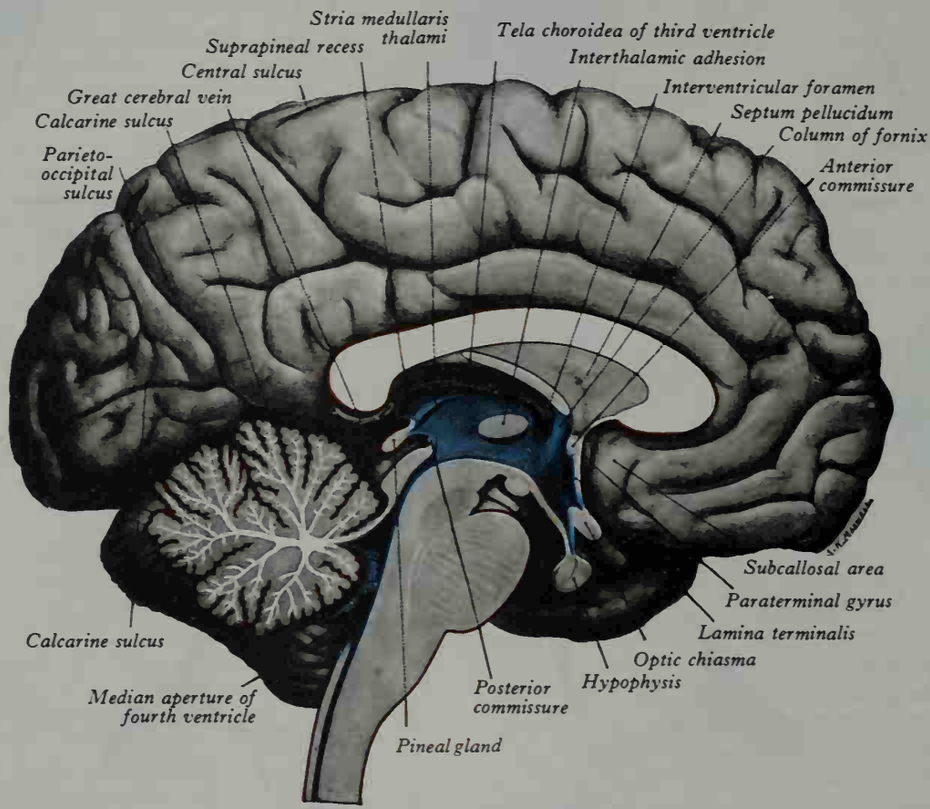
In describing the human lateral geniculate body, particularly as regards its intrinsic and external interconnexions and their functional interpretation, it is necessary to remember that such details are almost entirely extrapolated from experimental results observed chiefly in cats and monkeys, together with a considerable volume of comparative structural study in mammals, including many primates. Nevertheless, the commonly used experimental animals, especially monkeys, display such a similarity of structural organization in the lateral geniculate body that it is unlikely that data established thus cannot be extended, in most instances, to mankind.

The appearance and orientation of the laminae of the human lateral body are shown in illustration 7.108C–G. This orientation is often confusingly presented in textbooks and other accounts (consult Cooper 1945; Chacko 1955), its relation to other structures being obscured by omission of reference data. Often depicted in coronal sections (7.108C), it is also sometimes shown in sagittal section, and in both views the lamination is apparent, since the laminae are somewhat like a series of caps set one upon another. The lamination is best displayed in coronal sections from the central region of the nuclear mass and in a direction towards its posterior (caudal) pole. Anteriorly or cranially, i.e. near the entry of the optic tract, the layers are blended together into a common mass, and at the posterior extremity the number is reduced to four—in a region of the nucleus which is considered to be monopolized by terminating macular fibres. As illustration 7.108C shows, the laminae are curved, with a ventral concavity forming a kind of 'hilum', at which some of the retinal efferents enter from the adjacent optic tract. This hilum is much more prominent in the monkey than in man. Dorsally, the nucleus is dome-shaped and projects towards the thalamus; from this aspect the majority of the fibres of the optic radiation, or *geniculostriate projection*, emerge from the nucleus. Both medially and laterally the laminae blend, as if at the edge of the cap-shaped mass; and the lateral border is sharp; the blending layers reverse their curvature here, becoming ventrally convex, or upturned like the peak of a cap. It is also noteworthy that concave contours of the laminae are also reversed in the posterior (macular) part of the geniculate nucleus. As a result, the profiles of the laminae, in the coronal plane, are slightly sinuous on the lateral side. (Some of the confusion concerning the lamination of the lateral geniculate body is due to the fact that the order of the layers is reversed in some lower primates, the large celled laminae 1 and 2 being *external* and *dorsal* to the others—on the outer aspect of the curvature of the entire laminar structure. In *Tarsius* the situation is extreme, the layers being an inverted replica of the human situation—or vice versa. In the lemuroids transitional states occur. Much controversy has been entailed by the use of the terms inversion and eversion, which need not detain us here.)

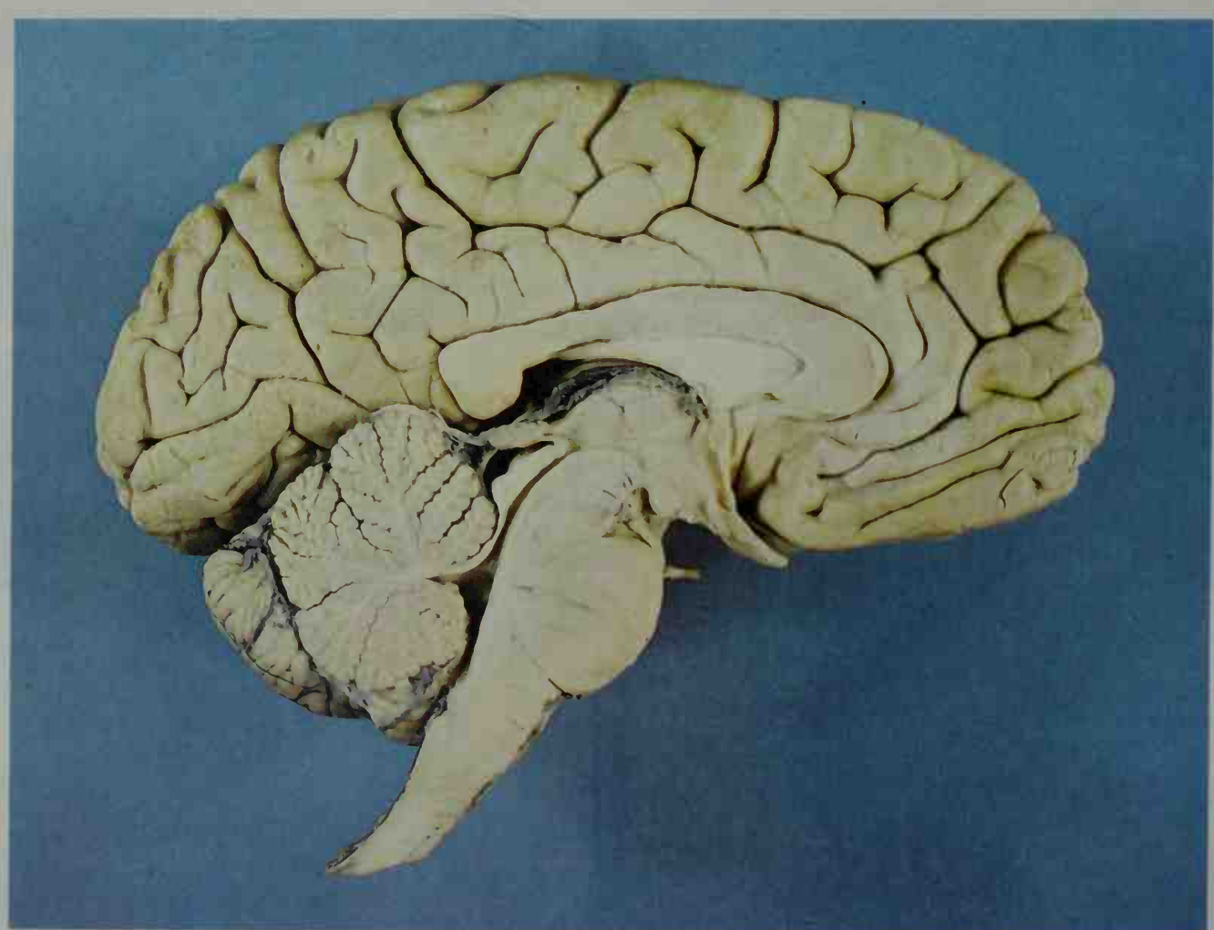


The most careful estimates (Kupfer *et al.* 1967) suggest that there are about 1 million nerve cells in the human lateral geniculate body, corresponding closely to the count of fibres in the optic nerve and tract. (Estimates in the macaque monkey are as much as 1·8 million, Le Gros Clark 1941 and 1·7 million, Rakic 1977, but only 1·2 million in the optic nerve, Bruesch and Arey 1942. *See*, however, Chow *et al.* 1950.) This 1:1 ratio in man does not, however, imply that each optic nerve fibre connects with only one geniculate cell. This relationship may be the case in respect of the macula, but such details are still uncertain. It has long been established (Minkowski 1913; Le Gros Clark 1941; Glees 1941) that each fibre, derived from the retinal ganglion cells, ends by dividing into no more than five or six terminals

connecting with a corresponding number of geniculate nerve cells in *one* lamina. (The geniculate cells may connect with terminals from more than one retinal fibre.) The laminae are usually numbered 1 to 6, starting from the concave, ventral, or hilar aspect of the nucleus. Fibres from the *contralateral* optic nerve end in layers 1, 4 and 6, *ipsilateral* fibres in layers 2, 3 and 5. Early recognition that transneuronal degeneration (p. 816) occurs in the lateral geniculate body (Minkowski 1913), coupled with an adequate terminal degeneration technique (Glees 1946), has led to the detailed elucidation of this bilateral representation of the retinae in each lateral geniculate body. Even with the Marchi degeneration technique alone (Brouwer and Zeeman 1926) it had been possible to show in monkeys—by studying the results of small retinal lesions—that fibres from different quadrants of the retinae are located correspondingly in the optic nerve (p. 1055 and 7.109), macular fibres occupying a central position. Similarly, an orderly but somewhat different arrangement was demonstrated in the optic chiasma and tract (7.109), with the difference that in the tract, fibres from corresponding quadrants in both retinae occupy the same location. This pattern is carried into the lateral geniculate body, where the macular fibres terminate in the central and posterior part of the nucleus, the peripheral fibres in its anterior part, the upper retinal quadrants ending laterally, the lower ones medially (7.109). Transneuronal techniques enabled much more precise plotting of the retinogeniculate connexions (Le Gros Clark and Penman 1934), and since the cortical projection fibres of the affected geniculate nerve cells also degenerate, it was demonstrable that the same kind of a precise point-to-point connexion continues through the optic radiation to the striate cortex (p. 1018). The precision of this topical organization in the visual pathway has been repeatedly confirmed in cats and monkeys (Polyak 1957; Meikle and Sprague 1964; Saavedra *et al.* 1969). (Some doubts as to the factors causing transneuronal degeneration in the lateral geniculate nucleus have been expressed. There is some evidence that the effect is not due solely to deafferentation by, for example, optic tract interruption. Consult Garey *et al.* (1976) for discussion.) As will be detailed elsewhere (p. 962), ablation of small parts of the striate cortex in the occipital lobe leads to highly localized patches of degenerating geniculate cells in *six layers* on the same side. These effects appear in a *columnar representation* of corresponding points of the two retinae, each in *three* of the six geniculate laminae. The results of transneuronal degeneration in the lateral geniculate nucleus, consequent upon destruction of the retinal ganglion cells or interruption of their axons, have been confirmed by the substantially equivalent but less dramatic effects of prolonged suturing of eyelids in kittens (Wiesel and Hubel 1963; and Guillery 1973) and infant monkeys (Von Noorden 1973; and Headon and Powell 1973). These experiments have been performed unilaterally and sometimes bilaterally. In the latter case (Headon and Powell 1978) one unexplained finding was that the shrinkage of geniculate neurons observed in such experiments was greater in those parts of the nucleus receiving fibres from the monocular fields of the retinae when *both* eyes had been subjected to prolonged closure. More recently the application of the technique of autoradiographic tracing of labelled amino-acids (which are subject to orthograde axoplasmic flow and even transneuronal transport) to the visual pathway has confirmed these earlier results (*see* Graybiel 1975, Hubel *et al.* 1976, and Rakic 1976), both as regards the laminar terminations of retinal ganglionic neurons in the lateral geniculate nucleus and anatomical orientation of neurons in this nucleus and the visual cortex.



So far this account has considered the visual pathway as a series of parallel conducting pathways, with no mention of possible interaction between them—whether from the same retina or from both. In fact, it has for long been assumed that, apart from inevitable convergence of activities in the far more numerous rods and cones of the retina upon the more limited population of optic nerve neurons (retinal ganglion cells—p. 1170), the remainder of the visual pathway consists of functionally isolated conductors, with a simple relay in the lateral geniculate body. This simple view has been customary textbook teaching, with the modification that the bringing together of fibres from both retinae in the geniculate body constitutes subcortical 'fusion'. The latter would be a naïve assumption in the absence of data beyond those recounted above. The neuronal organization of the retina itself is, of course, complex; there is clear evidence, both anatomical and physiological (p. 1166), of interaction between its neurons. Hence the pattern of impulses in the optic nerve is not the simple result of a mosaic of receptor responses, like the signals in a cable between a television camera and its monitor—even if the effects of corticofugal connexions are ignored (p. 1174). Integrative activities in the cat's lateral geniculate body have also been demonstrated (Hubel and Wiesel 1961) between corticofugal fibres and the incoming sensory projection, as in other sensory pathways. While unit recording has also shown the existence of lateral inhibition and of units responsive to specific modes of stimulation, there is apparently no clear evidence to indicate that individual geniculate cells receive impulses from both retinae (Glees 1961).



An increasing elaboration of cytological detail, particularly in respect to dendritic fields and synaptic characteristics, has been recorded in the cat and monkey. It is not possible even to survey this voluminous literature here, but reference to the reports of Peters and Palay (1966), Campos-Ortega *et al.* (1968), Lieberman (1973, 1974), and Lieberman and Webster (1974) will provide an introduction to the detailed synaptic organization of the dorsal lateral geniculate nucleus. Lieberman in particular has identified a wide variety of synapses, pre- and post-synaptic, inhibitory and excitatory, dendrodendritic, and the triplet synapses (triads) of the glomeruli (*vide infra*). These and other researches have been carried out in rodents, cats, and monkeys, and whilst species differences are apparent, the basic resemblances are predominant. While it is not yet possible to correlate these findings into a fully connected model of geniculate activity, it is obvious that the view of this as a comparatively simple relay mechanism is completely demolished. Three major elements are involved: (*a*) *afferents* from the retinae—to which may be added corticofugal fibres and perhaps fibres from the ubiquitous reticular system; (*b*) the *efferent geniculostriate projection*; and (*c*) the *intrinsic neuronal population*, consisting largely of Golgi type II nerve cells, not all the axons of which are confined to a single lamina, and hence might mediate connexions between bilateral retinal afferents. Most accounts say little of the precise arrangement of the cells (Golgi type I) whose axons stream dorsally through intervening laminae to form the geniculostriate pathway; attention has been predominantly concentrated—both in light and electron microscope studies—upon dendritic arrangements and the distribution and functional attributes of synapses. The profusion of the resultant neuropil is in itself suggestive evidence of highly complex interneuronal mediation between the afferents and efferents of the lateral geniculate body (Szentágothai 1963; Lieberman 1974). One particularly interesting feature is the occurrence of *glomeruli*—conglomerations of synapses between dendritic and axonal terminals, the latter in part derived from optic nerve fibres (Peters and Palay 1966; Campos-Ortega *et al.* 1968; Lieberman 1974). These are similar in some respects to the synaptic glomeruli described in the cerebellum (p. 924), and in other thalamic 'relay' nuclei (p. 956), and subserve the same kind of integrative function. The glomeruli are highly complex structures consisting of a main and peripheral axons, a main and peripheral dendrites, and various other neuronal and glial elements (see also p. 829). Some axons may be involved in the formation of several glomeruli; others, morphologically distinguishable, occur in the periphery of the glomerulus, making

7.109 A diagram of the visual pathway to show the spatial arrangement of nerve cells and their fibres in relation to the quadrants of the retinae and visual fields. The proportions at various levels are not exactly to scale, and in particular the macula is exaggerated in size in the visual fields and retinae. In each quadrant of the visual field, and the parts of the visual pathway subserving it, two shades of the respective colour are used—the paler for the peripheral fields and a darker shade for the macular part of the quadrant. From the optic tract onwards these two shades are both made more saturated to denote intermixture of neurons from both retinae, the palest shade being reserved for parts of the visual pathway concerned with uniocular vision. The path of the light reflex has also been indicated.

synaptic contacts not only with the dendrites in it but also with the central axon within its core. The latter type of synapse, like other *axoaxonal* connexions, is probably inhibitory (Eccles 1964; Shepherd 1974). Dendrodendritic and axodendritic, however, are the predominant types of synapses (Lieberman 1974). Such observations provide the anatomical substrate for the occurrence of inhibitory as well as excitatory receptive field effects identified by unit recording in the lateral geniculate nucleus (Hubel and Wiesel 1961). Glomerular structures of a similar nature have been identified in the monkey (Colonnier and Guillery 1964). Brauer

and Winkelmann (1976) have surveyed views of the functions of interneural participation in mammalian glomeruli. Such *synaptic* glomeruli are not to be confused with clusters of nerve cells, also called glomeruli, described at a much earlier date (Taboada 1927); these exist in all the laminae of the monkey's geniculate nucleus, the number in the clusters increasing from 12–15 in layer 1 to 60–100 in layer 6. It has been suggested (Peters and Palay 1966) that the somata of the neurons whose neurites are involved in a *synaptic glomerulus* may be clustered together as a *cellular glomerulus*, a view which tentatively equates the latter with the nerve cell groups described above. Electron microscope evidence suggests that the synaptic glomeruli may become more complex in the outer layers of the lateral geniculate nucleus. However this may be, the intricate synaptic relationships thus established provide an illuminating prelude to full structural delineation of the integrative mechanisms in the lateral geniculate nucleus.

The findings so far noted on the whole indicate only *intra*laminar integration; the question of *inter*laminar interaction is of special interest with regard to integration of information from both eyes. Since each retinal ganglion cell fibre terminates, as far as is known, merely in one lamina, any interaction between fibres derived, as is presumed, from the same locus in one retina but ending separately in three geniculate laminae, would require some form of interlaminar connexion. Even were such connexions unsupported by anatomical evidence, the results of unit recording at the geniculate level could indicate their existence. The same reasoning appertains to interaction between impulses derived from corresponding loci in *both* retinae. Again, as far as is known, each lamina projects separately to the striate cortex—and not, as some diagrams loosely depict, by a fictitious form of neuron with a soma in each lamina and a single conjoined axon projecting to the cortex! Physiological evidence has tended to corroborate the view that impulses from the two retinae are integrated only at the level of the striate cortex (Hubel and Wiesel 1969). However, it *was* claimed fairly recently that unit recording demonstrated binocular interaction at the geniculate level; and electron microscope observations suggest that in the fibre zones between laminae are synapses between neurons intrinsic to the lateral geniculate nucleus (Guillery and Colonnier 1970), however, *vide infra*. Neurons in the laminae—probably second order interneurons—have also been claimed to mediate interlaminar connexions (Guillery 1966, 1971); these *could* be concerned in channelling effects from both retinae into single geniculostriate fibres. It is precisely upon these problems that most of the intense synaptological research on the geniculate neurons is currently focused. The peculiarities of the intrinsic neurons (interneurons) have attracted special attention (consult Lieberman and Webster 1974). Many, perhaps almost all of these are amacrine (anaxonal) in rodents and some, at least, are without axons in monkeys (LeVay 1971). They are, therefore, integrative in function, as is obvious from their complex pre-synaptic contacts with retinal and cortical connexions in the glomeruli of the lateral geniculate. In the most recent summary of activity in the visual pathways (Hubel and Wiesel 1977) it appears that the weight of evidence is *strongly against* the existence of any neurons in the lateral geniculate nucleus which respond to impulses from both retinae. These two workers, pre-eminent in this field, firmly reject any 'fusion' of information from both retinae at the geniculate level.

The Third Ventricle

The third ventricle (7.97, 110), which is the derivative of the primitive forebrain vesicle, is a median cleft between the two thalami and hypothalami. It communicates posteriorly with the fourth ventricle through the cerebral aqueduct, and anteriorly with the lateral ventricles through the interventricular foramina. It has a roof, a floor, anterior and posterior boundaries, and two lateral walls.

The *roof* is formed by a layer of ependyma which stretches between the upper edges of the lateral walls of the cavity and is continuous with the rest of the ependymal lining of the ventricle. It is covered by, and adherent to, a fold of pia mater, named the *tela choroidea* of the third ventricle, from the inferior surface of which a pair of vascular fringed processes, the *choroid plexuses of the third ventricle*, project downwards, one on each side of the median plane, and invaginate the ependymal roof into the ventricular cavity (7.157).

The *floor* (7.110) descends ventrally and is formed mainly by structures which belong to the hypothalamus; ventrodorsally these are: the optic chiasma, the infundibulum and tuber cinereum, and the mamillary bodies. Posterior to the last-named, the floor is formed by the posterior perforated substance and by the tegmentum of the cerebral peduncles. The ventricle is prolonged downwards into the infundibulum as a funnel-shaped *infundibular recess*. The neurohypophysis is continuous with the apex of the infundibulum.

The *anterior boundary* (7.110) is inferiorly the *lamina terminalis*, which represents the cranial terminal of the primitive neural tube. It forms a thin layer of grey matter stretching from the superior surface of the optic chiasma to the rostrum of the corpus callosum. In its superior part the anterior boundary is formed by the columns of the fornix, which diverge as they descend into the lateral walls of the ventricle, and by the anterior commissure (p. 997), which crosses the median plane anterior to them. At the junction of the floor and anterior wall, immediately above the optic chiasma, the ventricle presents a small angular diverticulum, the *optic recess*. At the junction of the roof with the anterior and lateral limits of the ventricle is the *interventricular foramen*, through which the third and the lateral ventricles communicate with one another. It represents the site of the original diverticular outgrowth from the telencephalon which forms the cerebral hemisphere, and is *relatively* large and circular in a 10 mm human embryo. In the adult, however, it is altered to a somewhat crescentic slit, bounded anteriorly by the curving column of the fornix and posteriorly by the convex anterior tubercle of the thalamus.

The *posterior boundary* (7.110) consists of the pineal gland, the posterior commissure and the cerebral aqueduct. A *pineal recess* projects into the stalk of the pineal gland, while anterosuperior to the latter is a second, *suprapineal recess*, consisting of a diverticulum of the epithelial ventricular roof.

Each *lateral wall* consists of an upper part formed by the medial surface of the anterior two-thirds of the thalamus, and a lower formed by the hypothalamus and continuous with the grey matter of the ventricular floor. These two regions of the lateral wall are separated by the *hypothalamic sulcus*, which extends from the interventricular foramen to the cerebral aqueduct, but is not always an obvious feature. As noted previously (p. 953), the hypothalamic sulcus can be regarded as dividing the diencephalon into two. Above (dorsal to) the sulcus is the *pars dorsalis diencephali* consisting of the dorsal thalamus and the epithalamus, below (ventral) is the *pars ventralis diencephali* which constitutes the hypothalamus and subthalamus. Each lateral wall of the third ventricle is limited superiorly by the ridge covering the stria medullaris thalami (p. 954). The columns of the fornix curve ventrally rostral to the interventricular foramina, and then run in the lateral walls of the ventricle, where, at first, they form distinct prominences, but subsequently sink into them. The lateral walls are joined to each other across the cavity of the ventricle by a band of grey matter, the *interthalamic adhesion* (p. 955). An extensive description of the phylogeny and development of the third ventricle has been contributed by Kier (1977). The zones of specialized ependyma collectively forming the *circumventricular organs* are described on pp. 197, 836, 1442.

The interpeduncular fossa (7.55, 104, 115) is a trapezoid area of the cerebral base, limited anteriorly by the optic chiasma, posteriorly by the anterosuperior surface of the pons, anterolaterally by the converging optic tracts, and posterolaterally by the diverging cerebral peduncles. The structures contained in it have been described elsewhere; caudorostrally they are the posterior perforated substance, mamillary bodies, tuber cinereum pp. 966–973, infundibulum and hypophysis cerebri pp. 969, 1438.

THE TELENCEPHALON OR 'ENDBRAIN'

The expansion of the telencephalon and the development of the two cerebral hemispheres have already been described (pp. 170–174). In primitive vertebrates each cerebral hemisphere is predominantly concerned with olfactory impulses, which enter it rostrally at the *olfactory lobe*. This lobe may be drawn away to form an *olfactory bulb* which remains connected to the rest of the hemisphere by a stalk, the *olfactory tract*. In the basal parts of each hemisphere masses of grey matter, the *basal nuclei*, are present and form an early motor centre. The wall of the hemisphere constitutes the *pallium*, wherein olfactory and other flows of information are presumed to be integrated. In the course of evolution visual, auditory and other conduction paths have been extended, through the thalamus, to the pallium of the cerebral hemispheres, an instance of encephalization. Consequently, each cerebral hemisphere enlarges as a result of the formation of an additional region, the *neopallium*, the predominantly olfactory pallium being confined to a *piriform lobe* inferolateral in site. The medial wall of the hemisphere becomes specialized to form the *hippocampal formation*. This was for long also regarded as primarily part of the olfactory mechanism, but in recent years this view has become untenable (*see* p. 990). In higher mammals the neopallium is greatly enlarged; the piriform lobe, in contrast, is relatively reduced. With the growth of the neopallium motor pathways are developed from this, but the basal nuclei remain as essential parts of the motor control apparatus. The greatly increased growth of the neopallium in mammals is due to the formation of *association areas* concerned with the interaction of its multiplicity of afferent and efferent connexions. (It should be noted that the hippocampal formation is often termed the *archipallium*, or *primal* cortex, and the piriform lobe the *paleopallium*, or *ancient* cortex. Some authorities, however, group both these regions under the term *archipallium*, and also prefer to spell the term archeopallium.)

The telencephalon includes: (1) the cerebral hemispheres, the commissures which connect them, and the cavities which they contain; and (2) the anterior parts of the third ventricle, including the preoptic regions in the telencephalon impar, already described (p. 965). Each cerebral hemisphere consists of an outer layer of neurons, the so-called grey matter, termed the *cortex*, an inner mass of neuronal processes, the white matter (*centrum semiovale*), the deeply situated *basal nuclei* and a cavity, the *lateral ventricle*.

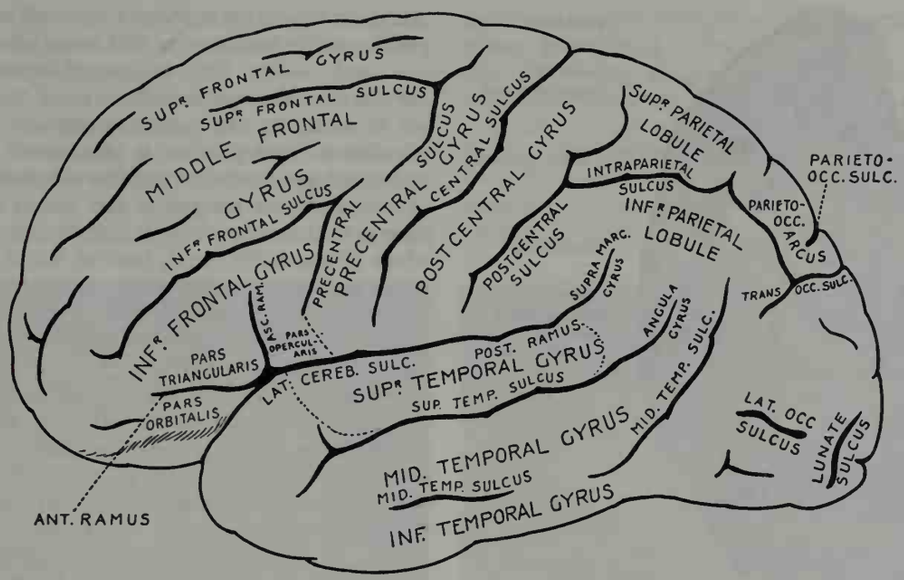
THE CEREBRAL HEMISPHERES

The cerebral hemispheres form the largest part of the brain, and, when viewed together from above, assume the outline of an ovoid mass broader behind than in front, the greatest transverse diameter corresponding with a line connecting the two parietal tuberosities. The hemispheres are incompletely separated by a deep median cleft, named the *longitudinal cerebral fissure*, and each possesses a central cavity, the *lateral ventricle*.

The longitudinal fissure of the cerebrum contains a sickle-shaped process of dura mater, the *falx cerebri*, and the anterior cerebral vessels. Anteriorly and posteriorly, the fissure completely separates the cerebral hemispheres from each other; centrally, however, it only extends down to a great central white commissure, named the *corpus callosum*, which connects the hemispheres across the median plane.

The Surfaces of the Cerebrum

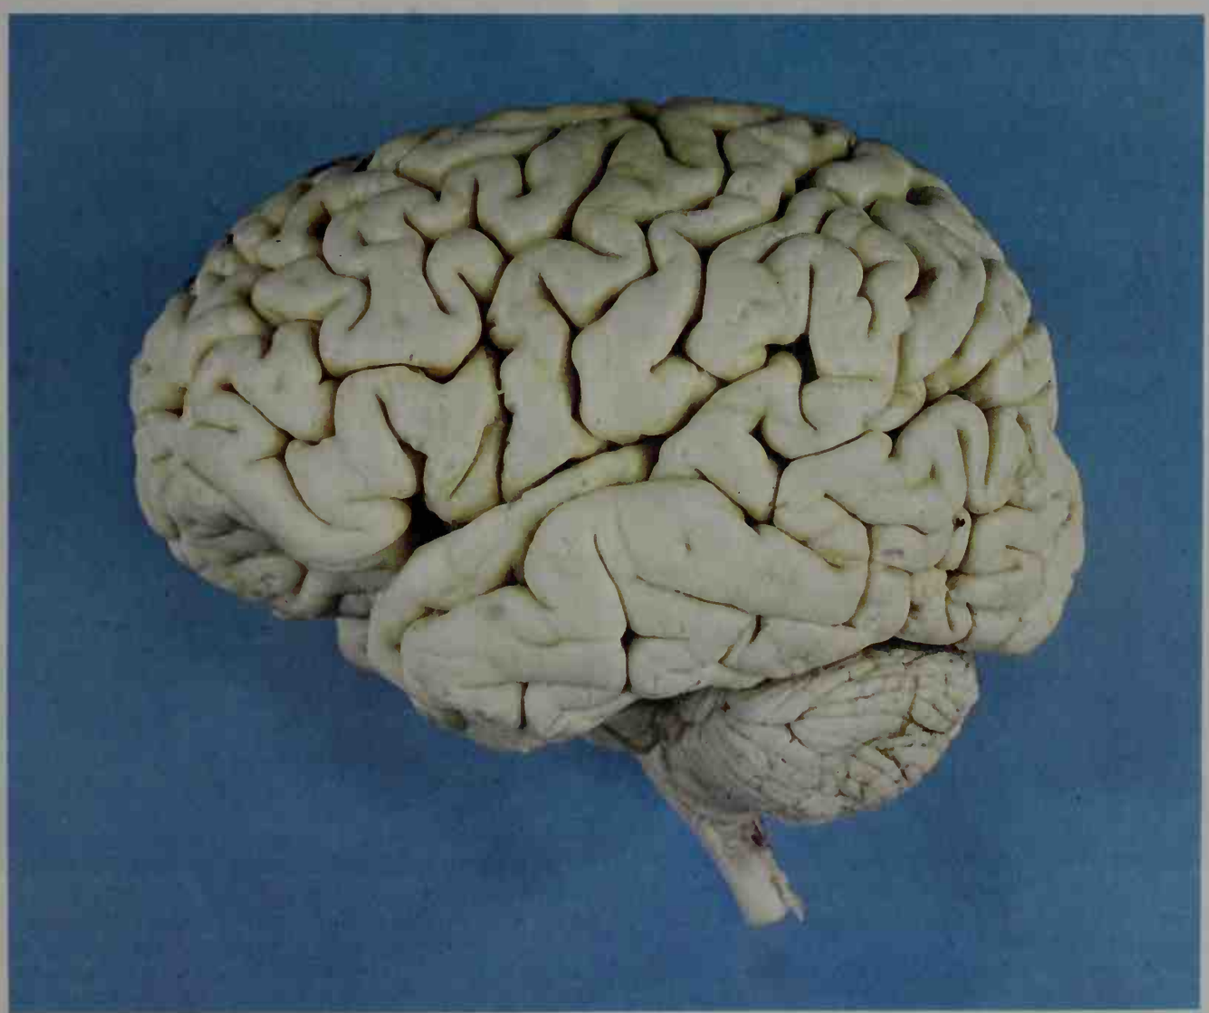
Each cerebral hemisphere presents three surfaces: superolateral, medial and inferior.



The *superolateral surface* is convex in adaptation to the concavity of the corresponding half of the vault of the cranium. The *medial surface* is flat and vertical and is separated from that of the opposite hemisphere by the longitudinal fissure and the falx cerebri. The *inferior surface* is of an irregular form, and may be divided into two parts: orbital and tentorial. The orbital part, being the orbital surface of the frontal lobes, is concave, and is above the orbital and nasal roofs; the tentorial part is concavoconvex, and is the inferior surface of the temporal and occipital lobes; anteriorly it is adapted to the corresponding half of the middle cranial fossa; posteriorly it rests upon the tentorium cerebelli, which intervenes between it and the superior surface of the cerebellum.

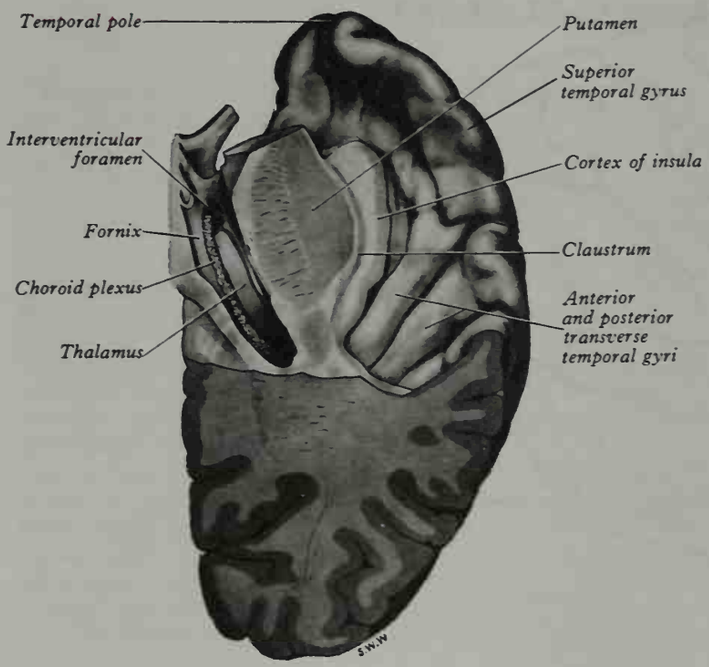
The three surfaces are separated by the following borders: (*a*) *superomedial*, between the superolateral and medial surfaces; (*b*) *inferolateral*, between the superolateral and basal surfaces; the anterior part of this border separates the superolateral from the orbital surface of the frontal lobe, and is known as the *superciliary* border; (*c*) *medial occipital*, between the tentorial part of the inferior and the medial surface; and (*d*) *medial orbital*, separating the orbital part of the inferior from the medial surface. The anterior end of the hemisphere is named the *frontal pole*, the posterior, the *occipital pole*; and the anterior end of the temporal lobe, the *temporal pole*. About 5 cm anterior to the occipital pole on the inferolateral border there is an indentation, the *pre-occipital incisure* or notch.

A paramedian line drawn from a point a little superolateral to the inion, forwards to a point just superolateral to the nasion, corresponds to the superomedial margin. The superciliary border follows the curve of the eyebrows at a slightly higher level as far as the zygomatic process of the frontal bone and then ascends to the pterion. The temporal pole can be indicated on the surface of the head by a line drawn, with a forward convexity, from the pterion to the middle of the upper border of the zygomatic arch, and this line, continued backwards just above the zygomatic arch and crossing the auricle a little above the external acoustic meatus, corresponds to the inferolateral margin of the hemisphere, which then curves downwards to reach the posterior end of the superomedial border (**6**.119).



The surfaces of the hemispheres are moulded into a number of irregular eminences, named *gyri* or *convolutions*, and separated by furrows termed *sulci* or *fissures*.

The irregular character of the surfaces of the cerebral hemispheres is a very prominent feature, but up to the end of the third fetal month these surfaces are smooth and unbroken, like the surfaces of the brains of reptiles and birds. Thereafter localized depressions become apparent, and they deepen and extend over the surfaces to form the sulci (*see* p. 170 and **2**.89A–G). Each sulcus corresponds to an infolding of the cortex; thereby the total amount of grey matter is about three times as much as might be inferred from the surface area of the hemisphere. In certain situations the sulci develop along lines separating areas which differ from one another in the details of their microscopic structure and in the functions which they predominantly subserve (Le Gros Clark 1945). Such sulci may therefore be termed *limiting sulci*, since they establish the limits of certain functional areas. The central sulcus is an example of a limiting sulcus, for it is set between two areas of cortex which differ in thickness so notably that this can be appreciated with the naked eye (**7**.115A). In other situations sulci develop in the long axis of a rapidly growing homogeneous area and are termed *axial sulci*. The posterior part of the calcarine sulcus is in the centre of the striate area and is merely a fold in the visual cortex. In other situations, again, a sulcus may be situated between two surface areas of cortex which are structurally different, but its lip and not its floor may form the dividing line between the two areas. In these cases a third area may be present in the walls of the sulcus without appearing on the surface at all. Such a sulcus is termed an



7.111A Lateral aspect of the superolateral surface of the left cerebral hemisphere.

operculated sulcus, and this type is represented in the human brain by the lunate sulcus, which separates the striate from the peristriate areas on the surface, and contains in its wall the submerged parastriate area, which really intervenes between them. These three varieties include all the sulci which develop on the surface of the brain, with the exception of the lateral sulcus and the parieto-occipital sulcus. The former is the result of the slower expansion of the cortex of the insula and its consequent submersion by the adjoining cortical areas, which eventually come into contact with one another so as to delimit the lateral sulcus. The latter is brought about subsequent to the development of the corpus callosum. The posterior end of this great commissure has to convey not only the fibres from the occipital lobes of the brain but also a large number of fibres from its

7.111B A left lateral view of the brain to show the pattern of gyri and sulci on the superolateral aspect of the cerebral hemisphere. Compare with 7.111A, which was drawn from a different specimen, for labelling of the many structures visible. Note also the contrasting cortical patterns of the cerebrum and cerebellum. 7.112 Horizontal section showing the superior surface of the right temporal lobe.

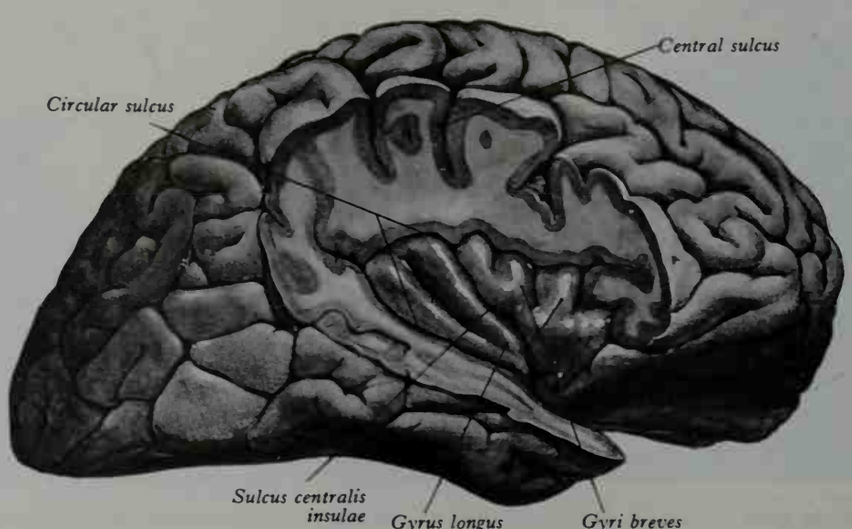
temporal lobes. As a result, a number of smaller axial and limiting sulci become crowded together and some of them become buried within the walls of the parieto-occipital sulcus. These two are really *secondary sulci*, since their occurrence depends on factors other than exuberant growth in closely adjoining areas.

Some of the sulci which indent the cerebral surface are deep enough to produce corresponding elevations in the walls of the lateral ventricles. The anterior part of the calcarine sulcus, which produces the calcar avis of the posterior horn, and the collateral, which produces the collateral eminence in the inferior horn, are therefore termed *complete fissures* or *sulci*. There is, however, no special morphological or functional significance to be attached to the fact that while some sulci are complete others are incomplete. (All the features mentioned in the above account can easily be identified in the illustrations in this section.)

The gyri and their intervening sulci are fairly constant in arrangement; at the same time they vary within certain limits, not only in different individuals, but in the two hemispheres of the same brain.



The convolutional pattern of the cerebral cortex is an inevitable concomitant of the much greater increase in volume of the pallium or mantle of nerve cells in the cortex as compared with the lesser increase in volume of the subjacent white matter. The actual area of the human cortex is about 2,200 cm², and only a third of this is visible on the surface, the rest being obscured from view in the sulci and fissures. By this form of evolution a large increase in cortical area is possible without great change in cranial capacity, but it would be misleading to explain the arrangement in this teleological manner, as is sometimes done. Similarly, any presumed association of high intelligence with great complexity of convolutional pattern is also fallacious. The most intricate arrays of sulci and gyri occur in the cerebra of the elephant and the whale (Hammelbo 1972), both of which have in addition much larger brains than man, though not so in relation to their total size. No close relationship between convolutional complexity and brain size with cerebral abilities has been established in man himself; abundant examples of highly able individuals with relatively small brains and the reverse of this have been attested. Attempts to draw deductions from the endocranial casts of fossil forms of man—as an indication of the development of certain gyri and hence abilities (such as the capacity for speech)—have likewise proved misleading and have been largely abandoned except by anthropologists.

It is convenient for description and reference to separate the surfaces of the cerebral hemisphere into a number of lobes, but it must be remembered that this division is purely one of convenience; moreover the lobes do not precisely correspond in surface extent to the cranial bones from which their names are derived.

THE SUPEROLATERAL SURFACE OF THE CEREBRAL HEMISPHERE

Two sulci, viz. the *lateral sulcus* and the *central sulcus*, take a large part in forming the boundaries of the lobes into which this surface is divided (7.111A, B).

The lateral sulcus (7.111, 115) is a deep cleft situated on the inferior and lateral surfaces of the cerebral hemisphere. It consists of a short stem which ends by dividing into three rami. The *stem* commences on the inferior surface at the anterior perforated substance and extends laterally between the orbital surface of the frontal lobe and the anterior part of the temporal lobe. It is occupied by the posterior border of the lesser wing of the sphenoid bone and the sphenoparietal venous sinus. On reaching the lateral surface it divides into anterior horizontal, anterior ascending and posterior rami. The *anterior ramus* runs forward for 2·5 cm or less into the inferior frontal gyrus, while the *ascending ramus* runs upwards for about an equal distance into the same gyrus. The *posterior ramus* is the longest division. It courses posteriorly and slightly upwards across the lateral surface for about 7 cm before turning upwards to end in the parietal lobe. The floor of this sulcus is formed by the limen insulae and the insula, and it conducts the middle cerebral vessels from the inferior to the superolateral aspect of the hemisphere. It can be

 7.113A The right insula, exposed by the removal of its opercula.

represented on the side of the head by a line drawn backwards and slightly upwards for 7 cm from the pterion and then curving upwards to end under the parietal eminence.

The central sulcus (7.111) commences in or near the superomedial border of the hemisphere a little posterior to the mid-point between the frontal and occipital poles (i.e. midway between nasion and inion). It runs sinuously downwards and forwards for about 8 to 10 cm and ends a little superior to the posterior ramus of the lateral sulcus, from which it is always separated by an arched gyrus. The general direction of the sulcus makes an angle of rather less than 70° with the median plane (7.111). It lies at the junction of the primary motor and somatosensory areas of the cortex (pp. 954 and 958).

When the central sulcus is opened up, the opposed walls are found to be marked by a number of small gyri which interlock with one another after the manner of gears in mesh, and are therefore termed *interlocking gyri*. This arrangement provides additional cortex without any corresponding increase in the

7.113B–G A series of dissections of the left cerebral hemisphere at progressively deeper levels to demonstrate the insula and subjacent structures. B the intact brain; not the position of the posterior ramus of the lateral cerebral sulcus on which the dissections are centred; C the cortical gyri of the insula exposed by removal of the frontal, temporal and parietal opercula; D the removal of the insular cortex, extreme capsule, claustrum and external capsule has exposed the lateral aspect of the lentiform nucleus (the putamen); E removal of the lentiform nucleus displays fibres of the internal capsule coursing across its medial aspect; F removal of part of the temporal lobe shows the internal capsular fibres converging on the crus cerebri of the midbrain; G removal of the optic tract, and superficial dissection of the pons and upper medulla, emphasizing the continuity of the corona radiata, internal capsule, crus cerebri, longitudinal pontine fibres, and the medullary pyramid. (Dissection by Dr. E. L. Rees, Dept. of Anatomy, Guy's Hospital Medical School.)

surface area of the hemisphere. Another feature is brought to light by opening up the sulcus. The floor is not the same depth throughout, for a little inferior to the middle of the sulcus its walls are usually connected to each other by a buried, transverse gyrus. The explanation of this condition is found in the mode of development of the central sulcus. When it makes its appearance in the sixth month, it does so in two distinct parts, superior and inferior, which are at first separated by a transverse gyrus connecting the precentral convolution to the postcentral. The two parts occasionally remain separate, but as a rule they run into each other, and the transverse gyrus becomes buried as a *deep transitional gyrus*.

The frontal lobe is the anterior part of the hemisphere. On the superolateral surface it is bounded behind by the central sulcus, above by the superomedial border and below by the superciliary border and the stem of the lateral sulcus.

The superolateral surface of the frontal lobe is traversed by three sulci which divide it into four gyri. The *precentral sulcus* runs parallel to the central sulcus, and is separated from it by the precentral gyrus. It is usually divided into upper and lower parts, but the two may be confluent. The *superior frontal sulcus* curves forwards from about the middle of the upper part of the precentral sulcus, while the *inferior frontal sulcus* is parallel to it at a lower level. The area of the frontal lobe which lies anterior to the precentral sulcus is thus divided into the superior, middle and inferior frontal gyri. An incomplete sulcus often divides the middle frontal gyrus (7.111).

The *precentral gyrus*, bounded posteriorly by the central sulcus and anteriorly by the precentral sulcus, extends from the superomedial border of the hemisphere, where it is continuous with the paracentral lobule on the medial surface, to the posterior ramus of the lateral sulcus. The cortex of this gyrus is the origin of many of the fibres of large corticonuclear and corticospinal (pyramidal) tracts (p. 877).

The *superior frontal gyrus* is above the superior frontal sulcus, and is continuous over the superomedial margin of the hemisphere with the medial frontal gyrus on the medial surface. It may be divided by an incomplete sulcus (7.111).

The *middle frontal gyrus* lies between the superior and the inferior frontal sulci.

The *inferior frontal gyrus* is below the inferior frontal sulcus and is invaded by the anterior and ascending rami of the lateral sulcus. The areas around these two rami on the left form the *speech area of Broca* (areas 44 and 45) and are associated with the motor element of speech (p. 1014). The region lying below the anterior ramus is termed the *pars orbitalis*, and it curves round the superciliary margin to the orbital surface of the frontal lobe. The area between the ascending and the anterior rami is termed the *pars triangularis*, while the area posterior to the ascending ramus forms the *pars opercularis* (*posterior*) and is continuous posteriorly with the inferior limit of the precentral gyrus.

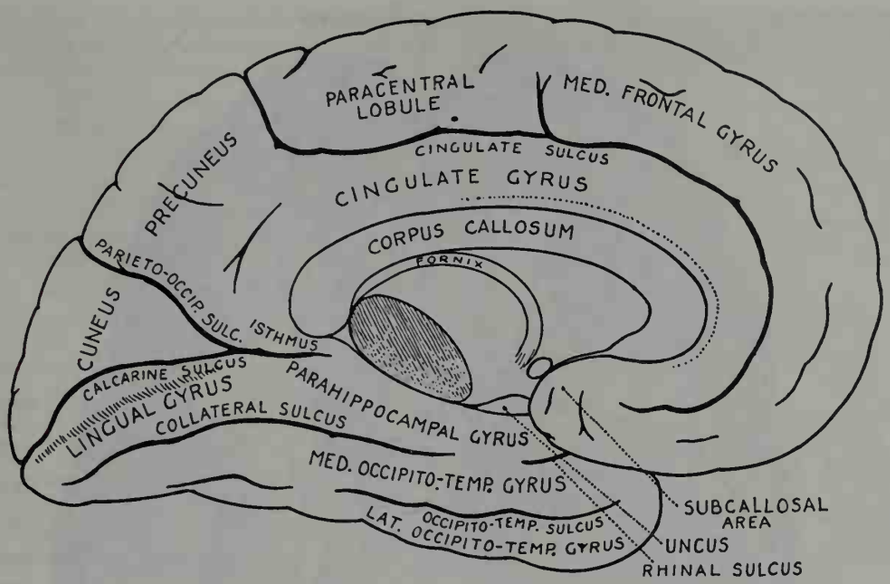
The temporal lobe is inferior to the lateral sulcus. Posteriorly, it is limited by an arbitrary line from the pre-occipital notch (p. 982) to the parieto-occipital sulcus, where it cuts the superomedial margin about 5 cm anterior to the occipital pole. The lateral surface of the temporal lobe is divided into three parallel gyri by two sulci.

The *superior temporal sulcus* begins near to the temporal pole and runs posteriorly and slightly upwards parallel to the posterior ramus of the lateral sulcus. Its posterior end curves up into the parietal lobe. The *inferior temporal sulcus* is subjacent and parallel to the superior sulcus. It is broken up into two or three short sulci, but its posterior end ascends into the parietal lobe, posterior and parallel to the upturned end of the superior sulcus.

In this way the lateral surface of the temporal lobe is divided into three parallel gyri, the *superior*, *middle* and *inferior temporal gyri*. Along its superior margin the superior temporal gyrus is continuous with the gyri in the floor of the posterior ramus of the lateral sulcus. These vary in number and extend obliquely forwards and laterally from the *circular sulcus* which surrounds the insula. They are termed the *transverse temporal gyri* (7.112). Most commonly there are two transverse gyri, which are then named *anterior* and *posterior*, but on one or other side, occasionally both, the gyrus is singular. (*See* Campain and Minckler 1976, for the incidence of variation.) The anterior transverse temporal gyrus and the part of the superior temporal gyrus with which it is in continuity are auditory in function (p. 963). The anterior gyrus is approximately equivalent to Brodmann's area 41; the posterior transverse temporal gyrus, and the adjoining superior temporal gyrus (in part), are held to correspond to area 42.

The parietal lobe is bounded anteriorly by the central sulcus and posteriorly by the line joining the pre-occipital incisure to the superomedial margin at the point where it is cut by the parieto-occipital sulcus. Its inferior limit is the posterior ramus of the lateral sulcus and a line drawn to the posterior boundary from the point where the ramus ascends. Thus, both the posterior boundary and the posterior part of the inferior boundary of the parietal lobe on this surface of the hemisphere are arbitrary.

The lateral aspect of the parietal lobe is subdivided into three areas by the *postcentral* and *intraparietal sulci*.

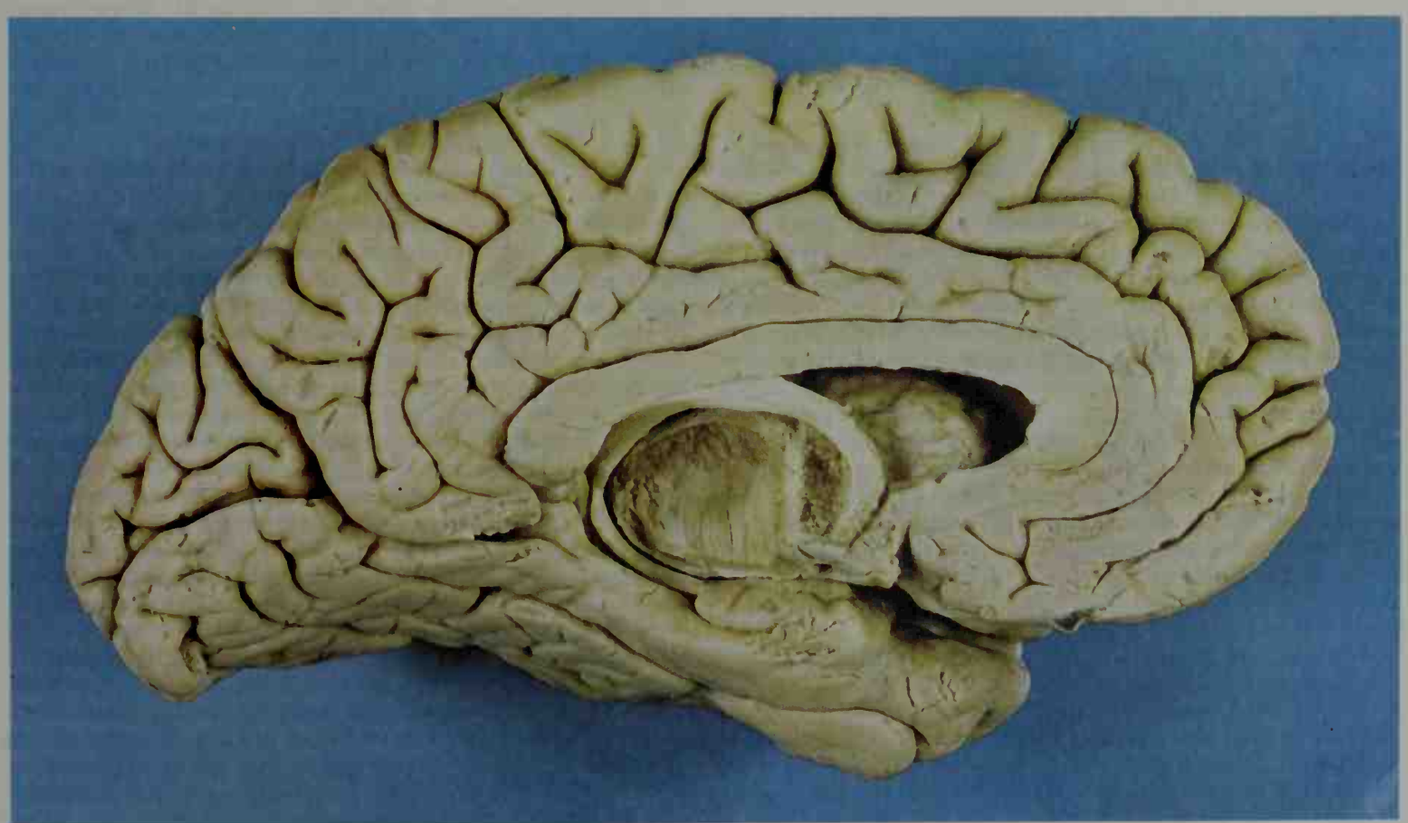


The *postcentral sulcus* (7.111A, B), which may be divided into upper and lower parts, is posterior and parallel to the central sulcus. Inferiorly it ends above the posterior ramus of the lateral sulcus and in front of its upturned end. It divides the parietal lobe into an anterior part, the postcentral gyrus, and a large posterior part which is further subdivided by the intraparietal sulcus. The *intraparietal sulcus* usually commences in the postcentral sulcus about its middle or at the superior end of its lower subdivision. It extends postero-inferiorly across the posterior part of the parietal lobe, dividing it into superior and inferior parietal lobules. Posteriorly, as the occipital ramus, it extends into the occipital lobe, where it joins the transverse occipital sulcus at right angles.

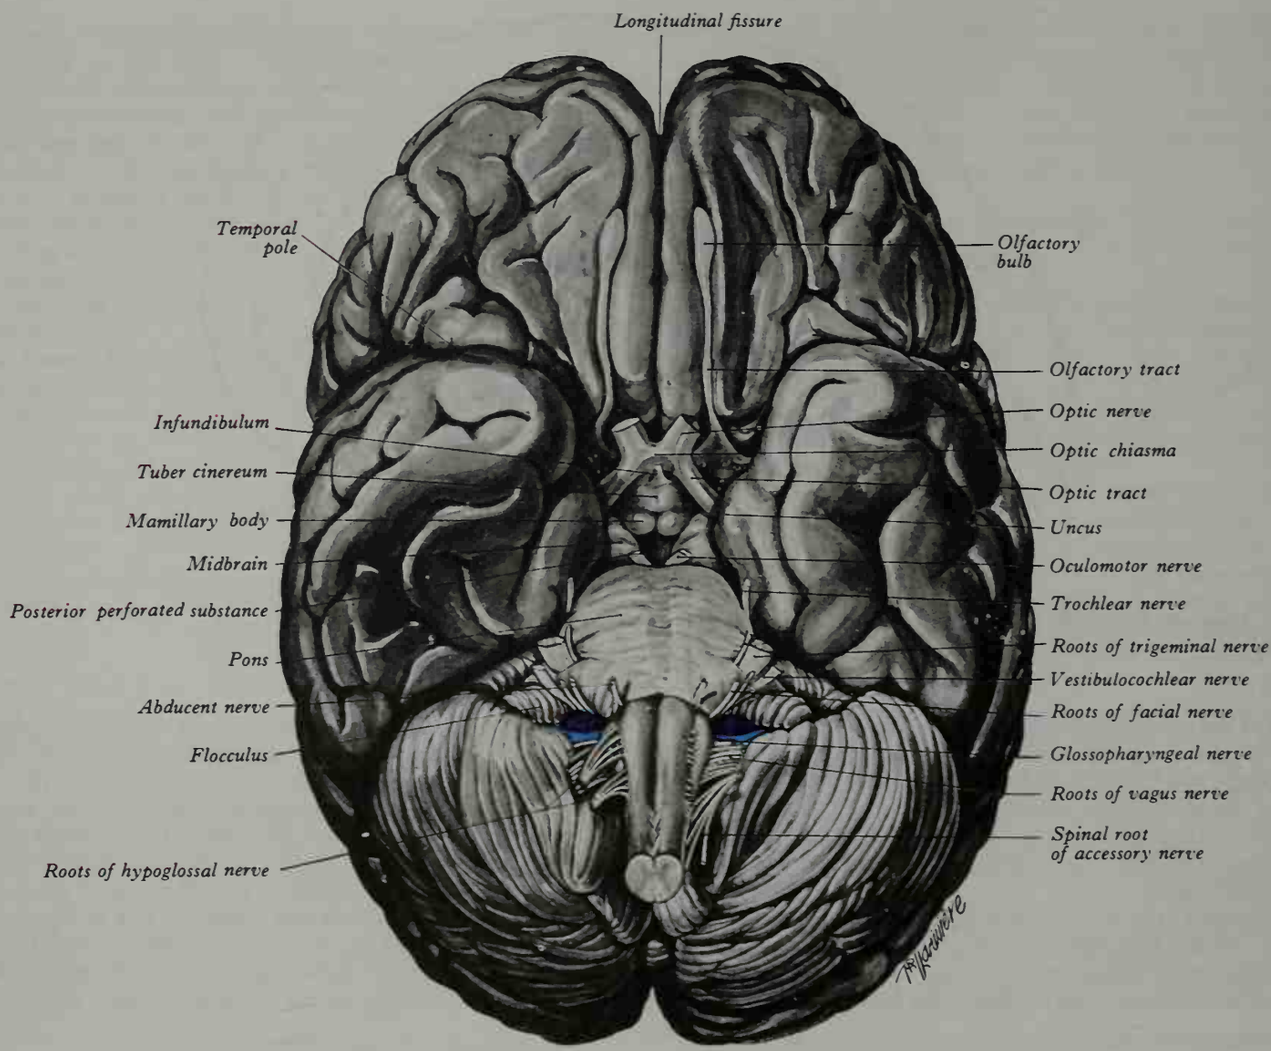
The *postcentral gyrus* lies between the central and postcentral sulci. Its cortex receives somatic sensory impulses (p. 958).

The *superior parietal lobule* is between the superomedial margin of the hemisphere and the intraparietal sulcus. Anteriorly, it is continuous with the postcentral gyrus round the upper end of the postcentral sulcus, while posteriorly it frequently runs into the *arcus parieto-occipitalis*, which surrounds the lateral part of the parieto-occipital sulcus (7.111A, B).

The *inferior parietal lobule* is inferior to the intraparietal sulcus and posterior to the lower part of the postcentral sulcus. It is divided into three parts. The *anterior part* is the *supramarginal gyrus* and arches over the upturned end of the lateral sulcus; it is continuous anteriorly with the lower part of the postcentral gyrus and below and behind with the superior temporal gyrus. Occasionally it is limited posteriorly by a small *sulcus intermedius primus*, which descends from the intraparietal sulcus. The *middle part* or *angular gyrus*, the cortex of which is believed to be concerned with the visual element in stereognosis (p. 966), arches over the upturned end of the superior temporal sulcus and is continuous behind and below with the middle temporal gyrus; sometimes a small *sulcus intermedius secundus* forms its posterior boundary. The anterior and middle parts of the inferior parietal lobule are subjacent to the parietal tuberosity (p. 331). The *posterior part* arches over the upturned end of the inferior temporal sulcus and extends on to the occipital lobe.



The occipital lobe lies behind the line joining the pre-occipital incisure to the parieto-occipital sulcus. The *transverse occipital sulcus* descends from the superomedial margin posterior to the parieto-occipital sulcus and is joined about its middle by the intraparietal sulcus. Its superior part is the posterior boundary of the *arcus parieto-occipitalis*, an arched gyrus which surrounds the end of the parieto-occipital sulcus. The *lateral occipital sulcus* is a short horizontal sulcus on the lateral aspect of the occipital lobe dividing it into *superior* and *inferior occipital gyri* (7.111A, B). The *lunate sulcus*, when present, is just in front of the occipital pole. It is placed vertically and sometimes joins the calcarine sulcus, although the two are more often separated from each other. The lips of the lunate sulcus, which is operculated in type, separate the striate from the peristriate area of the cortex, but the parastriate area is buried within the walls of the sulcus and intervenes between them. The lunate sulcus is the posterior boundary of the *gyrus descendens*, which lies behind the superior and inferior occipital gyri. Two curved sulci, named the superior and inferior polar sulci, are often present near the extremities of the lunate sulcus. The *superior polar sulcus* arches upwards on to the medial



7.114A Diagram of the medial surface of the left cerebral hemisphere, after sagittal section of the brain, and removal of the brainstem.

aspect of the occipital lobe from the neighbourhood of the upper limit of the lunate sulcus; the *inferior polar sulcus* arches downwards and forwards on to the inferior aspect from the lower limit of the same sulcus. These two polar sulci enclose semilunar extensions of the striate area (p. 1018) and indicate the expansion of the visual cortex associated with the formation of its large macular area (Smith 1930).

The insula (7.113A–D) is deep in the floor of the lateral sulcus and is almost surrounded by a *circular sulcus*. It has been overlapped by the overgrowth of the cortical areas which adjoin it, and can only be seen when the lips of the lateral sulcus are widely separated. These areas of the cortex are therefore termed the *opercula of the insula*, and they are separated from each other by the ascending and posterior rami of the lateral sulcus. The *frontal operculum* or lid lies between the anterior and ascending rami, and is formed by the pars triangularis of the inferior frontal gyrus. It may be of small size in cases where the two rami between which it lies arise by a common stem. The *frontoparietal operculum* is between the ascending and the upturned end of the posterior ramus of the lateral sulcus. It is formed by the pars posterior of the inferior frontal gyrus, by the lower ends of the precentral and postcentral gyri, and by the lower end of the anterior part of the

7.114B The medial surface of the left cerebral hemisphere after sagittal section of the brain, followed by removal of the brainstem and septum pellucidum. (For identification of the principal gyri and sulci of the cerebral cortex, compare with 7.114A.) The dissection has been deepened in the region of the dorsal thalamus and hypothalamus to demonstrate the column, body, crus and fimbria of the fornix, and the mamillothalamic fasciculus (compare with 7.117A and B). The head of the caudate nucleus is visible bulging into the floor of the anterior horn of the lateral ventricle. (Dissection by Dr. E. L. Rees, Dept. of Anatomy, Guy's Hospital Medical School.)

7.115A Basal aspect of the brain. The anterior perforated substance (unlabelled) is between the diverging lateral and medial roots of the olfactory tract and anterolateral to the optic tract.

inferior parietal lobule. The *temporal operculum* is below the posterior ramus and is formed by the superior temporal gyrus and the transverse temporal gyri. Anteriorly the inferior part of the insula adjoins the pars orbitalis of the inferior frontal gyrus.

When the opercula are removed, the insula is seen as a pyramidal eminence, the apex of which is directed inferiorly towards the anterior perforated substance (7.113). Here the circular sulcus is deficient and the medial part of the apex is termed the *limen insulae* (*gyrus ambiens*). The surface of the insula is divided into a larger anterior and a smaller posterior part by the *sulcus centralis insulae*, which runs up and back from the apex of the insula. The anterior part is divided by shallow sulci into three or four *short gyri*, while the posterior part is formed by one *long gyrus*, which is often divided at its upper end. The cortical grey matter of the insula is continuous with that of the various opercula in the depths of the circular sulcus. The insula overlies, and is more or less co-extensive with the claustrum and the putamen of the lentiform nucleus (7.113B, C, D).

The angio-architecture of the primate insula (including that of mankind) has been the subject of particular study by Vlahovitch *et al.* (1973). Despite the development of the opercula in man, in contrast to their exiguous size in, for example, the baboon or chimpanzee, these observations indicated a high degree of similarity of vascular pattern in all the primates examined.

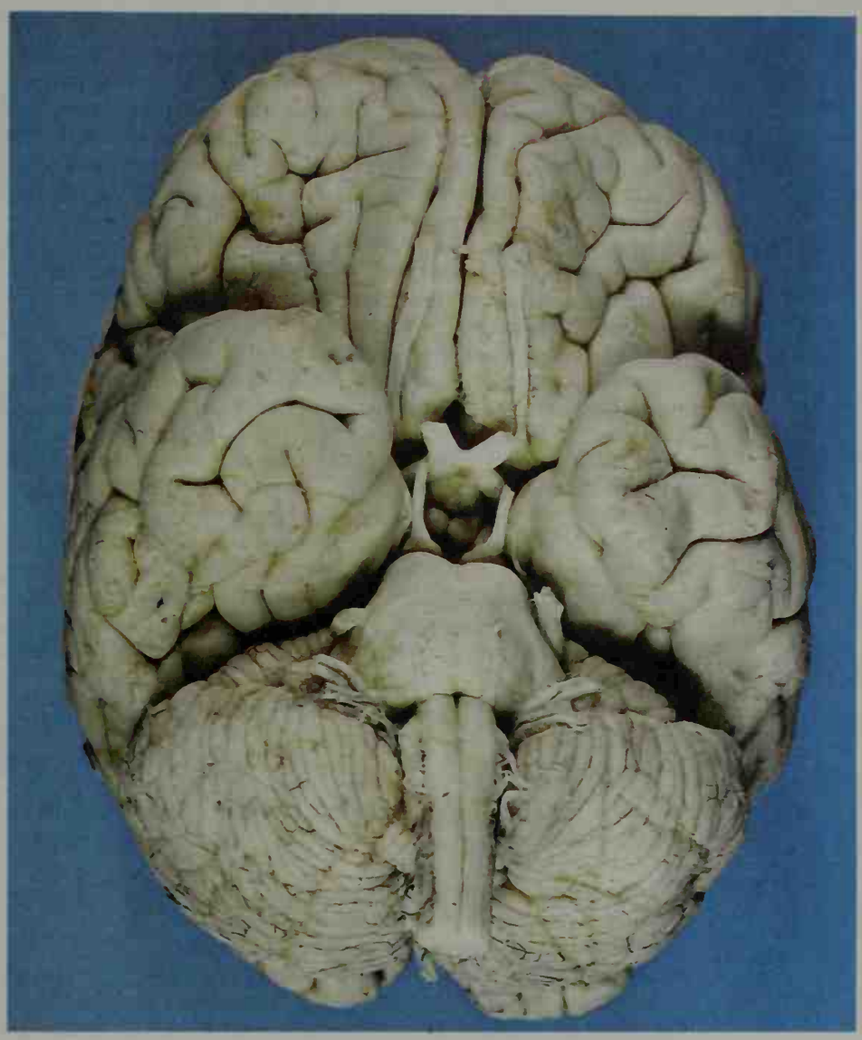
THE MEDIAL SURFACE OF THE CEREBRAL HEMISPHERE

The medial surface (7.114A, B) cannot be examined until the two cerebral hemispheres have been separated from each other by the division of (1) the commissures which connect them and (2) the roof, floor, anterior and posterior walls of the third ventricle (7.114A, B). The most conspicuous feature on this surface is the great commissure which is termed the *corpus callosum*. It forms a broad arched band which lies in the floor of the central part of the longitudinal fissure (7.110). The recurved, anterior end of the corpus callosum is termed the *genu*. Below, it is continuous with the *rostrum*, which narrows rapidly as it passes backwards to become connected to the upper end of the lamina terminalis; above, it is continuous with the *trunk* or main 'body' of the commissure, which arches upwards and backwards to end in a thick, rounded posterior extremity, the *splenium*. To the concave surfaces of the trunk, genu and rostrum are attached the laminae of the septum pellucidum, which occupy the interval between them and the fornix—a curved, flattened band of white fibres inferior to it. Immediately in front of the lamina terminalis and almost co-extensive with it, there is a narrow, triangular field of grey matter, the *paraterminal gyrus* (p. 995). Anteriorly it is separated from the rest of the cortex by a shallow *posterior parolfactory sulcus*. A little anterior to this a second, short, vertical sulcus may be present and is termed the *anterior parolfactory sulcus*. The portion of cortex which lies between these two sulci is the *subcallosal area* (*parolfactory gyrus*) (7.110, 119). The anterior sloping edge of the paraterminal gyrus is sometimes called the *prehippocampal rudiment* (p. 997).

The anterior part of the medial surface of the hemisphere is divided into an outer and an inner zone by the curved *cingulate sulcus*. This commences below the rostrum of the corpus callosum and passes first forwards, then upwards and finally backwards, conforming with the curvature of the corpus callosum. Its

posterior end turns up to reach the superomedial margin of the hemisphere, about 4 cm behind the mid-point between the frontal and occipital poles, and is posterior to the upper extremity of the central sulcus (7.110, 114). The outer zone demarcated by the cingulate sulcus forms, with the exception of its extreme posterior end, a part of the frontal lobe. It is subdivided into larger anterior and smaller posterior parts by a short sulcus ascending from the cingulate sulcus above the middle of the trunk of the corpus callosum. The larger anterior region is the *medial frontal gyrus*, while the smaller posterior area is termed the *paracentral lobule*. The superior end of the central sulcus usually cuts into the posterior part of the paracentral lobule and the precentral gyrus is directly continuous with the cortex of the lobule. This area mediates control of movements of the lower limb and perineal region of the opposite side, and clinical evidence suggests that it exercises voluntary control over the defaecation and micturition reflexes (pp. 1357, 1409).

The zone within the curve of the cingulate sulcus is the *cingulate gyrus*. Commencing below the rostrum this gyrus follows the curve of the corpus callosum, from which it is separated by the *callosal sulcus*, and it continues round the splenium on to the inferior surface of the hemisphere to become continuous with the parahippocampal gyrus through the narrow *isthmus* (7.117A).

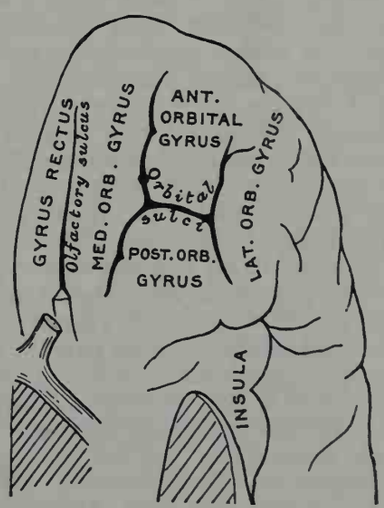


The line of the cingulate sulcus is interrupted posterior to the paracentral lobule, but is partially continued by a short variable *subparietal (suprasplenial) sulcus*.

The posterior part of the medial surface of the hemisphere is traversed by two deep sulci which converge anteriorly and meet a short distance posterior to the splenium of the corpus callosum. These are the parieto-occipital and the calcarine sulci. The *parieto-occipital sulcus* commences on the superomedial margin of the hemisphere about 5 cm anterior to the occipital pole and is directed downwards and slightly forwards to meet the calcarine sulcus. When the lips of the sulcus are separated it will be found that, although on the surface of the hemisphere the parieto-occipital and the calcarine sulci are apparently continuous, they are in reality separated from each other by the deeply situated *cuneate gyrus*. In addition, the walls of the sulcus show the presence of two or more vertically disposed sulci. These were originally exposed on the medial surface of the hemisphere, but they were included in the parieto-occipital sulcus owing to the growth of the splenium (p. 171). The walls of the parieto-occipital sulcus thus resemble those of the lateral sulcus, although the contained sulci and gyri are fewer in number and smaller in extent.

The *calcarine sulcus* commences near the occipital pole. Although it is usually restricted to the medial surface of the hemisphere its posterior end may extend on to the lateral surface. It runs anteriorly a little above the inferomedial margin of the hemisphere, taking a slightly curved course with an upward convexity, and joins the parieto-occipital sulcus at an acute angle a little posterior to the splenium of the corpus callosum. Continuing forwards the calcarine sulcus crosses the inferomedial margin and gains the inferior aspect of the hemisphere, where it forms the inferolateral boundary of the *isthmus*, which connects the cingulate with the parahippocampal gyrus. At its junction with the parieto-occipital sulcus the floor of the calcarine sulcus is crossed by the buried anterior cuneolingual gyrus. The posterior part of the calcarine sulcus, behind its junction with the parieto-occipital, is an axial sulcus, set in the long axis of the visual cortex (p. 966), but the anterior part is a limiting sulcus and separates the striate, visual cortex from that of the isthmus. The anterior part conforms to the definition of a complete sulcus, since it produces an elevation in the medial wall of the posterior cornu or horn of the lateral ventricle (the *calcar avis*).

The quadrilateral area, bounded anteriorly by the upturned end of the sulcus cinguli, posteriorly by the parieto-occipital sulcus, superiorly by the superomedial margin and inferiorly by the suprasplenial sulcus, is termed the *precuneus* and, together with the part of the paracentral lobule posterior to the central sulcus, constitutes the medial surface of the parietal lobe.



The wedge-shaped area bounded in front by the parieto-occipital sulcus, below by the calcarine sulcus and above by the superomedial margin, is termed the *cuneus*. Its surface is usually indented by one or two small irregular sulci, and forms the medial surface of the occipital lobe.

7.115B The base of the brain. For labelling compare with 7.56, 115A. (Dissection by Dr. E. L. Rees, Dept. of Anatomy, Guy's Hospital Medical School.)

THE INFERIOR SURFACE OF THE CEREBRAL HEMISPHERE

The surface is divided into a smaller part, anterior to the stem of the lateral fissure, and a larger part posterior to it (7.115A, B; 116).

7.116 The orbital surface of the left frontal lobe.

The anterior region forms the orbital part of the inferior surface of the cerebral hemisphere. It is concave from side to side and rests on the cribriform plate of the ethmoid bone, the orbital plate of the frontal and the lesser wing of the sphenoid bone. An anteroposterior sulcus traverses this surface near its medial margin and, since it is overlapped by the olfactory bulb and tract, it is termed the *olfactory sulcus*. The medial strip of cortex which it marks off is the *gyrus rectus*. The rest of this surface is marked by irregular sulci, the *orbital sulci*, generally H-shaped, dividing it into a number of *orbital gyri*. Four can usually be recognized, named, according to their position, anterior, medial, posterior and lateral orbital gyri (7.116).

The larger, posterior region of the inferior cerebral surface is its tentorial part since it is immediately superior in part to the tentorium but also to the middle cranial fossa. It is traversed by two anteroposterior sulci, the collateral and occipitotemporal. The *collateral sulcus* commences near the occipital pole and extends anteriorly, roughly parallel to the calcarine sulcus, from which it is separated by the *lingual gyrus*. Anteriorly the collateral sulcus may be continued into the *rhinal sulcus*, but the two are usually separated. The *rhinal sulcus* runs forwards in the line of the collateral sulcus and separates the temporal pole from a somewhat hook-shaped projection posteromedial to it and termed the *uncus*. This fissure marks the lateral limit of the piriform lobe of the cortex (7.119).

The *occipitotemporal sulcus* is parallel to the collateral sulcus and lateral to it. As a rule it does not extend as far as the occipital pole, and it is frequently divided into two or more parts.

The *lingual gyrus* lies between the calcarine and collateral sulci. Anteriorly it passes without interruption into the *parahippocampal gyrus*, which commences at the *isthmus*, where it is directly continuous with the cingulate gyrus, and then passes forwards medial to the collateral and rhinal sulci. Anteriorly the parahippocampal gyrus becomes continuous with the uncus, its medial edge being lateral to the midbrain. The *uncus* is the hook-like, anterior end of the parahippocampal gyrus and forms the posterolateral boundary of the anterior perforated substance. The medial part of the uncus extends laterally above its lateral part and will be described later (7.119); its inferior surface cannot be exposed completely until its lateral and more superficial part has been removed (7.120). The uncus forms part of the *piriform lobe*, which is part of the olfactory system (*vide infra*) and is phylogenetically one of the oldest parts of the pallium. (For further details of the uncal region, and the complex terminology applied to this and surrounding areas, consult illustrations 7.117A and 7.119.)

The *medial occipitotemporal gyrus* extends from near the occipital to the temporal pole. It is limited medially by the collateral and rhinal sulci and laterally by the occipitotemporal sulcus. The lateral part of this area forms the *lateral occipitotemporal gyrus*, which is continuous round the inferolateral margin of the hemisphere with the inferior temporal gyrus.

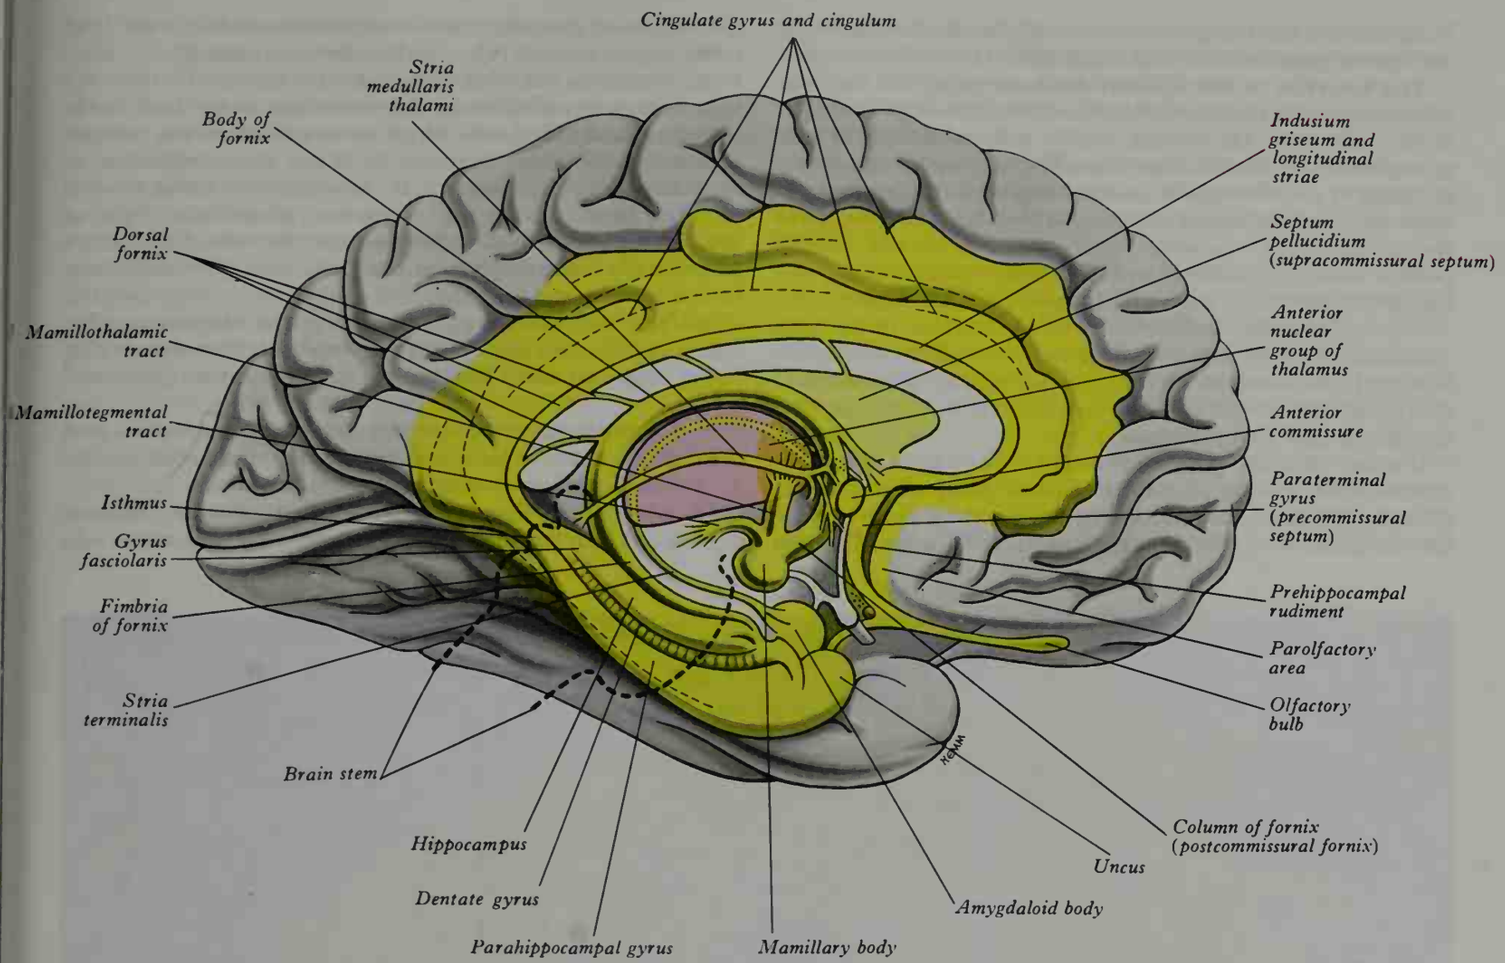
THE LIMBIC LOBE AND OLFACTORY PATHWAYS

During development the superolateral surfaces of the diencephalon gradually merge with the central areas of the inferomedial surfaces of the two cerebral hemispheres (p. 170). Completely *bordering* the area of fusion on each side, a series of structures develop in the wall of the hemisphere and constitute the **limbic lobe**—a term introduced in 1878 by Broca on comparative anatomical grounds. Many of the structures constituting the limbic lobe (literally the *bordering* lobe) are phylogenetically old, and have a highly arched form; topographically they are interposed between the diencephalon and the massive neopallial areas of the cerebral hemisphere (7.117). Interest in the limbic lobe was heightened when Papez (1937) suggested its role in emotional behaviour. Since that time an ever-increasing volume of research has emphasized that the lobe has profuse interconnexions with the olfactory system, the hypothalamus, thalamus, epithalamus and, to a lesser extent, areas of the neocortex. It is intimately associated with the higher integration of visceral, olfactory and somatic information, and the patterning of complex long and short term homeostatic responses. The latter include seeking and capturing prey, courtship, mating, rearing of young, the subjective and expressive elements in emotional responses, and the balance between aggressive and social behaviour in community living (Maclean 1958, 1969; Livingston 1970). For modern comprehensive reviews including extensive bibliographies consult Isaacson (1974), Isaacson and Pribram (1975), Livingston and Hornykiewicz (1978).

The terminology applied to these regions is complex; alternative schemes are in use, and common agreement in terms of a rational basis for scientific definition has proved impossible to achieve (*see* discussion in White 1965; Brodal 1969; Bargmann and Schadé 1963). Broadly, however, the increasingly widespread use of the terms limbic lobe and limbic system indicate that, at the present state of our knowledge, many investigators believe that such collective names serve a useful purpose, despite differences in detailed application of the terms by some workers, and the strong opposition to their use at all by a minority (Brodal 1969). Most authorities include a series of subcortical nuclei and their connexions, the phylogenetically older areas of cortex, the archipallium and paleopallium, and the immediately adjacent border of the neopallium—the cingulate and parahippocampal gyri, and their associated fibre tracts. Difficulties arise when attempts are made to place precise boundaries between these regions and adjacent ones, with which some of them are functionally interconnected. For example, opinions differ concerning what areas of frontal cortex should be included, and whether or not the intimately related hypothalamus should be embraced by the term. Of greater practical importance is the need for an agreed international nomenclature for as many orders of subdivision of the brain as possible, based upon the most widely acceptable criteria currently available, with a continuous process of revision as further knowledge accumulates. In the present account the terms limbic lobe and system are included, and the structures described under these headings will be listed below.

Even greater terminologic difficulty attaches to the widely used name **rhinencephalon** (Bargmann and Schadé 1963). Traditionally, the name was used to indicate all those brain structures associated with olfaction, and for many years it was assumed that most of the structures of the limbic lobe were primarily olfactory pathways and centres of integration. However, with advancing researches in comparative and developmental neurology, olfactory physiology, more detailed neuroanatomical studies, together with behavioural and other functional studies on the limbic system and hypothalamus, there has been a considerable change of emphasis. Since the term rhinencephalon has many shades of meaning in the hands of different workers using different approaches, and when investigating different species, it will not be included in this account.

The structures mentioned or described here or elsewhere in this volume, which are included in **the limbic system** are:



(1) The olfactory nerves, bulb and tract (together with the nervus terminalis, and the transient accessory olfactory bulb and vomeronasal nerve).

(2) The anterior olfactory nucleus.

(3) The medial, intermediate and lateral olfactory striae and the medial and lateral olfactory gyri.

(4) The olfactory trigone, the anterior perforated substance with the olfactory tubercle, and the diagonal band of Broca.

(5) The piriform lobe which includes: (*a*) the lateral olfactory gyrus continuing into the gyrus ambiens—together forming the prepiriform cortex; (*b*) the lateral olfactory stria continuing into the gyrus semilunaris (periamygdaloid area); (*c*) the uncus hippocampi including the uncinate gyrus, the tail of the dentate gyrus (band of Giacomini), and the intralimbic gyrus; (*d*) the

7.117A A diagram of a dissection of the medial aspect of a cerebral hemisphere to demonstrate the majority of the structures included under the term limbic system in the present account; these are coloured yellow. The anterior nuclear group of the dorsal thalamus is coloured orange and included with the limbic system; the remainder of the dorsal thalamus is magenta. The approximate position of the brainstem which was removed in the course of dissection is outlined in a heavy interrupted line. This diagram should be compared with the colour photograph of a dissection prepared from the *lateral* aspect of a hemisphere (7.117B).

entorhinal area (area 28)—the cranial part of the parahippocampal gyrus.

(6) The amygdaloid complex of nuclei.

(7) The septal areas, including the septum pellucidum, and the septum verum—a nuclear complex much of which is deeply placed but in part corresponds to the paraterminal gyrus.

(8) The hippocampal formation which includes: (*a*) the prehippocampal rudiment, the indusium griseum and longitudinal striae; (*b*) the gyrus fasciolaris, Ammon's horn, the dentate gyrus, the subiculum, and related regions.

(9) The fornix and its various ramifications and divisions.

(10) The stria terminalis.

(11) The stria habenularis.

(12) The cingulate and parahippocampal gyri.

The hypothalamus, medial part of the thalamus, pre-frontal cortex, and the anterior commissure, all of which are intimately related to the foregoing structures, are described elsewhere in the present section. In particular, the hypothalamus is regarded by some authors as the *essential centre* of the limbic system (*see* Isaacson 1974).

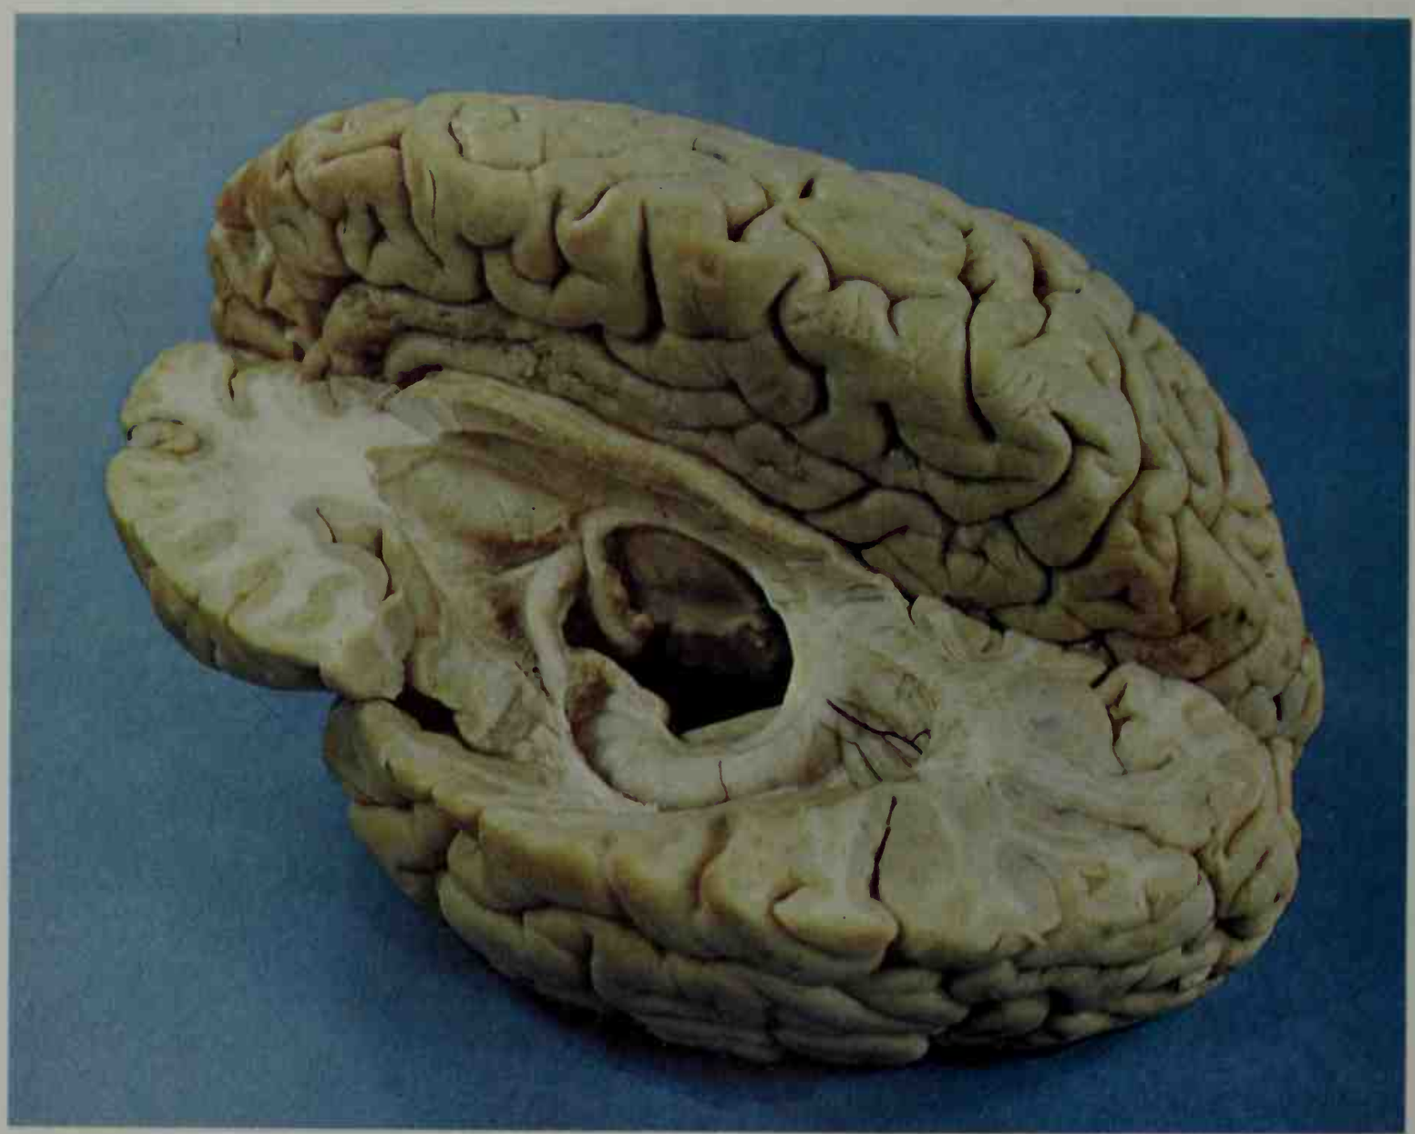
THE OLFACTORY BULB

The olfactory bulb (7.115A) is a flattened, oval, reddish-grey mass which lies superior to the medial edge of the orbital plate of the frontal bone near the lateral margin of the cribriform plate of the ethmoid. It is inferior to the anterior end of the olfactory sulcus, on the orbital surface of the frontal lobe of the brain; the gyrus rectus is directly superior to the cribriform plate.

The olfactory nerve fibres which are the central processes of the olfactory cells of the nasal mucosa (p. 1054) converge upon the inferior surface of the cribriform plate and collect into about twenty bundles which pass through the foramina in the plate, and then continue to enter the inferior surface of the bulb.

As described previously (p. 170) the olfactory bulb and tract develop as a hollow diverticulum from the anteromedial part of the floor of the primitive cerebral hemisphere. With growth, the basal part of the diverticulum elongates to form the olfactory tract and, in the human embryo, the cavity of the terminal olfactory bulb (the 'olfactory ventricle') and that of the elongating tract are gradually obliterated by approximation and subsequent fusion of their walls. However, the site of the original cavity is sometimes marked by deeply-placed vestigial aggregations of modified ependymal cells. Thus, the olfactory bulb has a *radial organization* consisting of a number of superimposed layers with increasing depth from the surface. This laminar pattern is particularly well defined in many mammals other than man, and also in the human fetus, but often becomes less distinct as the brain matures. The detailed histology of the olfactory bulb, as revealed by the light microscope after staining with the Nissl and Golgi methods, has been known since the turn of the century (Cajal 1890, 1911, 1955; Blanes 1898; Le Gros Clark 1951, 1957; Valverde 1965), and this has been supplemented by the experimental studies using degeneration techniques, e.g. (Powell and Cowan 1963; Price 1968; Heimer 1968), physiological studies, e.g. (Sem-Jacobsen *et al.* 1956; Døving 1967), more recently, by detailed ultrastructural analyses (Pinching and Powell 1971; Shepherd 1974, 1977), and currently by electron microscopic autoradiography, and immunofluorescence (p. 819).

From the surface, and progressing towards the central core, the olfactory bulb consists of: (1) the olfactory nerve fibre layer; (2) the layer of synaptic glomeruli and interglomerular spaces; (3) the



molecular and external granular layer; (4) the mitral cell layer; (5) the internal granular layer; and (6) the fibres of the olfactory tract.

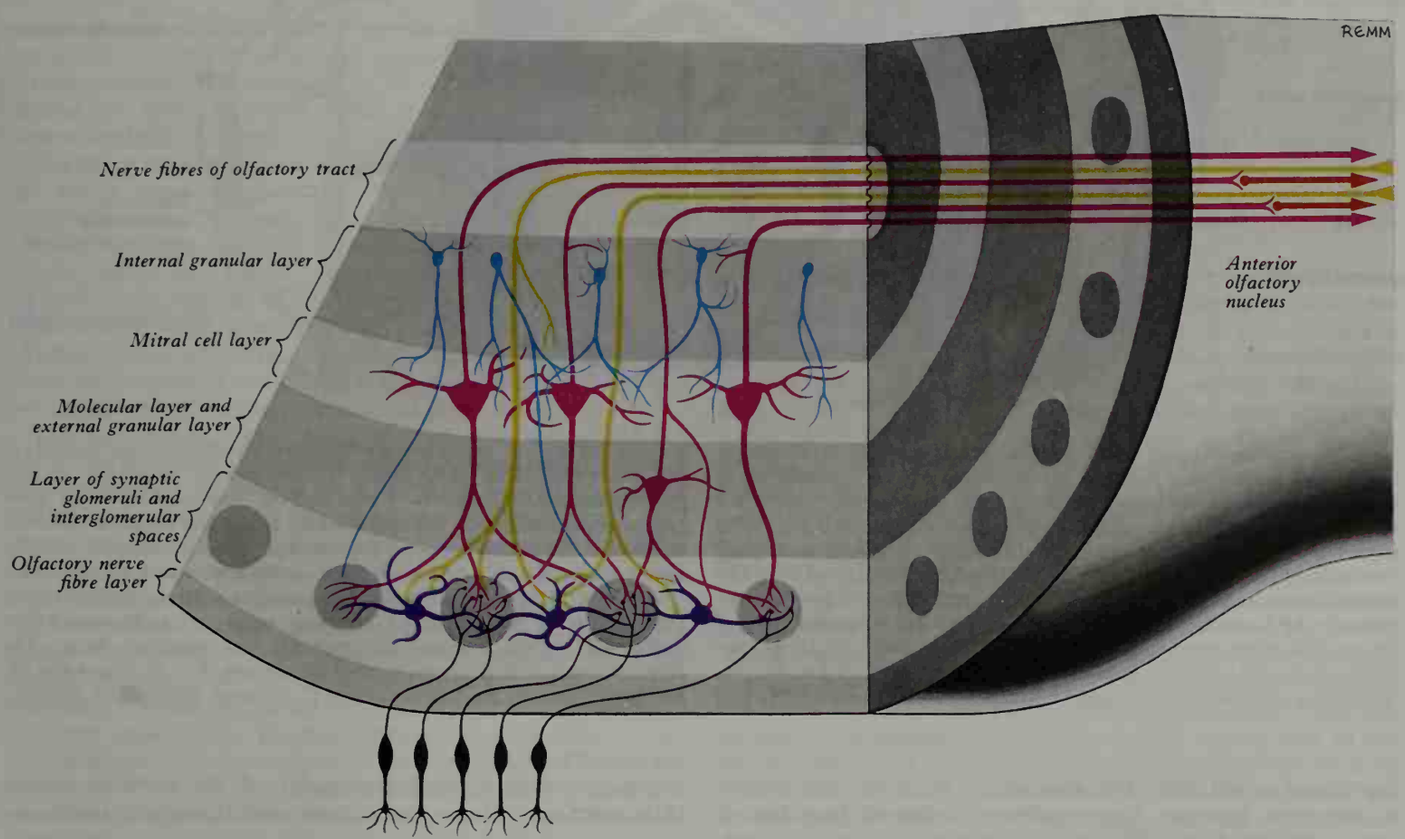
The neurons of the olfactory bulb comprise: (1) the large characteristically shaped *mitral cells* which form a layer only one or two cells thick; (2) internal, middle and external *tufted cells*, analogous to, but smaller than, the mitral cells, and progressively reducing in size throughout the thickness of the molecular layer from the superficial aspect of the mitral layer to the deep aspect of the glomeruli; (3) numerous small round or stellate *internal granule cells*; (4) various types of small *periglomerular cell* distributed around, within, and deep to the synaptic glomeruli. The periglomerular cells and the small external tufted cells constitute the *external granular layer* of the earlier histologists. Modern histofluorescence techniques (p. 819) have demonstrated that the periglomerular cells are *dopaminergic*; they are classified as cell aggregate A15 (*see* p. 949).

It is now clear that previous accounts of the mechanism of the olfactory bulb as a simple relay between incoming olfactory nerve fibres and the dendrites of mitral cells, the axons of which proceed into the olfactory tract, were a gross over-simplification. The bulb is a region of great structural complexity to which only brief reference can be made here (*see* the references quoted for details). In particular the following features are to be noted: (1) there is a great *convergence* of olfactory nerve fibres on to the dendrites of the mitral and tufted cells which occupy much of the synaptic glomeruli (*vide infra*); (2) a number of cell types, mitral, tufted and others, contribute axons to the olfactory tract which proceed to other brain centres; (3) a number of different types of interneuron provide pathways for complex patterns of interaction between the main conduction channels, and also complicated feedback paths; and (4) transmission in the bulb is modulated by centrifugal axons which converge on it from the contralateral olfactory bulb, anterior olfactory nucleus and other centres (*vide infra*). Some of these features are summarized in illustration 7.118.

It is convenient to consider first the main conduction path through the bulb, followed by the complications introduced by local interneurons and centrifugal pathways.

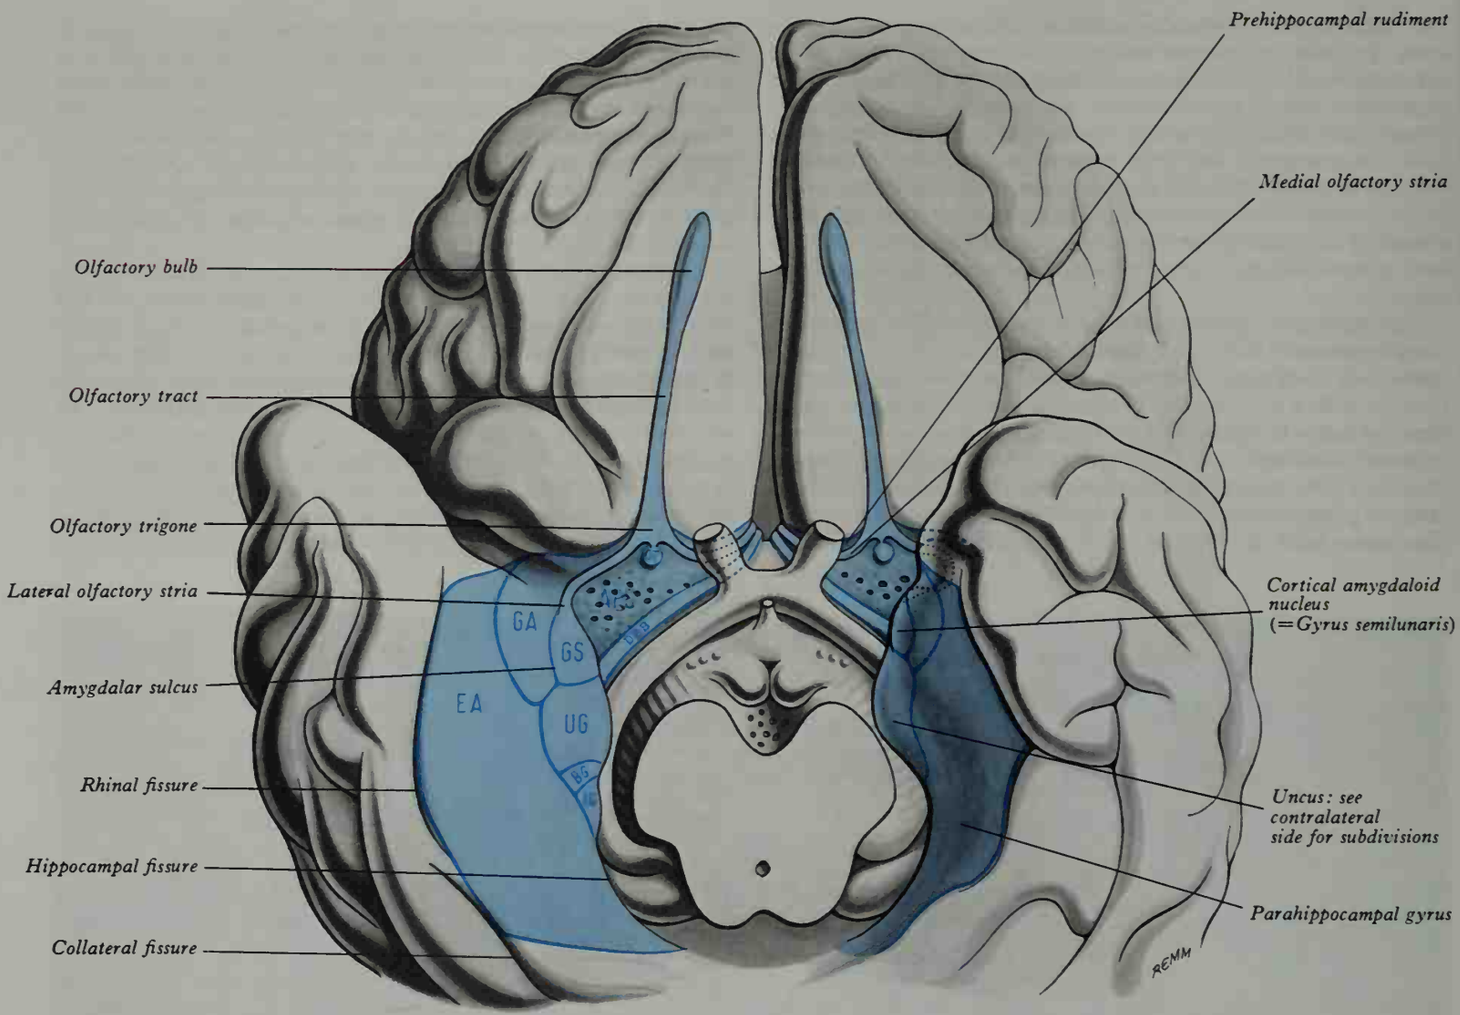
In addition to *basal* dendrites which establish synaptic connexions with granule cell processes, both the large mitral cells

7.117B A dissection of the left cerebral hemisphere from the superolateral aspect to demonstrate various structural features of the limbic system. The corpus callosum is divided sagittally in the region of its body only; the frontal, temporal and occipital lobes have been sectioned horizontally and their superior parts removed. The left lentiform nucleus, much of the caudate nucleus and dorsal thalamus have been removed, and the floor of the inferior horn of the lateral ventricle laid open. Note: (1) the horizontally sectioned head of the caudate nucleus; (2) the spiral disposition of the fornix as it curves from the mamillary body through its left column, body, crus and fimbria; (3) the curved elevation of the hippocampus projecting into the floor of the inferior horn of the ventricle, and ending anteriorly as the grooved pes hippocampi; (4) the anterior commissure entering the left hemisphere immediately anterior to the column of the fornix, and passing laterally, to diverge into small anterior and large posterior components; between the latter the deep aspect of the anterior perforated substance is visible; (5) within the curve of the fornix the medial aspect of the *right* thalamus crossed superiorly by the stria medullaris thalami; (6) coursing above the corpus callosum a longitudinal white stria is visible, and above this arches the right gyrus cinguli. Compare with 7.117A. (Dissection by Dr. A. M. Seal, Department of Anatomy, Guy's Hospital Medical School.)



(the shape of their somata resembling a bishop's mitre) and the more prominent external tufted cells possess large *apical* dendrites which pass superficially towards the glomerular layer where they branch and form rich arborizations in a number of synaptic glomeruli. The incoming olfactory nerve fibres converge upon the glomeruli, and form numerous axodendritic synapses with the apical dendrites of the mitral and tufted cells, whilst the axons of the latter pass through the inner granular layer, giving off a number of collateral branches, before continuing into the deep zone of nerve fibres to form the main constituents of the olfactory tract.

The synaptic glomeruli of the olfactory bulb are large, roughly spherical territories, often exceeding 100 μm in diameter, containing many thousands of nerve cell processes from various sources, with a wide variety of types of synaptic interconnexion between them. In addition to the large dendrites of the mitral and internal tufted cells just described, the glomerulus also receives dendrites from various types of *periglomerular cell* (including the external granule cells, the external tufted cells, and the superficial short-axon cells of different authors, *see* Pinching and Powell 1971). In all, about 100 individual neurons contribute dendrites to each glomerulus, and (in the rabbit) each receives the terminals of some 25,000 olfactory nerve axons. Further, the axonal terminals of a number of periglomerular cells also penetrate the glomerulus. Detailed analyses of the synaptic contacts between these different elements, and their possible modes of operation, are still in progress (Price and Powell 1970; Pinching and Powell 1971; Shepherd 1974, 1977, 1978); in outline, the following synaptic contacts have been described.



The terminal parts of the olfactory nerve axons do not receive axoaxonic (presynaptic) contacts from other sources, but they establish the axodendritic contacts with mitral and tufted cell dendrites mentioned above, and also with the dendrites of periglomerular cells. The periglomerular cell dendrites also form complex reciprocal dendrodendritic contacts with mitral and tufted cell dendrites; often one or both of the elements in such a double dendrodentritic contact also receive an axodendritic synapse from an olfactory nerve axon terminal. Finally, the dendrites of the periglomerular cells receive a number of axodendritic synapses from the axons of other periglomerular cells.

The interglomerular spaces are occupied, in part, by the cell somata of the different categories of periglomerular cell and their processes. Some of these cells have dendrites which ramify both in the spaces and also in the glomeruli as described above. Other interneurons which have been designated short-axon cells have dendritic trees which are wholly extraglomerular. The interglomerular spaces are also penetrated by mitral cell dendrites, many of the axonal ramifications and terminals of the periglomerular cells themselves, and the termination of centrifugal axons from the olfactory tract. Again, reciprocal dendrodendritic contacts between periglomerular cell dendrites and those of mitral and tufted cells are found, together with axodendritic contacts between either extrinsic or intrinsic axons and the periglomerular cells. The details of these contacts and the other varieties described will not be pursued further here (for these *see* Pinching and Powell 1971; Shepherd 1974, 1978).

The internal granular layer which lies deep to the mitral cell layer consists of large numbers of microneurons or *amacrine granule cells* (Rall *et al.* 1966; Price and Powell 1970; Shepherd 1974, 1977, 1978) which possess no true axon. Their dendrites branch repeatedly, some spreading locally, whilst others pass deeply into the molecular layer where, once again, reciprocal dendrodendritic synapses are established with the dendrites of

7.118 A scheme of the olfactory bulb based upon neurocytological and experimental studies in a number of mammalian types. The radial organization of the bulb into 'layers', with their principal neuron types, and an approximate indication of their main connectivity patterns, is shown. The 'layers' of the bulb which receive the names indicated are, of course, merely a convenient descriptive frame of reference; they should not obscure the functionally essential interconnexions which cross the boundaries between these zones. The colours used indicate—*red:* mitral and tufted neurons and their processes; *blue:* internal granule neurons; *purple:* periglomerular neurons; *black:* olfactory receptor neurons and their processes. Note that the olfactory tract consists of (1) centripetal axons of mitral and tufted cells, some of which synapse with neurons in the anterior olfactory nucleus, and (2) centrifugal axons (yellow) which terminate in the different zones indicated. Refer to text for a more detailed description of both the organization of the bulb, and the destinations of olfactory tract fibres.

7.119 A diagram of structures on the inferior aspect of the human brain in the area immediately surrounding the optic nerves, chiasma, optic tracts and interpeduncular fossa. Many of these structures are intimately related to the olfactory and limbic systems; they are coloured blue. The right temporal pole has been displaced laterally to expose underlying structures. In addition to the features which have been labelled fully, the abbreviations used have the following significance: OT—olfactory tubercle; APS—anterior perforated substance; DBB—diagonal band of Broca. The uncus hippocampi is divided into three areas; IG—the intralimbic gyrus; BG—the band of Giacomini; and UG—the uncinate gyrus. The lateral olfactory stria continues into the gyrus semilunaris (GS); this is bordered laterally by the gyrus ambiens (GA); whilst further laterally is the entorhinal area (EA) which is the rostral extension of the parahippocampal gyrus. Note the curved extensions of the prehippocampal rudiments, medial olfactory striae, and diagonal bands of Broca on to the medial aspect of the hemisphere. The triangular midline zone between the converging diagonal bands, and superior to the optic chiasma, is the lamina terminalis. The occasional intermediate olfactory stria which merges with the olfactory tubercle, is illustrated but unlabelled. (After Kuhlenbeck: redrawn and modified from: *The Hypothalamus*, with the permission of the authors W. J. H. Nauta and W. Haymaker, and the publishers Charles C. Thomas, Springfield, Illinois.)

mitral and tufted cells. The granule cell dendrites also receive axodendritic synapses from recurrent collateral branches of mitral and tufted cell axons, and also from many of the terminals of centrifugal axons in the olfactory tract.

In short, the neurons of the olfactory bulb and their processes present some of the most complex sets of synaptic patterns yet described in the nervous system. The granule and periglomerular cells are considered to be inhibitory interneurons, and by their geometric organization and array of contacts, they provide the substrate for interaction between the principal conduction channels through the bulb. Thus, they mediate feed-forward, lateral and feed-back inhibitory processes, and also inhibitory effects by the centrifugal axons which pass into the bulb from the opposite olfactory tract. Much remains to be determined concerning the detailed operation of these various elements.

In many non-primate mammals, and submammalian forms, a diverticulum lined by specialized epithelium called the *vomeronasal organ* (of Jacobson) lies on each side of the nasal septum. The nerve bundles from this epithelium run with the ventral groups of olfactory nerve fibres and then converge to form the *vomeronasal nerve*, which ends in an *accessory olfactory bulb*, situated on the dorsomedial aspect of the main bulb. Although an accessory bulb and vomeronasal nerve are present on one or both sides in a proportion of human embryos, both structures degenerate with increasing maturity of the nervous system (McCotter 1915; Hume 1940; Crosby and Humphrey 1941).

THE OLFACTORY TRACT

The olfactory tract (7.115, 119) is a narrow white band which issues from the posterior aspect of the olfactory bulb and continues posteriorly on the inferior (orbital) surface of the frontal lobe, where it covers the line of the olfactory sulcus. The tract is triangular in outline in transverse section, its narrow apex being recessed into the olfactory sulcus. It consists of the centrally directed axons of the mitral and tufted cells of the bulb, and also some centrifugal axons which have crossed from the opposite bulb and anterior olfactory nucleus in the anterior commissure, and other centrifugal axons arising from neurons in or near the anterior perforated substance (*vide infra*). The precise contribution of these and other possible sources to the centrifugal outflow is still under active investigation (Cragg 1962; Powell and Cowan 1963; Powell *et al.* 1965; Price 1968; Heimer 1968).

The Anterior Olfactory Nucleus

At the posterior end of the olfactory bulb its various characteristic cell layers disappear, but the deeply placed granule cell layer is replaced throughout the length of the olfactory tract by scattered

groups of medium-sized multipolar neurons which constitute the *anterior olfactory nucleus*. Posteriorly, these groups of neurons continue into the olfactory striae and trigone (*vide infra*) to abut on or become continuous with the grey matter of the prepiriform cortex, the anterior perforated substance and the precommissural septal areas. Many of the centripetal axons from mitral and tufted cells which constitute the olfactory tract relay in, or give collaterals to, the anterior olfactory nucleus, and then the axons of the latter continue with the direct fibres from the bulb to form the olfactory striae.

THE OLFACTORY STRIAE AND TRIGONE

Posteriorly, as the olfactory tract approaches the anterior perforated substance, it flattens and becomes splayed out into a smooth *olfactory trigone* (olfactory pyramid) from the caudal angles of which the fibres of the tract continue as separate diverging bundles, the *medial* and *lateral olfactory striae* which border the anterior perforated substance (7.119). In some brains a small *intermediate stria* can be distinguished passing from the centre of the trigone to sink into the anterior perforated substance.

The lateral olfactory stria courses along the anterolateral margin of the anterior perforated substance as a whitish bundle distinguishable by the naked eye. It continues into the limen insulae (p. 988), at which point it makes an abrupt bend posteromedially to merge with an elevated region of grey matter called the gyrus semilunaris which bounds the cranial margin of the uncus hippocampi (7.119). The gyrus semilunaris incorporates part of the *corticomedial* subdivision of the *amygdaloid complex* of nuclei (*vide infra*). A tenuous layer of grey matter which clothes the lateral olfactory stria is called the *lateral olfactory gyrus* and this merges laterally with grey matter of the *gyrus ambiens* which in part forms the limen insulae. The lateral olfactory gyrus and gyrus ambiens, together, constitute the *prepiriform region* of the cortex which passes caudally into the *entorhinal area* of the parahippocampal gyrus.

The prepiriform region, the periamygdaloid region and the entorhinal area (area 28) together comprise **the piriform lobe** of the cerebrum; it is bounded laterally by the *rhinal sulcus* and is relatively more prominent in macrosmatic mammals, and during the early fetal stages of human brain development. The relative positions of these structures and their surroundings are more easily appreciated by reference to illustration 7.119.

The medial olfactory stria, covered by a thin veil of grey matter—the *medial olfactory gyrus*—passes medially along the cranial boundary of the anterior perforated substance and converges towards the medial continuation of the diagonal band of Broca (*vide infra*). Together they curve superiorly on the medial aspect of the hemisphere, anterior to the line of the lamina terminalis (7.119). The diagonal band continues into the paraterminal gyrus, whilst the medial stria becomes indistinct from surface view as it approaches the boundary zone which includes the paraterminal gyrus, parolfactory gyrus, and between them, the narrow prehippocampal rudiment. (*See* illustration 7.117A.)

THE ANTERIOR PERFORATED SUBSTANCE

This is an important topographic landmark on the base of the brain. It lies caudal to the olfactory trigone and the diverging medial and lateral olfactory stria, in the angle between the optic chiasma and tract medially, and the uncus caudally (7.119). Medially, it is continuous above the optic tract with the grey matter of the tuber cinereum, and more anteriorly, with the paraterminal gyrus. Laterally, it reaches the limen insulae, where it is continuous with the prepiriform cortex, and more caudally it merges with the periamygdaloid area (gyrus semilunaris). Superiorly, it is continuous with the grey matter of the corpus striatum and claustrum through the aggregations of grey and white matter which form the *substantia innominata*. Part of the latter, together with fascicles of the ansa lenticularis and anterior commissure separate the anterior perforated substance from the globus pallidus.

The inferior aspect of the anterior perforated substance is related to the termination of the internal carotid artery and the origins of the anterior and middle cerebral arteries; from the latter a number of central arteries pierce the surface of the brain and supply deeper structures (p. 984), and when removed during dissection their paths form the perforations from which the region derives its name.

Immediately caudal to the olfactory trigone the anterior perforated substance presents a small *olfactory tubercle* which varies in its prominence, and into the base of which the occasional intermediate olfactory stria sinks. The tubercle is a large structure in macrosmatic animals but is greatly reduced and sometimes indistinguishable in man. Similarly, the intermediate stria, although sometimes absent, is occasionally represented by two or three fine intermediate striae which radiate into the perforated substance. The caudal zone of the anterior perforated substance where it adjoins the optic tract, is formed by the smooth surface of the *diagonal band of Broca*. Caudolaterally, the band is continuous with the periamygdaloid area, whilst rostromedially it continues above the optic chiasma to merge with the paraterminal gyrus (precommissural septum).

GENERAL ORGANIZATION OF LIMBIC GREY MATTER

The variations in cytoarchitectonic patterns, and the numerous and sometimes divergent views concerning the connexions of these various regions cannot be reviewed in detail here; for this the reader should consult original papers and large works devoted exclusively to neuroanatomy. In summary, the following points may be noted.

The six laminae, which, although varying in their prominence in different regions, are widely held to characterize the neocortex (p. 1006), are not found in the same form in the archipallial and paleopallial regions of the limbic system. In some areas of the latter a laminar pattern is either absent or scarcely distinguishable, whilst in other areas an obvious but distinctive lamination exists, varying from a primitive three-layered to a transitional six-layered variety, where limbic cortex adjoins and merges with neopallial regions. Thus, the medial and lateral olfactory gyri, prepiriform cortex and indusium griseum consist of isolated patches or a thin veil of grey matter and associated fibre bundles, with no laminar pattern. Similarly, the rostral and caudal zones of the anterior perforated substance, the diagonal band of Broca, paraterminal gyrus and the periamygdaloid cortex are poorly differentiated without an obvious laminar pattern, but specific cell aggregations occur in some of them. These include the *nucleus of the lateral olfactory tract* in the periamygdaloid region, and the *nucleus of the diagonal band of Broca*. The central zone of the anterior perforated substance is better differentiated and presents three layers—an outer plexiform, an intermediate pyramidal and a deep polymorphic layer. This region also has a number of characteristic cup-shaped aggregations of granule cells in the pyramidal layer (and these sometimes extend into the plexiform layer). These are the *islands of Calleja*, which vary considerably in size, the medial being the largest—it is closely related to another prominent group of larger pleomorphic cells, the *nucleus accumbens septi*. The structure of the hippocampal formation is further discussed below, but it may be noted at this point that the dentate gyrus and Ammon's horn both consist of a primitive trilaminar type of cortex which shows a gradual transition through the subicular region until a modified six-layered variety is found in the entorhinal area of the parahippocampal gyrus.

THE TERMINATION OF THE OLFACTORY TRACT

The areas of termination of olfactory tract fibres have been widely studied experimentally in mammals, including monkeys, and despite minor differences in some accounts, substantial agreement has been reached. What obtains in the human brain is, of course, less certain.

As we have seen, the olfactory tract fibres are the axons of mitral and tufted cells in the olfactory bulb, some of which synapse with cells in the anterior olfactory nucleus, the axons of the latter then

continuing with the direct fibres of the tract. Through the medium of the *lateral olfactory stria*, tract fibres reach and synapse with neurons in the lateral part of the anterior perforated substance, the lateral olfactory gyrus, the prepiriform cortex and in the corticomedial group of amygdaloid nuclei (*vide infra*). These regions are often grouped as the **primary olfactory cortex**, and it should be noted that in contrast to all other sensory pathways, fibres reach these cortical areas directly without a synapse in one of the thalamic nuclei. The entorhinal area (area 28) of the parahippocampal gyrus, which occupies the caudal part of the piriform lobe, receives few or no tract fibres directly, but receives profuse connexions from the primary cortex; accordingly, it is sometimes called the **secondary olfactory cortex**. It is thought that the primary and secondary olfactory cortices are the principal areas responsible for the subjective appreciation of olfactory stimuli.

The variable *intermediate olfactory stria* ends in the anterior perforated substance, but the destination of fibres in the *medial stria* is much less certain. Some of the latter also end in the anterior perforated substance, whilst others have been described as reaching the paraterminal gyrus and adjacent regions, but such claims cannot be regarded as established in the human brain. A number of fibres in the medial olfactory stria cross the midline in the anterior commissure for distribution to the contralateral anterior olfactory nucleus and olfactory bulb.

In addition to the entorhinal area, the primary olfactory cortex also projects to the basolateral part of the amygdaloid complex, the septal areas, the nucleus medialis dorsalis of the thalamus, and to many of the hypothalamic nuclei.

THE AMYGDALA

The amygdala (amygdaloid body, amygdaloid nuclear complex), so named because its general shape resembles that of an almond, consists of a series of neuronal masses and associated nerve fibres in the dorsomedial part of the temporal pole of the cerebrum. It forms the ventral, superior and medial walls of the ventral tip of the inferior horn of the lateral ventricle. Its topographical relationships are complicated. Superiorly, it is partly continuous with the inferomedial margin of the claustrum, and fibres of the external capsule and substriatal grey matter incompletely separate it from the putamen and globus pallidus; it is closely applied to the optic tract. The amygdala is partly deep to the gyrus semilunaris, the gyrus ambiens and the uncinate gyrus (7.119); transitional zones connect it with the anterior perforated substance, prepiriform cortex and parahippocampal gyrus. Caudally, it is closely related to the ventral part of the hippocampus; it fuses with the tip of the tail of the caudate nucleus, which has coursed ventrally in the roof of the inferior horn of the lateral ventricle; the stria terminalis issues from its caudal aspect.

(For a comprehensive review of the neurobiology of the amygdala consult Eleftheriou 1972.)

Divisions of the Amygdala

The amygdaloid complex is divided into two main groups of nuclei, *corticomedial* and *basilateral*, together with junctional zones where these adjoin or partly fuse with adjacent areas. A detailed account of the subdivisions, connexions and homologies of these groups will not be attempted here (*see* Crosby and Humphrey 1941; Crosby *et al.* 1962; Eleftheriou 1972; Isaacson 1974) and only some of the main points will be outlined.

The corticomedial amygdaloid complex consists of the *central*, *medial*, and *cortical amygdaloid nuclei*, the *nucleus of the lateral olfactory stria*, and a transitional poorly differentiated *anterior amygdaloid area*. The cortical nucleus, as its name suggests, may be regarded as a rudimentary cortex, with irregular groups of pyramidal and granule cells; it occupies the surface elevation of the gyrus semilunaris.

The corticomedial complex is continuous through transitional zones with the anterior perforated substance, the diagonal band of Broca, the substantia innominata, and with the putamen, caudate nucleus, and surrounding cortical areas of the uncus and parahippocampal gyrus. It is relatively small in the human brain.

The basilateral amygdaloid complex, large and well differentiated in the human brain, consists of *lateral*, *basal*, and *accessory basal amygdaloid nuclei*. It is partly continuous with the claustrum, and, through a corticoamygdaloid transitional zone, with the cortex of the parahippocampal gyrus.

The Connexions of the Amygdaloid Complex

These are incompletely established for the human brain; most of the available information is derived from degeneration and electrophysiological studies in a variety of mammals, including monkeys (*see*, for example Le Gros Clark and Meyer 1947; Allison 1954; Powell *et al.* 1965; Gloor 1960; Wendt and Albe-Fessard 1962; Eleftheriou 1972).

Briefly, **afferent connexions** reach the corticomedial complex via the lateral olfactory stria from the olfactory bulb and anterior olfactory nucleus, whilst the basilateral complex receives many afferents from the cortex of the piriform lobe (p. 990). Other afferents converge on the amygdala from the hypothalamic nuclei, both specific and non-specific thalamic nuclei, the brainstem reticular formation, and probably a number of areas of neocortex (*vide infra*).

The best understood *outflow* from the amygdaloid nuclei occurs via the stria terminalis to the septal areas, the preoptic and adjacent regions of the hypothalamus, whilst some continue into the stria medullaris to reach the habenular nucleus. Other *amygdalofugal fibres* do not run with the stria terminalis, but follow more ventrally placed direct routes (p. 968) to reach many of the hypothalamic nuclei, the cortex of the piriform lobe, the nucleus medialis dorsalis of the thalamus, and the reticular formation of the midbrain tegmentum. Reciprocal connexions probably exist between the amygdaloid complex and the oribitofrontal, cingulate and temporal regions of the neocortex, whilst *interamygdaloid fibres* run with the other components of the anterior commissure (*vide infra*). For a brief review of the more recent views concerning the monoaminergic connexions of the amygdaloid complexes *see* pp. 943–948.

THE STRIA TERMINALIS

This is a small, discrete bundle of fine myelinated nerve fibres, which is visible to the unaided eye throughout much of its course. Fibres pass in both directions within the bundle to a number of different destinations. Topographically, the stria issues from the posterior aspect of the amygdaloid complex and runs caudally in the roof of the inferior horn of the lateral ventricle, on the medial side of the tail of the caudate nucleus. It follows the curve of the nucleus and then passes ventrally in the floor of the body of the ventricle, occupying the groove which separates the caudate nucleus from the thalamus, where it is closely related to the thalamostriate vein. It passes inferior to the interventricular foramen to approach the region of the anterior commissure, where it diverges into a series of components which are *supracommissural*, *commissural*, and *subcommissural* in position. As the stria nears the anterior pole of the thalamus, within its various subdivisions scattered groups of small neurons are found; these constitute the *bed nucleus of the stria terminalis*, within which a number of its fibres relay. Many of the fibres in the supra- and sub-commissural components are amygdalofugal, and are passing to the septal areas (*vide infra*), the preoptic and anterior hypothalamic nuclei, whilst others descend to the anterior perforated substance and adjacent regions of the piriform lobe. Some of the subcommissural fibres recurve to join the column of the fornix, and yet others pass caudally with the stria medullaris to the habenular nucleus. It is probable that reciprocal connexions are established between some of these regions and the amygdaloid nuclei, by fibres which pass in the reverse direction through the stria. It will be appreciated that interamygdaloid fibres pursue a most intricate topographical course. Leaving one amygdaloid complex they pass through almost the whole length of the highly curved stria terminalis to reach the anterior commissure, where they cross the midline and then curve in the reverse direction through the contralateral stria to reach the opposite amygdaloid complex.

THE ANTERIOR COMMISSURE

The anterior commissure is a compact bundle of myelinated nerve fibres which crosses the midline anterior to the columns of the fornix, embedded in the lamina terminalis, where it forms part of the anterior wall of the third ventricle some 1·5–2·0 cm superior to the optic chiasma (7.110, 114, 141). When seen in sagittal section it is oval in shape with its long diameter (about 2·5 mm) placed vertically. Traced laterally, its fibres are twisted and entwined like the strands of a rope; further laterally, it separates into two principal bundles. The smaller *anterior bundle* curves forwards on each side towards the anterior perforated substance and olfactory tract. The large *posterior bundle* curves backward and laterally on each side and for some distance is lodged in a deep groove on the antero-inferior aspect of the lentiform nucleus. Beyond the latter, the posterior bundle forms a fan-shaped radiation into the anterior part of the temporal lobe including the parahippocampal gyrus. Commissural fibres have been described in various mammals, including primates, as interconnecting the following structures with their fellows—(1) the olfactory bulb and anterior olfactory nucleus; (2) the anterior perforated substance, olfactory tubercle and diagonal band of Broca; (3) the prepiriform cortex; (4) the entorhinal area and adjacent parts of the parahippocampal gyrus; (5) part of the amygdaloid complex—in particular, the nucleus of the lateral olfactory stria; (6) the bed nucleus of the stria terminalis, and the nucleus accumbens septi; (7) the middle and inferior gyri of the temporal lobe in their anterior regions; and (8) possibly other neocortical areas, including small regions of the frontal lobe.

The intertemporal neocortical connexions form the largest component of the anterior commissure in primates, including the human brain. However, in the latter many of the detailed connexions of the fibres in the commissure remain to be elucidated. Further, a proportion of its fibres may not be truly commissural, but decussating pathways between dissimilar centres on the two sides.

THE SEPTAL AREAS

In subprimate mammals, the *septal areas* consist of the thick medial walls of the cerebral hemispheres situated immediately anterior and superior to the lamina terminalis and anterior commissure. They consist of nuclear masses of grey matter together with relatively coarse bundles of white fibres, and according to their relationship to the anterior commissure may be divided into *pre-* and *supra-commissural* parts.

In higher primates and particularly in the human brain, the septal areas are considerably modified in association with the great expansion of the neocortex and corpus callosum in these forms. The supracommissural septum now corresponds in large measure to the bilateral thin laminae of white fibres, sparse grey matter, and neuroglia, which form the right and left halves of the septum pellucidum. The precommissural septum (*septum verum* of some authors) in contrast, consists of relatively well-defined dorsal, ventral, medial and caudal *groups of nuclei*—each of these may be subdivided into a series of individual nuclei, but these will not be detailed here. However, the precise topographical limits of the human septum verum, and the terminology applied to the surface topography and nuclear groups of this region, have been the source of some confusion and disagreement. (For detailed reviews consult Stephan and Andy 1962; Andy and Stephan 1968; Nauta and Haymaker 1969.)

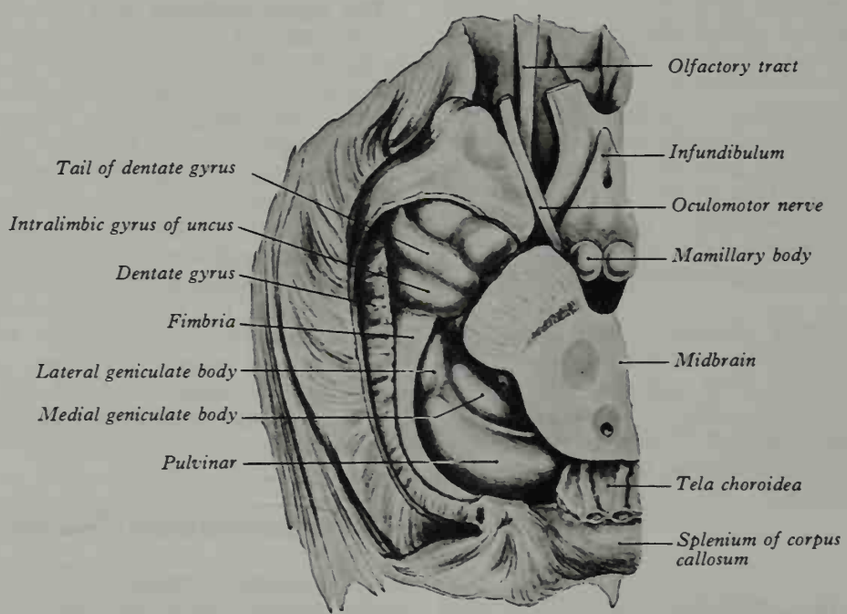
Most authorities agree that the precommissural septum corresponds in part to the paraterminal gyrus. The latter has been mentioned elsewhere (p. 988) as a narrow vertical strip which lies between the anterior surface of the lamina terminalis and the posterior parolfactory sulcus. The anterior slope of the gyrus which passes into the sulcus is sometimes called the *prehippocampal rudiment*. Inferiorly, the gyrus and rudiment are continuous with the diagonal band of Broca and with the medial olfactory stria (7.119). Superiorly, they narrow, and spread around the rostrum and genu of the corpus callosum to become continuous with the indusium griseum (p. 998). However, some investigators hold that only the prehippocampal rudiment is continuous with the indusium griseum, whilst the detailed connexions of the medial olfactory stria are uncertain in the human brain.

Whilst some of the septal nuclei are located within the paraterminal gyrus, others are more deeply placed and are interspersed with fibres of the precommissural fornix (p. 1001). Scattered cell groups interconnect the precommissural septum with the septum pellucidum, the substantia innominata and the anterior perforated substance.

The main afferent connexions to the septal nuclei are from: (1) the amygdaloid complex via the diagonal band and stria terminalis; (2) the anterior perforated substance by fibres which probably run with the medial olfactory stria; (3) the hippocampus via the fornix; (4) the midbrain reticular formation and hypothalamic nuclei through ascending fibres in the medial forebrain bundle (the monoaminergic status of some of the latter afferents are mentioned on pp. 943–948).

The main outflows from the septal nuclei are—(1) fibres which return to the hippocampal formation in the fornix; (2) descending fibres in the medial forebrain bundle which are distributed to many of the hypothalamic nuclei and to the midbrain reticular formation; (3) fibres which pass in the stria medullaris thalami to the habenular nuclei.

Finally, interconnexions are probably established between the septal areas and the vestigial indusium griseum and also with the cingulate gyrus, but details of these remain uncertain.



Thus, the septal areas are important focal zones through which many of the principal limbic and hypothalamic structures are interconnected. For long thought to be reduced, atrophic, and perhaps functionless in primates, recent studies have demonstrated that in fact the septal nuclei have increased in prominence throughout the primates and reach their highest degree of primate development in the human brain (Andy and Stephan 1968).

The Hippocampal Formation

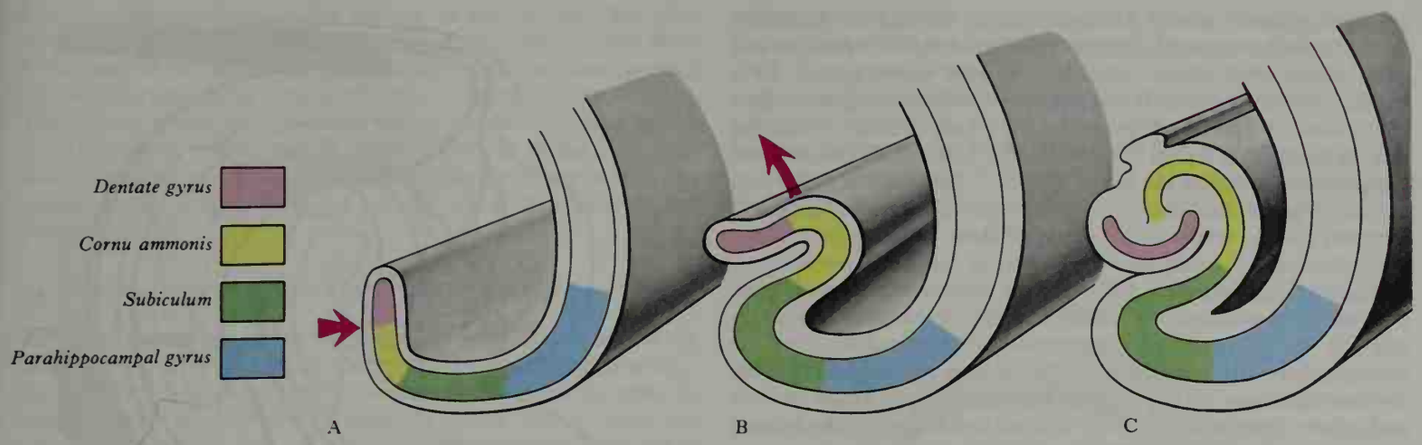
The hippocampal formation develops in the medial pallial fringe of the cerebral hemisphere, immediately adjacent to the outer convex border of the choroidal fissure (p. 980), where, with progressive development, it assumes a highly arched form extending from the interventricular foramen to the ventral extremity of the inferior horn of the lateral ventricle. The modifications in the superior part of the formation, which accompany the expansion of the neopallium and the corpus callosum, have also been discussed previously (p. 171). Essentially, the hippocampal formation consists of a curved band of phylogenetically ancient cortex (the *archipallium*), limited on its concave aspect by the choroidal fissure, and merging on its convex aspect with surrounding areas of *neopallium*. Traced in a radial direction from the choroidal fissure towards the neopallium, three main zones may be distinguished within the archipallium, namely, the *dentate gyrus*, the *cornu ammonis* and the *subiculum*. The dentate gyrus and cornu ammonis show some contrasting structural features, but are generally regarded as the most primitive *trilaminar* types of cortex, whilst the subiculum shows a graded variation in structure from a four, through a five, to a modified six-layered type of cortex where it merges with the surrounding full six-layered neocortex. With further development profound growth changes cause an infolding of these archipallial zones towards the neighbouring cavity of the lateral ventricle. To assist understanding, these zones and their changes in relative position, are shown in a highly simplified manner in illustration 7.121. The general form of infolding is similar throughout Mammalia. However, its *degree*, and the *areas* of hemispheric wall in which a well-differentiated hippocampal formation persists, varies greatly in different groups. These variations will not be detailed here, but they reflect the differences in relative expansion of the neopallium, corpus callosum and temporal lobe in the different groups. In the human brain, that part of the hippocampal arch related to the medial wall and roof of the body of the lateral ventricle becomes greatly reduced in association with the relatively enormous size of the corpus

callosum, a well-developed hippocampal formation being confined to the floor and medial wall of the inferior horn of the ventricle.

Antero-inferiorly, the extremities of the archipallial arch are continuous with the septal area including the paraterminal gyrus, the anterior perforated substance and parts of the piriform lobe (p. 990). Further, the topographical limits of the structures to be included in the *hippocampal formation* vary somewhat in the accounts of different authorities. Here, it is considered to include—(1) the indusium griseum, and the longitudinal striae and their extensions; (2) the gyrus fasciolaris; (3) the dentate gyrus, cornu ammonis and subiculum; (4) parts of the uncus. The term *hippocampus* is often used to denote the macroscopic swelling in the floor of the inferior horn of the lateral ventricle consisting of the interlocked dentate gyrus, cornu ammonis and related structures.

7.120 Basal aspect of part of the brain dissected to display the uncus, dentate gyrus, fimbria, etc.

What follows is a brief topographical account of these regions, some further structural details of the hippocampus, and a description of the functionally related fornix.



THE INDUSIUM GRISEUM

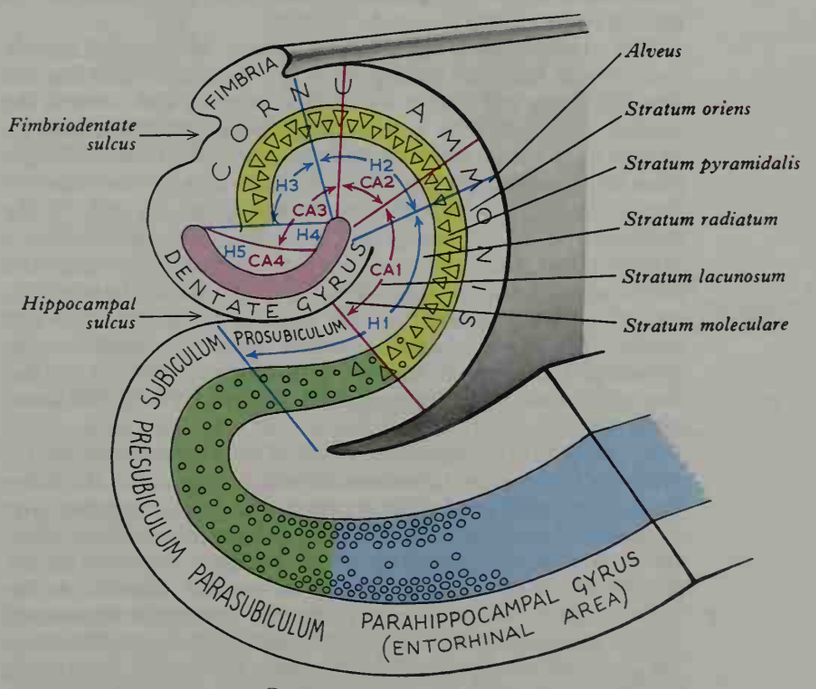
The indusium griseum or *supracallosal gyrus*, is a thin, poorly differentiated veil of grey matter which covers the superior surface of the corpus callosum. Laterally, on each side, it passes into the callosal sulcus to become continuous with the cortex of the cingulate gyrus. Anteriorly, it sweeps around the genu and rostrum of the corpus callosum to merge on each side, with the superior end of the paraterminal gyrus. It will be recalled that the latter is continuously inferiorly with the diagonal band of Broca and, through this, with the anterior perforated substance and periamygdaloid area. Posteriorly, the indusium griseum passes on to the splenium of the corpus callosum where it diverges to become continuous with the right and left *gyrus fasciolaris* (*splenial gyrus*). The latter is a delicate strip of grey matter which curves downwards, forwards and laterally, to blend with the posterior extremity of the *dentate gyrus*. Embedded in the indusium, and causing a ridging of its free surface, are two narrow bundles of white fibres on each side, the *medial* and *lateral longitudinal striae* (of Lancisi) (7.139). The medial striae course near the midline whilst the lateral striae are in the depths of the callosal sulci. The striae are regarded as the reduced white matter of the vestigial indusium. Anteriorly, they pass towards the paraterminal gyri, whilst posteriorly they continue through the gyrus fasciolaris to reach the fimbriae of the fornix (p. 1001). The detailed connexions of the striae are uncertain, but in the supracallosal part of their course they probably contribute fibres which pierce the corpus callosum and form part of the *dorsal fornix* (p. 1002).

THE HIPPOCAMPUS

As noted above, the hippocampus consists of the complex interfolded layers of the dentate gyrus and cornu ammonis, the latter being continuous through the subicular region with the cortex of the parahippocampal gyrus. The name hippocampus stems from the supposed resemblance of these cell laminae, when viewed in coronal section, to the outline of a sea-horse. Grossly, the hippocampus is superior to the subiculum and medial part of the parahippocampal gyrus, where it forms a curved elevation about 5 cm long extending throughout the entire length of the floor of the inferior horn of the lateral ventricle. Its anterior extremity is expanded, and at this point its margin sometimes presents two or three shallow grooves with intervening elevations giving a paw-like appearance—the so-called *pes hippocampi*. The ventricular surface is convex in coronal section and, of course, covered by ependyma, beneath which pass tangential white fibres of the *alveus* converging medially upon a longitudinal projecting bundle of white fibres, the *fimbria of the fornix*. The general relationships of these various cell layers and fibre bundles as seen in coronal section are best appreciated by preliminary references to a simplified diagram (7.121). It will be noted that passing *medially* from the line of the collateral sulcus, the neocortex of the *parahippocampal gyrus* merges with the transitional cortex of the *subiculum*. The latter curves superomedially to reach the inferior surface of the *dentate gyrus*, and then continuing to curve laterally becomes continuous with the cell laminae of the *cornu ammonis*. The latter continues to curve, first superiorly and then laterally above the dentate gyrus, and finally ends pointing towards the centre of the superior surface of the dentate gyrus. However, it should be appreciated that the degree of curvature of these regions varies somewhat along the length of the hippocampus and also in different specimens.

Topographically, the *dentate gyrus* (7.120) is a crenated strip of cortex which is related inferiorly to the subiculum, laterally to the cornu ammonis, and superiorly to the recurved part of the cornu ammonis, the alveus and, more medially, to the fimbria of the fornix (7.121). However, the distribution and form of the fimbria is quite variable (*vide infra*), but medially it is separated from the notched medial margin of the dentate gyrus by the *fimbriodentate*

7.121A–C The hippocampus and related structures seen in coronal section A, B and C are a series of diagrams to assist understanding of the assumption of the definitive positions of the dentate gyrus, cornu ammonis, subiculum and parahippocampal gyrus, in the floor of the inferior horn of the lateral ventricle in the human brain. Note that these are *not* tracings from a series of embryonic sections, and that they have been somewhat simplified in the interests of clarity. Note also that the amount of curvature and infolding which occurs varies along the length of the hippocampus, and in different specimens. It is important to appreciate that following folding, the original *external* surfaces of the dentate gyrus and part of the subiculum are in contact, and that the degree of tissue fusion which occurs along the line of the hippocampal sulcus is quite variable.



sulcus. The *hippocampal sulcus*, of variable depth, intervenes between the dentate gyrus and the subicular extension of the parahippocampal gyrus. Posteriorly, as noted above, the dentate gyrus is continuous with the gyrus fasciolaris, and through this, with the indusium griseum. Anteriorly, the dentate gyrus is continued into the notch of the uncus, where it makes a sharp bend medially across the central part of its inferior surface. This transverse part is smooth and featureless, being termed the *tail of the dentate gyrus* (band of Giacomini), and it becomes indistinguishable on the medial aspect of the uncus. The tail separates the rest of the inferior surface of the uncus into an anterior *uncinate gyrus* and a posterior *intralimbic gyrus* (7.119, 120).

THE STRUCTURE OF THE HIPPOCAMPUS

Since the extensive pioneering researches of Cajal (1890, 1911) and Lorente de Nó (1934) a vast literature has accumulated concerning the structure and connexions of the hippocampus. Only a few salient points can be mentioned here, and for details texts devoted wholly to neuroanatomy (e.g. Kappers *et al.* 1936; Crosby *et al.* 1962; Brodal 1969) and original papers should be consulted. Detailed earlier reviews of the complex terminologies proposed for the various laminae and their subdivisions are to be found in the writings of Lorente de Nó (1934), Rose (1927), and Gastaut and Lammers (1960). Examples of the many investigations into the connectivity patterns of the hippocampus using degeneration techniques may be found in (Blackstad 1956, 1958; Raisman *et al.* 1965, 1966; White 1959, 1965), using ultrastructural techniques (Blackstad 1967; Blackstad and Kjaerheim 1967; Blackstad and Flood 1963; Hamlyn 1962), and neurophysiological recording methods (Andersen *et al.* 1964 *a* and *b*; Andersen *et al.* 1966). More recent comprehensive collections of essays devoted to many aspects of the structure, development, neurophysiology, and behavioural aspects, the product of many leading authorities and containing extensive bibliographies are brought together in two volumes entitled *The Hippocampus* and edited by Isaacson and Pribram (1975).

Some aspects of the terminology used and some of the main structural features are shown in outline in illustration 7.122.

It should be noted that because of the form of cortical folding which occurs during development, the original *external* surfaces of the dentate gyrus and subiculum (the *stratum moleculare*) are closely applied to each other in the depths of the sulcus hippocampi (or along the obliterated line of the sulcus). Throughout much of its extent, the subicular region merges laterally with the modified six-layered cortex of the *entorhinal area* of the parahippocampal gyrus. (Some authorities prefer to include the subiculum with the parahippocampal gyrus, rather than with the hippocampal formation.) As noted above, during its curved course from the entorhinal area to the beginning of Ammon's horn, the subiculum exhibits a gradual change in its structure from a modified six-layered to a four-layered type of cortex, with accompanying differences in its patterns of connectivity. Accordingly, the subiculum is often divided into four zones, the *parasubiculum*, *presubiculum*, *subliculum* and the *prosubiculum*. Their structural differences will not be detailed here, but it should be appreciated that the prosubiculum merges into the cornu ammonis which, using the same criteria, may be regarded as a primitive trilaminar cortex possessing *molecular*, *pyramidal* and *polymorphic* layers from its original external surface towards its ventricular surface. However, using other methods and criteria, many more sub-layers are often described in Ammon's horn (*vide infra*). Further, although the general

7.121D An analysis of the major topographical zones and the complex terminology applied to the hippocampus and related structures seen in a coronal section of the floor of the inferior horn of the lateral ventricle in a mature human brain. Colour code for tissue zones as in A–C. The approximate limits of the various subdivisions of the subiculum are labelled. CA 1–4 are the cornu ammonis fields of Lorente de Nó (1934), and H 1–5 are the hippocampal fields of Rose (1927).

cytoarchitectonic pattern is roughly similar throughout Ammon's horn, there are regional differences in its detailed structure and connexions. For these reasons, different investigators have proposed various methods and criteria for subdividing this region into a series of radially disposed fields (7.122). These include the **cornu ammonis fields** CA1 to CA4 of Lorente de Nó, and the **hippocampal fields** H1 to H5 of Rose. Unfortunately, these do not correspond; the former, as the name implies, are limited to Ammon's horn, whilst the H1 field of Rose includes part of the subiculum, the prosubiculum, and part of Ammon's horn.

The cornu ammonis, following the intensive studies of Cajal, is usually considered to consist of the following sub-layers starting on its ventricular aspect—(1) the *ependyma*; (2) the *alveus*; (3) the *stratum oriens*; (4) the *stratum pyramidalis*; (5) the *stratum rqdiatum*; (6) the *stratum lacunosum*; and (7) the *stratum moleculare*. Many authors group the last two sub-layers as a single *stratum lacunosum-moleculare*.

The *alveus* is a subependymal layer of white fibres both entering and leaving the hippocampus. The efferent fibres are predominantly the axons of the large neurons of the stratum pyramidalis, together with a smaller number from some cells of the stratum oriens and dentate gyrus. These axons converge to form the large efferent component of the *fimbria of the fornix* (*vide infra*) but before joining it they give rise to fine collateral branches which re-enter the hippocampus. Afferent fibres from other regions of the nervous system, including commissural fibres from the opposite hippocampal formation, also approach the cell layers of the hippocampus through the alveus.

The *stratum oriens* is interlaced with the axons and collateral branches of fibres entering and leaving the hippocampus; it is penetrated by some of the basal dendrites of the large pyramidal cells of the adjacent layer, and it contains the cell somata and dendrites of relatively small, irregularly shaped neurons, some of which are termed *basket cells*. These small cells have been shown to be inhibitory interneurons. They receive axosomatic and axodendritic synapses from some of the afferent fibre collaterals to the hippocampus, and also collaterals from efferent fibres. Some of the axons of these interneurons penetrate the radiate and molecular layers establishing axodendritic contacts with pyramidal cells, but the most distinctive terminals are those of the basket cells, which form numerous, crowded, axosomatic synapses on the cell bodies of the pyramidal neurons.

The *stratum pyramidalis* is a particularly well-defined double layer of both large and small pyramidal cells. Their bases face the stratum oriens and alveus, whilst their apices point towards the stratum radiatum. The axon of a pyramidal cell issues from its base or from a basal dendrite, and passes into the alveus, where it gives collateral branches and then continues into the fimbria of the fornix. Some of these collateral branches end on cells in the stratum oriens, but many (the *Schaffer collaterals*) pursue a recurrent course to the stratum moleculare where they terminate on the apical dendrites of adjacent pyramidal cells. The dendritic tree of a pyramidal cell has two main components, basal and apical. The *basal dendrites* radiate into the neighbouring pyramidal layer, but the majority pass into the stratum oriens and overlying alveus; they are beset with dendritic spines. The *apical dendrites* pass deeply, and together with associated axons and a few pyramidal cells, make up the bulk of the *stratum radiatum*. On reaching the *stratum lacunosum-moleculare*, the apical dendrites branch profusely, and these terminal branchlets, together with their stem dendrite, are also covered with dendritic spines. Thus, these deepest layers consist of the terminal dendrites of the pyramidal cells, axonal terminals of various afferents to the hippocampus, the recurrent (Schaffer) collaterals mentioned above, and the cell bodies, dendrites and axonal arborizations of the scattered, deeply placed interneurons, from which the stratum lacunosum receives its name. Whilst the connexions of the hippocampus are treated in a subsequent paragraph, it may be noted here that the various zones of the dendritic tree of the pyramidal cell receive distinctive types of axonal terminal. Thus, commissural fibres from corresponding regions of the opposite hippocampus end upon basal dendrites, whilst those from non-corresponding regions end on the apical dendrites in the strata lacunosum and moleculare. Afferents from the entorhinal cortex

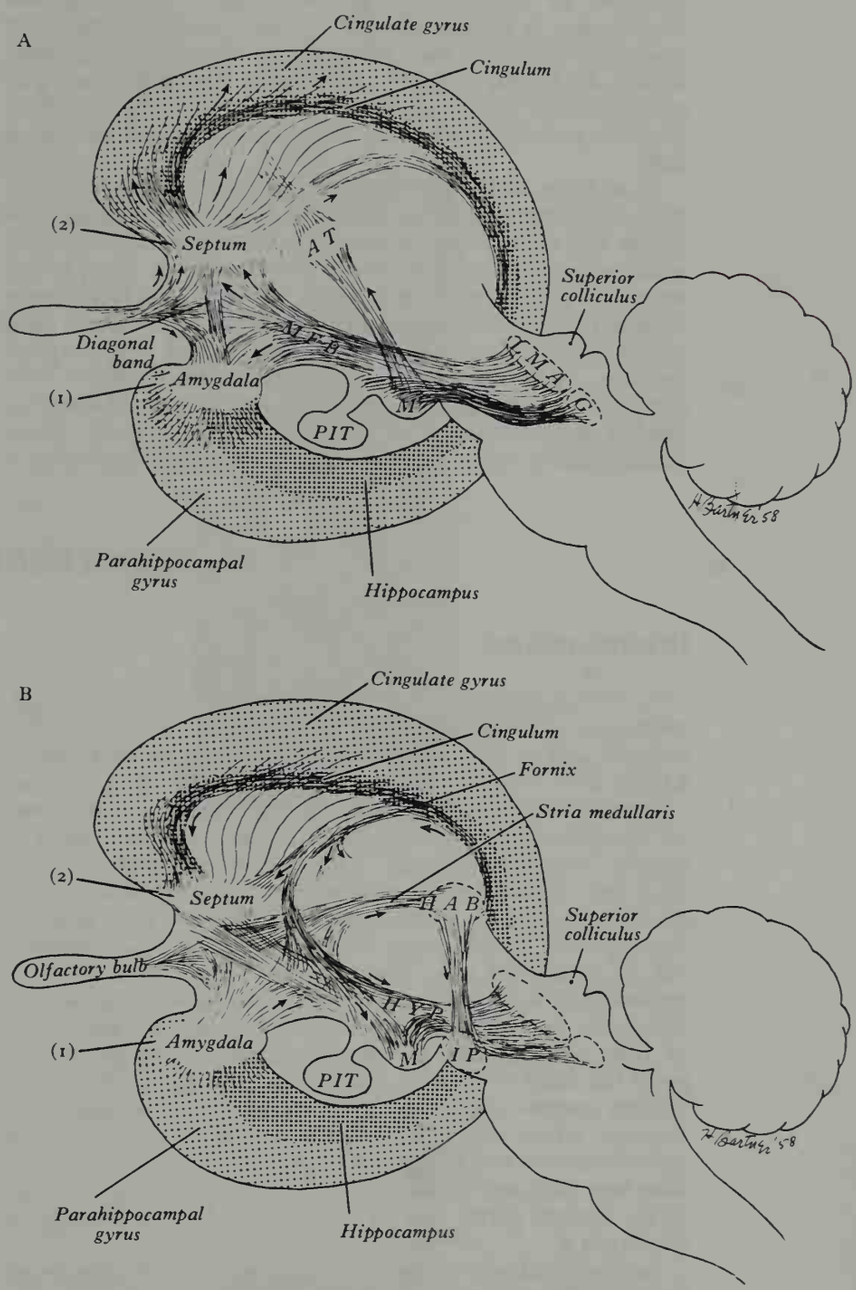
7.122 A diagram of some of the main features of the neuronal organization and connectivity patterns of the dentate gyrus, cornu ammonis, subiculum and parahippocampal gyrus. The cell somata, dendrites and axons of the pyramidal neurons of the cornu ammonis are yellow; their axons form the efferent hippocampal fibres of the alveus and fimbria. Afferent fibres to the cornu ammonis from the fimbria are purple, those following the alvear path are green, whilst those following the perforant path are blue. Basket neurons are in black. The neurons of the dentate gyrus, and their axons which form the mossy fibres of the hippocampus, are in magenta. See text for further details.

form synapses with the most terminal branches of the apical dendrites in the molecular layer, whilst the synaptic endings of the Schaffer collaterals are found in the stratum lacunosum. The mossy fibres derived from dentate gyrus cells form large synaptic terminals which enclose the prominent dendritic spines of the apical dendrites in the stratum radiatum, but as noted above, basket cell terminals form a dense population of axo-somatic synapses. Attempts have been made to correlate these interesting zonal variations in axonal terminals with differences in the character of the electrical recordings made with microelectrodes inserted to varying depths in Ammon's horn (Andersen *et al.* 1964 *a* and *b*; Andersen *et al.* 1966). Thus, many of the afferent systems, and the pyramidal cells themselves, are now known to be excitatory, and some of the interneurons, particularly the basket cells, are known to be inhibitory in their action.

The dentate gyrus is less well understood, but is considered to be a trilaminar cortical structure. Extending deeply from the line of the hippocampal sulcus it consists of: (1) a superficial *molecular layer*; (2) an intermediate *granular layer*; and (3) a deep *polymorphic cell layer*. These will not be considered in detail here. Briefly, the various cell types in the three laminae have spine-studded dendritic trees which either radiate locally or pass in the superficial layer. They receive synaptic terminals from some of the afferent fibres to the hippocampus from extrinsic sources, and also from the axons of neighbouring neurons. Some of the cells are Golgi type II neurons with axons which terminate locally; others have much longer axons which, after collateral branching, run to

join the efferent fibres in the fimbria of the fornix. The most distinctive axons, however, are called *mossy fibres*. They arise from many of the cells in the granular layer and then pass through the polymorphic layer giving collateral branches to its neurons. The mossy fibres then proceed along a curved course in the superficial part of the stratum radiatum of the cornu ammonis, making a series of very large ('giant') synaptic contacts with the spines on the initial segments of the apical dendrites of the pyramidal cells.

THE CONNEXIONS OF THE HIPPOCAMPUS



Afferent pathways to the hippocampus arise in: (1) parts of the cingulate gyrus; (2) the septal nuclei; (3) the entorhinal cortex; (4) the indusium griseum; (5) commissural fibres from the opposite hippocampal formation; (6) possibly some fibres from the prepiriform cortex, and (7) a dual monoaminergic fibre input derived from brainstem reticular cell aggregates—*see* pp. 943–953.

The fibres from the cingulate gyrus reach the hippocampus via the cingulum (p. 971) and are distributed both directly to the cornu ammonis, and indirectly after relays in the subicular region. The afferents from the septal nuclei retrace the curved path of the fornix back to the hippocampus. The commissural fibres from one hippocampal formation pass through the fimbria and crus of the fornix on the same side to reach, and cross the midline in the commissure of the fornix (*vide infra*). Thereafter, they recurve back through the opposite crus and fimbria to reach the contralateral hippocampus. Some fibres derived from cells in the indusium griseum run posteriorly in the longitudinal striae, with which they pass through the gyrus fasciolaris to reach the fimbria, which conducts them to the hippocampus.

The most profuse afferent connexions of the dentate gyrus and the cornu ammonis, however, are derived from the entorhinal cortex and subicular regions, and for long were held to pass by two distinct routes. Fibres from the medial part of the entorhinal area and parasubiculum follow an *alvear path* through the prosubiculum to reach the alveus and stratum oriens of the cornu ammonis. In contrast, the afferents derived from the lateral part of the entorhinal area follow a *perforant path* through the subiculum, which crosses the alvear path, and continues into the stratum lacunosum-moleculare of the cornu ammonis and adjacent parts of the dentate gyrus. These routes, and those entering from the fimbria are shown in illustration **7**.122. It should be noted that the perforant path predominates and is the best attested; some authors doubt the significance or even the existence of an alvear path, at least in some mammals.

THE FORNIX

In addition to the afferent hippocampal fibres and commissural fibres described above, the fornix constitutes the sole **efferent system** from the hippocampus. These efferent fibres are mainly the continuations of the axons of the pyramidal cells of Ammon's horn, but a small proportion are derived from neurons in the stratum oriens and the dentate gyrus. These various axons pass through the alveus and converge upon the medial border of the ventricular surface of the hippocampus to form the *fimbria*. The latter is a flattened band of white fibres which lies superior to the dentate gyrus and forms the inferior boundary of the choroidal fissure. The disposition of the fimbria is variable. It may project above the dentate gyrus with a free medial edge, the *taenia fornicis*, and a lateral border which merges into the alveus; alternatively, its free border may be twisted over towards the lateral side, uncovering the dentate gyrus (**7**.140). Anteriorly, the fimbria continues into the hook of the uncus (**7**.120). Traced posteriorly on the floor of the inferior horn of the ventricle, it ascends towards the splenium and the majority of its fibres now pass anteriorly below the splenium, and then curve forward above the thalamus, forming the *crus of the fornix*. The two crura are closely applied to the inferior surface of the corpus callosum and are connected to each other by transverse fibres which pass between the hippocampal formations of the two sides and form the *commissure of the fornix* (hippocampal commissure). The commissure is a thin triangular sheet which, together with the converging crura, is sometimes termed the *lyra* or *psalterium* (an instrument resembling a harp). Between the commissure and the corpus callosum, a horizontal cleft (the so-called *ventricle of the fornix*) is sometimes found. Anteriorly, the two crura come together in the median plane to form the *body of the fornix* which is really a symmetrically disposed bilateral structure. The body of the fornix lies above the tela choroidea and the ependymal roof of

AT: anterior group of thalamic nuclei; G: tegmental reticular nuclei; HAB: habenular nucleus; HYP: hypothalamus; IP: interpeduncular nucleus; LMA: limbic midbrain area (of Nauta); M: mamillary body; PIT: hypophysis cerebri; (From P. D. MacLean in: *The American Journal of Medicine*, **25**, 1958; by courtesy of the author and publishers.)

the third ventricle (7.157) and is attached to the inferior surface of the corpus callosum and, more anteriorly, to the inferior borders of the laminae of the septum pellucidum. Laterally, the body of the fornix overlies the medial part of the upper surface of the thalamus, and the choroidal fissure is placed below its free lateral edge. Through this fissure the choroid plexus in the lateral margin of the tela choroidea passes into the body of the lateral ventricle (7.157). Anteriorly, above the interventricular foramina, the body of the fornix diverges into right and left bundles which curve inferiorly towards the anterior commissure forming the anterior boundary of the foramina. As each bundle approaches the commissure it divides around it into two components—a *precommissural fornix*, and a *postcommissural fornix* (column of the fornix). Each column continues to curve inferoposteriorly and gradually sinks into the corresponding part of the lateral wall of the third ventricle to reach the superior aspect of the mamillary body.

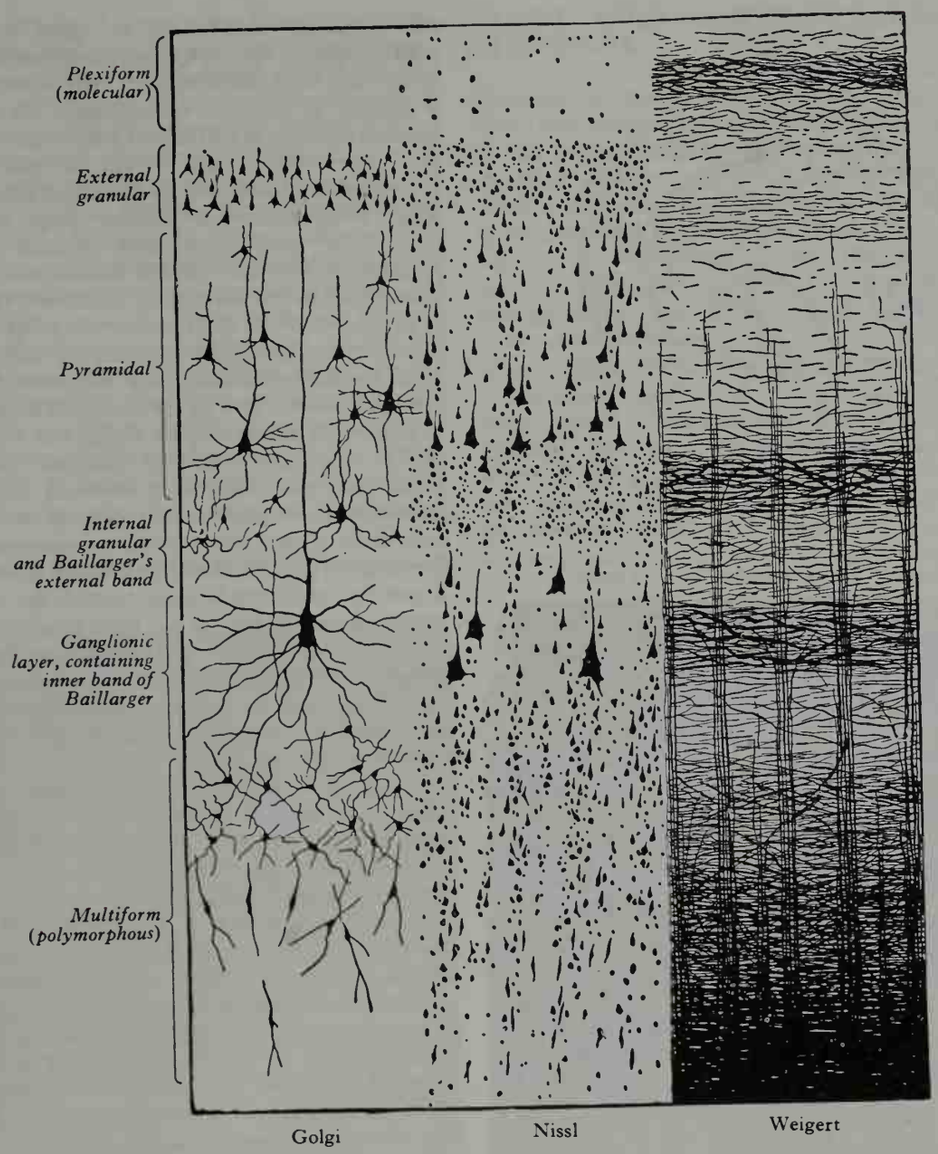
In addition to the foregoing bundles, some fibres leave the fimbria near the splenium to run anteriorly with the supracallosal medial and lateral longitudinal striae, where they are joined by others arising from the indusium griseum. Some fibres of the striae then pass inferiorly between the fibre bundles of the corpus callosum, where they are joined by other fascicles which pass straight into the corpus callosum from the fimbria. These various fascicles, which intersect the callosal bundles, constitute the *dorsal fornix*. Some fibres of the dorsal fornix relay in the scattered patches of grey matter in the septum pellucidum, whilst others course directly on through the septum; both direct and indirect fibres largely rejoin the main body of the fornix.

Thus, following these different bundles of the fornix, *hippocampal efferents* pass to: (1) the gyrus fasciolaris, indusium griseum, cingulate gyrus, and the septum pellucidum via the *dorsal fornix*; (2) to the precommissural septum, the preoptic and anterior hypothalamic nuclei via the *precommissural fornix*; (3) during its descent the *postcommissural column of the fornix* gives direct fibres to the anterior nuclei of the thalamus and to many of the hypothalamic nuclei (p. 968), before proceeding to its main termination in the medial mamillary nucleus; (4) other fibres curve caudally from the column of the fornix to join the stria medullaris thalami to reach the habenular nuclei, whilst yet others continue into the reticular formation of the midbrain tegmentum.

In summary, illustrations 7.123A and B show the main inflow and outflow pathways associated with the limbic system (based upon MacLean 1958, 1969); but these will obviously require repeated revision in the future.

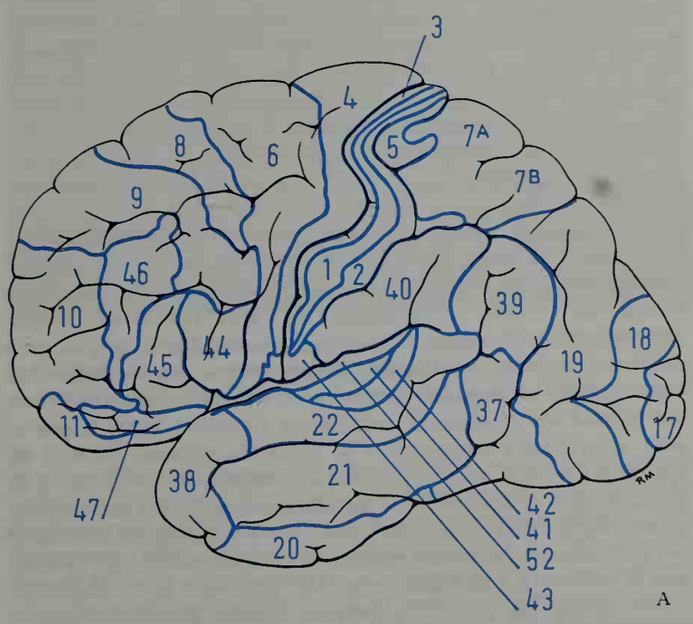
An immense volume of research has been directed towards a better understanding of the biological roles of the various complex and interconnected structures which are often grouped together under the term limbic system, described in the previous pages. Despite this their significances can, at present, only be described in the most general terms. Even a brief review of the experimental results is beyond the scope of the present volume and the interested reader is directed towards the wealth of information and pertinent bibliographies to be found in Eleftheriou (1972); Isaacson (1974); Isaacson and Pribram (1975); Livingston and Hornykiewicz (1978).

THE CEREBRAL CORTEX

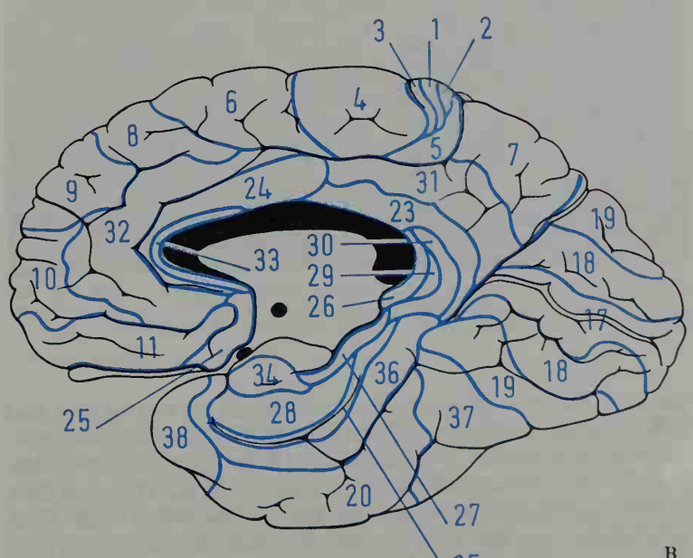


Introduction

The cerebral cortex has been studied over several centuries, with increasing momentum. It was examined by the first microscopists, and as early as 1776 the stria in the occipital cortex named after him was noted by Gennari, this being the first recorded structural detail. Only with the advent of improved microscopes in the 1830s and later did effective investigation of cortical organization begin; it has continued uninterruptedly since then, producing an increasing number of papers which has become an almost unmanageable deluge in this century. Consequently, no more than the most outstanding contributions can be mentioned here, and emphasis must be chiefly upon reports of work done in recent decades. However, it is important to note the basic discoveries from which the intricate knowledge of today has expanded, if only to maintain a wider perspective amid the flood of detailed description and speculation which renders current activity so interesting and yet confusing in its constant sallies and revisions. The accent of endeavour has naturally varied with the availability of techniques; but the major aims have been and remain the elucidation of the *modus operandi* in the cerebral cortex and the localization of different forms of activity in it.



Earlier investigations, inevitably microscopic, were stimulated by the techniques of Nissl, Golgi, Cajal, and Weigert (7.124), amongst others. Even prior to this, with less satisfactory methods, Baillarger (1840) and Meynert (1867–8), had ascribed a *laminar pattern* to the cortex, with particular emphasis upon fibre structure—*myeloarchitecture*. Subsequent workers using newer techniques (Lewis 1878; Campbell 1905; Cajal 1909–11; Brodmann 1909; Vogt and Vogt 1926; von Economo and Koskinas 1929; Lorente de Nó 1949) confirmed this, but with notable variations and disagreements, now largely overlooked. A six-layered schema prevailed (Brodmann), although this was based upon Nissl-stained material alone, in which all the highly significant details of dendrites studied by other workers were invisible; moreover, the data were accumulated from a comparative series which, although including simian brains, did not include the human cortex. These studies, in which a six-layered pattern became almost a dogma, led to the recognition of great variations in this theme in different cortical regions or 'areas', no less than fifty-two being distinguished. These results, embodied in the familiar 'Brodmann maps'—still widely current—were transferred somewhat arbitrarily to man by others, and they gained much credence amongst physiologists, perhaps because they provided a useful numerical reference guide to the cortex (7.125A, B) as they still do today.



Techniques such as Nissl's merely reveal the morphological variations and distribution of nerve cell bodies, and this *cytoarchitectural* mode of study requires *myeloarchitectural* methods to display myelinated nerve cell processes. Only with both methods of examination, coupled with somatic and neurite staining by such techniques as the Golgi method—to which must be added the more recent availability of electron microscopy and refined experimental degeneration techniques—could the finer details of cortical organization be discerned. Unfortunately, the Nissl-based cytoarchitectonic mapping of the cerebral cortex initially attracted more attention than other available techniques, and its continued use, together with myelin staining, has led to an almost excessive parcellation of the cortex into different areas, few of which can be accorded clear physiological significance. One useful outcome of these sometimes rather unfruitful studies was the diversion of interest among younger workers to physiological studies. The rapid advance in this field of cortical investigation gradually lead to much discordance between the results of stimulation studies and architectonic mapping (except in broad details), and this prompted several notable critical reviews (Lashley and Clark 1946; Scholl 1956). These have not entirely deterred the 'architectonicians', and it must be stated that in the *broader* aspects of their schemata there is considerable accord between their structurally established areas and the results of physiological experimentation.

The definition of five or six major types of cortical organization (cf. Campbell 1905, and von Economo and Koskinas 1925, 7.126A, B) has proved valid in functional terms, but the excesses of architectonics are reminiscent, except in their admittedly serious structural basis, of the multi-faculty maps of phrenology. The division of the cortex into such a multiplicity of 'organs' seems basically improbable. As the critics of such concepts have stressed, variations in a single area in different individuals of the

7.126A and B. The distribution of the five major types of cerebral cortex, as projected on to the superolateral surface of the hemisphere, according to C. von Economo and G. N. Koskinas (1925). The numbering of cortical areas (A) corresponds to the cytoarchitectonic types (B). See text for further details and references. Compare with 7.125.

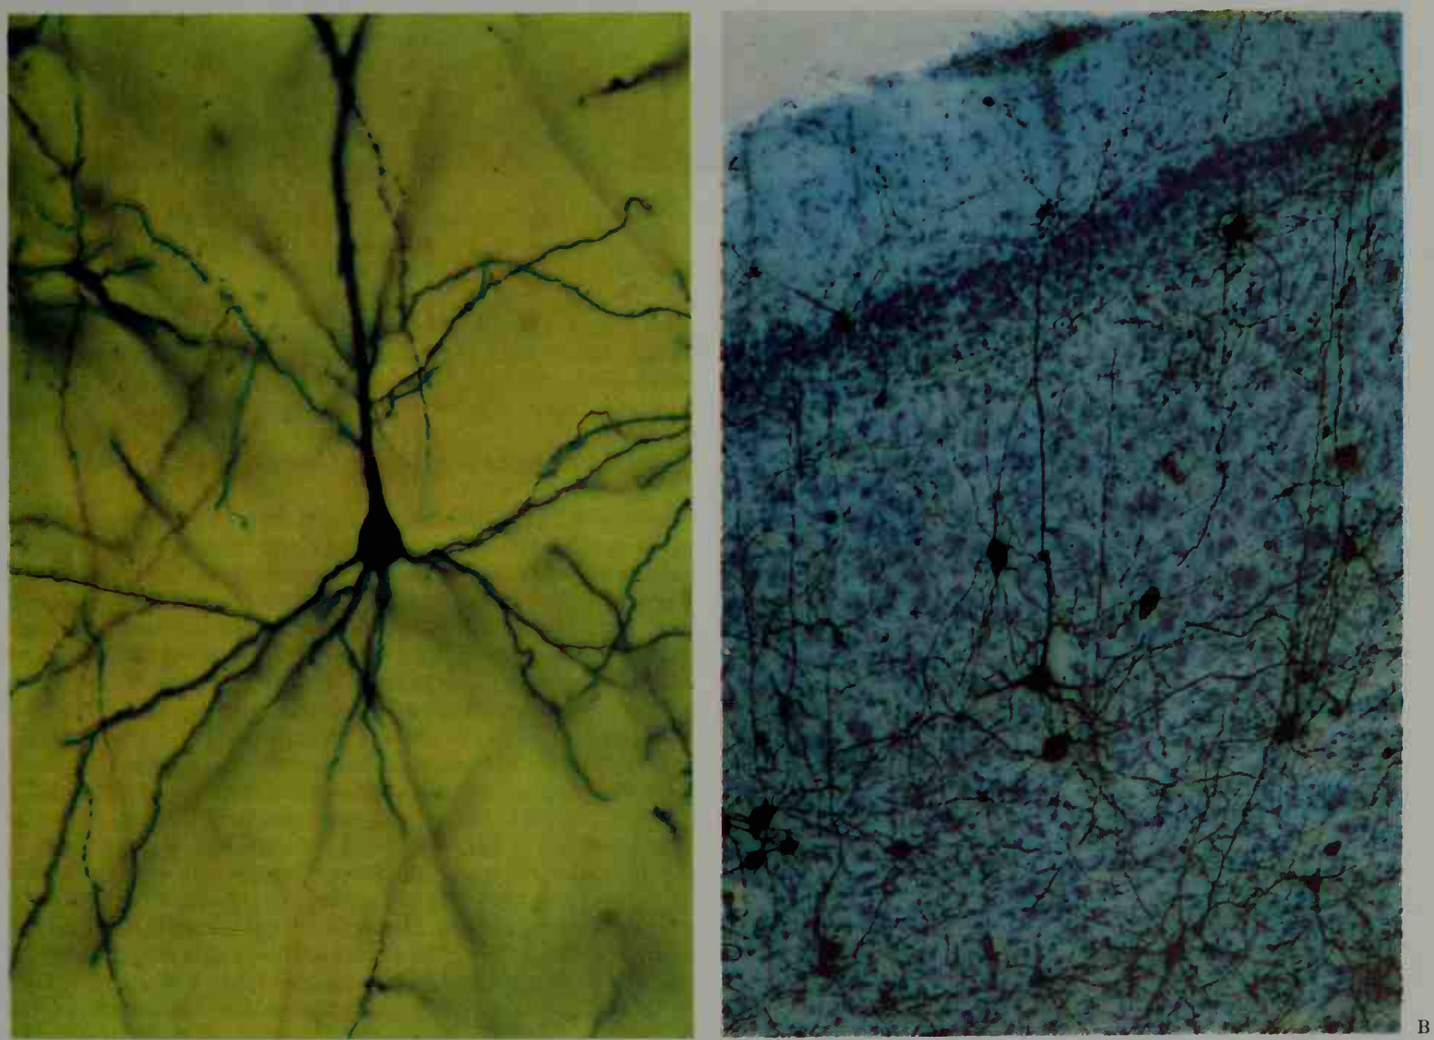
same species, the effects of cortical development and folding, and other factors, particularly the pattern of subcortical connexions, may all contribute to variable structural appearances in the cortex—and to variations which are not uniform. The need for a more quantitative approach to the problem has also been emphasized by the same critics, but this remains largely an exhortation, though its ultimate necessity is generally recognized.

That a laminar appearance characterizes the cerebral cortex cannot be denied, but dogmatic views on the number of layers in this neuronal continuum, or upon the variations in, and equivalence of, the customarily numbered six layers in different areas, have been shown to be of little or no functional significance, if pushed to excess. Nevertheless, the Brodmann schema of numbered layers is still almost universally employed, perhaps as a mere convenience, and it will perforce be described below. Localization of function to a considerable degree—inasmuch as some areas receive or project large and easily identifiable subcortical connexions—also remains undeniable, and the polemics which this concept occasioned in the late nineteenth century are largely forgotten (Clarke and O'Malley 1968). But the original extents of such 'motor' and 'sensory' areas, as defined (and perhaps artificially confined) by architectonic studies, have been markedly modified and augmented by physiological investigations, and also by the results of degeneration experiments.

Studies of the cortex by Golgi and silver-staining methods, though originally somewhat obscured by work based on Nissl technique, have received a renewed impetus with the recent development of micro-recording from the larger individual nerve cells of the cortex. Prior to this the elaborate structural studies of the neurites of cortical neurons, which have been available for half a century, could not be equated with the results of physiological experimentation; but, as has been mentioned elsewhere (p. 817), during the last decade or so the intimate arrangement of neurons and their individual activities have shown a growing correlation in elaborating concepts of the mode of action of small volumes of nervous tissue, in a variety of sites in the central nervous system, including cerebral cortex.

While classical cyto*architectonic* teaching has become perhaps little more than a useful mode of geographical definition of cortical areas (and a source of some confusion in the 'translation' of areas from species to species of experimental animals), cyto*architectural* details, as revealed by the methods of Golgi and Cajal, are beginning to fit the observed behaviour of individual 'units' in the living cortex. Classical neurite studies of the cerebral cortex—chiefly in lower mammals, such as rodents (*see*, for example Lorente de Nó 1934)—have led to recognition of a large number of nerve cell types. The familiar pyramidal and stellate (granule) cells of Nissl-stained material were chiefly differentiated by relative size into a few unsatisfactory categories, subjectively assessed as large, medium, or small, and so on, with few attempts at measurement. The comparatively unilluminating results of this kind of study are well represented in 7.126B. This should be compared with 7.127B which illustrates the much more useful information afforded by techniques capable of revealing the interconnexions between cortical neurons. It is upon such criteria that a much larger range of neuronal differentiation can be based; and since it is ultimately interneuronal connexions which must be correlated with their activities in life, this approach to cortical structure is inevitably more appropriate than cytoarchitectonic study of Nissl-stained material. Broadly the results of the two methods do not conflict, but one is overwhelmingly more informative. Even though light microscopy proved unequal to the task of full visualization of synapses in the cerebral cortex, the patterns of interconnexion of cortical neurons were in major details well clarified many years before electron microscopy became available.

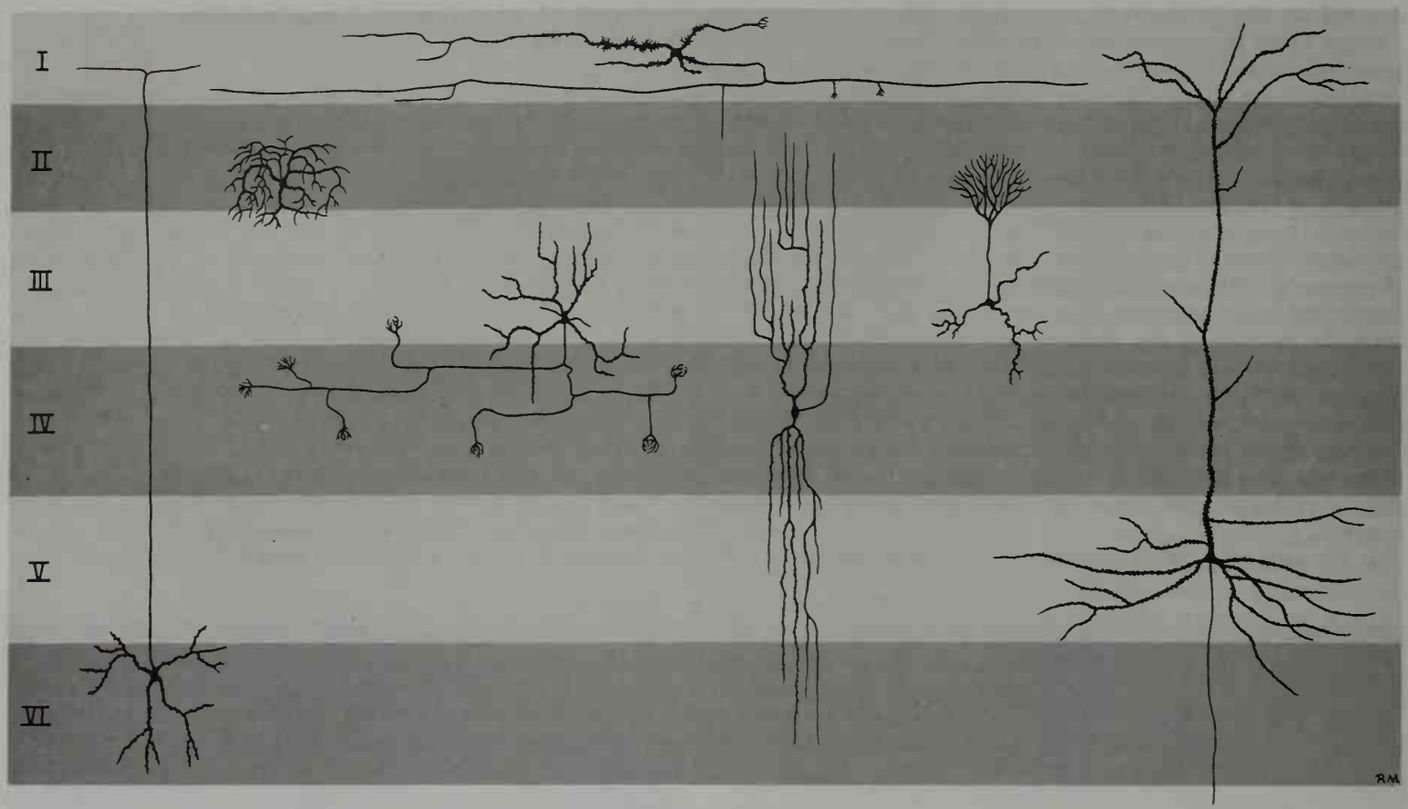
The termination of afferent nerve fibres in the superficial layers of the cortex, nearer the surface than the somata of efferent neurons the existence of recurrent axon collaterals from the latter which turn back superficially to form contacts through interneurons with their own dendrites, and the existence of a marked 'vertical' organization in the cortex—these and other features were all available as the basic cortical 'circuitry' before the refined microelectrode techniques of recent years began to seek a structural background to their recordings. As will be apparent later, the 'chains' of neurons, emphasized by Lorente de Nó, arranged in innumerable cortical units, repeated through the cortex, have fitted particularly well into physiological studies of the postcentral and striate regions (*see* Mountcastle 1957; Hubel and Weisel 1962; Colonnier 1974; Zeki 1974; and pp. 1016, 1018).



As elsewhere in the central nervous system, unit recording and more precise physiological study of the transmission processes of excitatory and inhibitory synapses have generated a renewed

demand for the finest details of connexions between neurons. Various forms of synapse and their ultrastructural features are given full description elsewhere (p. 826); though identification of these structures in the cerebral cortex was achieved comparatively late (Gray 1959), a large literature concerning cortical synaptology has now accumulated. Axodendritic and axosomatic synapses predominate in the cerebral cortex, and for a period were thought to be the only types present, but dendrodendritic synapses have now been identified in some locations. The profusion of synapses, especially in relation to the dendritic spines of pyramidal cells, obviously provides a structural *mélange* for most complex interactions, however far we may yet be from anything more than the simplest interpretations of the full significance of such arrangements. Nevertheless, structure and function are rapidly progressing together in cortical study; and even if the joint 'models' of cortical activity which are currently evolving evince a somewhat hectic tendency to change, almost from year to year, this is surely a healthier state than the stagnating dogma which has sometimes becalmed neurological research.

In the relatively simple account of the cerebral cortex and its specific areas which follows, space will not permit an adequate reflexion of the intense activity in current research; for this the reader must consult recent original papers and surveys, e.g. Colonnier (1966, 1968, 1974); Shepherd (1974); Rakic (1975); Szentágothai (1975); Schmitt *et al.* (1976). It may be noted here that vascular patterns (Pfeifer 1940), and distribution of enzymes (e.g. Pope 1967) have also been used as criteria of differentiation of 'areas' in the cerebral cortex.



QUANTITATIVE ASPECTS OF CORTICAL STRUCTURE

Quantitative studies of the cerebral cortex have been comparatively few; the first serious attempt to ascribe numerical values to its features was made by von Economo and Koskinas (1925), who recorded data on variation in cortical depth which remain the most detailed for man. They also computed the total surface areas as 220,000 mm^2, a more recent figure being 285,000 mm^2 (Scholl 1956), with a volume of 300 cm^3. Naturally the total number of cortical nerve cells has attracted much interest and computation, and figures of 14,000 million (von Economo and Koskinas 1925), 6,900 million (Shariff 1953), 5,000 million (Scholl 1956), and 2,600 million (Pakkenberg 1966) are representative, and illustrate a downward trend which may be due to improving technique. Stereological techniques have been applied to the cortex; for example, Foh *et al.* (1973) have estimated the total lengths of neuronal and glial processes in unit volumes of visual cortex, in cats, arriving at the figure of 5000 m/mm^3 for neurites. Such numbers are beyond real comprehension, and it is easier to grasp the magnitude of such a cell population by its proportions in a smaller sample. For example, a column of cells 1 mm square and 2·5 mm deep may contain as many as 60,000 neurons; and in one study of the motor cortex (precentral gyrus) each neuron was considered to take part in about as many synapses and to connect with some 600 other nerve cells (Cragg 1967). Such a small volume of cortex, in itself containing perhaps 3×10^9 synapses, might be multiplied a quarter of a million times to represent the whole cortex. The wealth of interconnexions of such huge

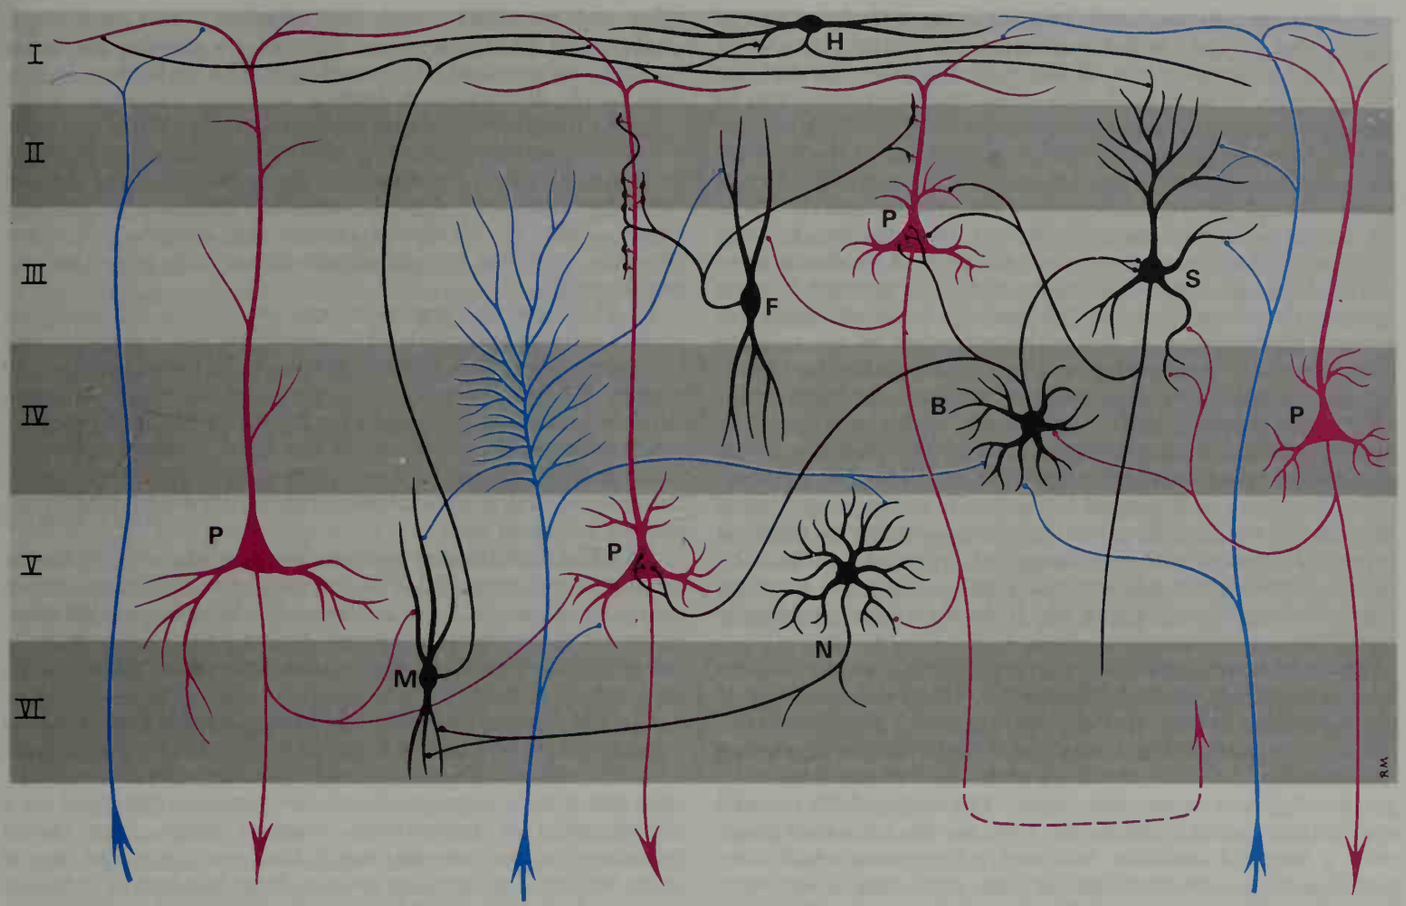
In B isolated Golgi-stained neurons are prominent amongst the remaining Nissl-stained cortical elements. (Preparations provided by Dr. A. R. Lieberman, University College, London.)

7.128A Typical outlines of characteristic neocortical neurons as seen in sections prepared by the metallic impregnation techniques introduced by Golgi and Cajal. From left to right are shown Martinotti, neurogliaform, basket, horizontal, fusiform, stellate, and pyramidal types of neuron. Many other forms and variants have been described. See text for literature.

numbers of cells is clearly very great. In the striate area (Scholl 1955) where about one-tenth of the cortical neurons are said to be concentrated, the dendrites of a single neuron may connect with 2,000–4,000 other cells, and an incoming afferent projection fibre may ramify through a volume of cortex containing 5,000 cells. Even the figures given above are, however, dwarfed by the cerebellar neuronal population—*see* p. 924.

The density of packing of nerve cells in different areas and their laminae shows much variation, being most dense in the striate area and perhaps least so in the precentral gyrus. The ratio by volume of the somata of neurons to all other constituents in the cortex (the grey/cell coefficient) has been estimated, and average ratios of 27:1 (von Economo and Koskinas 1925) and 70:1 (Haug 1956) for man have been cited. It is claimed that the ratio shows a phylogenetic increase up to man, due to an increase in the amount of neuroglia.



Various other quantified data regarding the mammalian cortex are scattered through the literature, which should be consulted for further details. In general—apart from an impression of the enormous potentialities for interconnexion and interaction—such figures have no immediate usefulness. The knowledge that each afferent or efferent projection fibre may have upwards of 1,000 neurons associated with it, more or less remotely, merely emphasizes the general truism of an extremely intricate field of interaction between them. The time may be far off when happenings in such large numbers of neurons can be defined in precise spatial and temporal terms, if indeed this can ever be expected in other than generalized statistical approximations. For the present, the limited events in minuscule volumes of cortex offer a more promising and primarily essential field of investigation. Examples of such studies will be mentioned in connexion with the particular cortical areas in which they have been most successful. Arising from such research, a profusion of concepts of neuronal 'circuitry', diagrams to illustrate these, and even models employing artificial 'neurons' have appeared in recent literature, e.g. Walter (1953); Ashby (1960); Weiner and Schadé (1963); Taylor (1964); Young (1964); Arbib (1964); Minsky (1965); Shepherd (1974, 1978); Colonnier (1974); Rakic (1975); Szentágothai (1975). Naturally, these speculations undergo rapid change and modification as knowledge in the very active fields of synaptology and unit recording advances; and hence, despite their great interest, it is as yet premature to include such details here.

The Structure of the Cerebral Cortex

To the unaided eye the cerebral cortex forms a complete mantle or *pallium* covering the hemisphere and obviously variable in thickness (1·5 to 4·5 mm) when seen in section. It is thicker on the exposed convexities of gyri than in the depths of sulci, in which the larger part of the cortex is hidden from surface view. Such variations in thickness might well correspond to structural variations in the pallium; and it has in fact been suggested that the positioning of gyri and sulci is conditioned by such structural differences (Le Gros Clark 1945), but this cannot be claimed with respect to the *functionally* differentiated areas, which in many instances depart in their outlines from the sulcal pattern. In freshly cut cerebral cortex laminar details can often be appreciated even without a simple magnifying lens (e.g. the visual stria of Gennari); and by such means horizontally disposed layers of nerve fibres, the inner and outer bands of Baillarger (p. 1008), can usually be discerned. It has even been claimed that using such simple methods more than a score of structurally distinct areas of cortex can be identified (Smith 1907).

In its **microscopic structure** the cortex of the cerebrum, like 'grey matter' elsewhere, consists of an intricate blending of nerve cells and fibres, neuroglia and blood vessels. Neuroglial cells and the vascular arrangements have been dealt with in other sections (pp. 834 and 837). The features of the neurons and their interconnexions and distributions must now be considered. It should, however, be noted here that variation in the distribution of the blood vessels has also been utilized as a criterion in differentiating cortical areas (Pfeifer 1940).

The neurons of the pallium have been described and categorized in great detail, but they can be assigned to a relatively small number of classes, the great majority in fact falling into two such groups, the *pyramidal* cells and the *stellate* (granule) cells. Both types may be assorted into a variable number of subdivisions on the basis of size and the appearances of their neurites (7.128).

7.128B A diagrammatic representation of the most frequent types of neocortical neuron, showing typical connexions with each other and with afferent fibres (*blue*). Neurons limited to the cortex in their distribution are indicated in *black*. Efferent neurons are in *magenta*. The right and left afferent fibres are association or cortico-cortical connexions, the central afferent is a specific sensory fibre. Neurons are shown in their characteristic lamina, but many types have somata in more than one layer. They are indicated thus: P = pyramidal, M = Martinotti, F = fusiform, H = horizontal, N = neurogliaform, B = basket, S = stellate. See text for details and compare with the stereodiagram in 7.132.

Both types are found at most levels in the cortex and in almost all areas, though their numbers and distribution vary greatly from place to place. (These variations, together with alterations in size, provide the criteria for distinguishing different cortical areas in Nissl-stained material, of course.) Other types of cells commonly distinguished are *fusiform*, *horizontal*, and *neurogliaform cells*, and the *cells of Martinotti*.

Pyramidal nerve cells, so named from the shape of their somata (7.15), vary from small elements measuring about 10 μm across to the giant pyramidal cells (of Betz) which reach 70 μm and more. Their apices are usually orientated towards the surface of the cortex, and from this region of the cell a thick *apical dendrite* ascends a variable distance, giving off collateral branches and often ending in a complex spray of terminal dendritic twigs. From the other, basal angles of the cell body *basal dendrites* sprout, spreading laterally into the surrounding neuropil to form dendritic fields of varying shapes and extents (Colonnier 1964). A statistical analysis of the branching of such dendrites and those of the stellate cells in the visual cortex has been attempted (Scholl 1953), but this quantitative kind of dendrological study is still a neglected and indeed difficult field. On the whole, the vertical extent of the dendritic extensions of pyramidal cells is markedly greater than it is in the horizontal or tangential direction. The dendrites are studded, especially in their smaller branches, with very large numbers of *dentritic spines* (p. 822), which are now known to be the sites of axodendritic synapses (Gray 1959). Since the number of these synapses, even by the crudest estimates, is very large, it is at once evident that there is a physical basis for the most elaborate interneuronal reactions in the cortex. The axons of pyramidal cells, which are invariably much smaller in calibre than the trunks of their main dendrites, behave in a variety of manners. From larger elements, chiefly in lamina V (*vide infra*), *projection axons* extend centripetally out of the cortex to reach more or less distant subcortical structures, such as the basal nuclei, brainstem nuclei, and the grey matter of the spinal cord. Some may pass back into more or less distant parts of the cortex as *long* or *short association fibres*. The axons of smaller pyramidal cells usually ramify entirely within the cortex, and even those which leave it commonly divide by giving off a small number of collaterals which remain as intrinsic or *intracortical axons*. These latter may extend horizontally, but they more often pursue an obliquely recurrent course towards the more superficial laminae of the cortex. Even from this brief description it is clear that the larger pyramidal cells, whose somata appear in Nissl-stained sections to be sited in a single lamina, in fact extend through most and often all levels of the cortex, since their apical dendrites frequently reach the superficial, *plexiform lamina* (*vide infra*). Thus, each pyramidal neuron forms a species of *columnar unit* extending through the cortex together with its numerous connexions, including other pyramidal elements, many forms of interneuron, and afferent projection fibres. Lateral interconnexions are mediated by various forms of intracortical horizontal neurons and by association neurons.

Stellate nerve cells, often called *granule cells* because of their small size and appearance in Nissl-stained material, appear in variable density of distribution in all the cortical laminae except the most superficial (lamina I); but they are usually concentrated in greater abundance in laminae II and IV (*vide infra*). Like pyramidal cells, stellate neurons would probably have been designated as multipolar if they had not first been described in Nissl-stained sections. They are small, of the order of 6 to 10 μm in diameter, with a rounded soma drawn out at numerous angles by their richly branching dendrites and a single, relatively short axon. They are hence members of the Golgi type II series of neurons. Their dendrites carry numbers of spines, indicating abundant synapses with other neurons. A wide variety of stellate

cells have been distinguished, principally upon the behaviour of their axons. These, though confined to the cortex, may travel considerable distances in it, chiefly in a vertical direction but also horizontally in some instances. The vertical axons may be centripetal or centrifugal in direction, the latter reaching as far as lamina I. One particular type of stellate cell, the *basket cell*, which is horizontally extended, has a short vertical axon which almost immediately divides into a horizontal family of collaterals. These end in pronounced terminal sprays or arborizations, forming synapses with the somata and proximal parts of the dendrites of pyramidal cells. Such cells have a particular interest in their horizontal extension, because of the perhaps excessive attention at present concentrated on vertical organization in the cerebral cortex (p. 1018). Another type of stellate cell is in fact *fusiform* in appearance, due to the emergence of two large dendrites which sprout from opposite poles of the soma, dividing at once into elaborate bouquets of branches which extend vertically in the cortex. The axon, sometimes a branch of a stem dendrite, extends centrifugally towards lamina I. The entire neuron may stretch through the whole thickness of the cortex, probably establishing synaptic contacts with a number of pyramidal cells. The *neurogliaform stellate cells* are small, with a dense and localized dendritic arborization, within which the short axon also usually ramifies.

The horizontal cells (of Cajal) are confined to the plexiform lamina I; they are small and fusiform and their dendrites spread short distances in two opposite directions in the plexiform layer. Their axons, often derived from one of the dendrites, divide into two branches which depart from each other to travel to much greater distances in the same layer. **The cells of Martinotti** occur at most levels in the cortex. They are small and multipolar, with a localized dendritic field and a long axon which runs centrifugally to the plexiform lamina, producing a few short horizontal collaterals *en route*. The so-called **pleomorphic cells** are considered to be modified pyramidal cells with axons entering the white matter. Their somata are variously shaped, perhaps in accord with differences in their dendritic sproutings; the dendrites spread widely into the cortex.

Many other forms of nerve cell have been detailed in the cerebral cortex, but since even the array of types mentioned above cannot yet be linked into a fully coordinated scheme of interaction, it is merely confusing to multiply the details. It should never be overlooked that the most intensive studies of cortical neurons have been carried out on subprimate mammals; and although appearances in the primate cortex, as chiefly pursued in material from macaque monkeys, are similar, investigations of even 'cold' structural arrangements in the human cortex have been remarkably few (Economo and Koskinas 1929; Bailey and von Bonin 1951; Conel 1939–1959).

For an account of ultrastructural details of human cerebral cortex consult Braak (1975), Cragg (1976), and Rees (1976).

Laminar Pattern in the Cerebral Cortex

The cortex or pallium of the cerebrum may be conveniently divided into an older and original part, the *allocortex*, consisting of the archicortex and paleocortex (also known as archipallium and paleopallium), which are considered elsewhere (p. 997), and a newer development, the *neocortex* (isocortex or neopallium). The latter may be equated with those systems of sensory and motor activity which originally had little or no connexions with the forebrain, but have acquired these over evolutionary time by the process of prosencephalization. The remarks which follow apply only to the neocortex.

As already stated in the Introduction to this section (p. 1002), the customary description of a six-layered cortical structure successfully promulgated by Brodmann and his followers has, by its general acceptance, obscured earlier disagreements and widespread dissatisfaction with its arbitrary nature. The same strictures must be applied to excessively detailed architectonic mapping of the cortex which has stemmed from the same somewhat dogmatic views. However, Brodmann's numbered layers and areas provide a reference grid of considerable practical value and are widely used; and therefore, until some more intellectually satisfying system emerges, the details—insofar as they are useful—must be repeated here. The six laminae (7.124, 126) may be described as follows:

I. **The plexiform lamina** (molecular or zonal layer) contains the sparsely scattered horizontal cells (of Cajal), and consists apart from this of a dense net of tangentially orientated fibres, derived from pyramidal cells (apical dendrites), stellate cells (vertical axons), cells of Martinotti (centrifugal axons), and other elements, including cortical afferent fibres, both projection and associational.

II. **The external granular lamina** contains the somata of stellate and small pyramidal cells, usually packed densely, though this varies, like other laminar details, in different areas of the cortex. Passing through the lamina are vertically arranged dendrites and axons from subjacent layers, intermingling with the dense neuropil of local dendrites and axons. Ascending afferent fibres make extensive multiple synaptic contacts with the apical dendrites of large pyramidal cells (with somata in lamina V) in this and the subjacent layer.

III. **The pyramidal lamina** contains the cell bodies of medium-sized pyramidal cells, the smaller of which are situated nearer to lamina II. Some stellate cells also occur in this layer, including horizontally disposed basket cells, and vertically orientated fusiform cells, their dendrites and axons extending far beyond the layer itself.

IV. **The internal granular lamina** is usually narrower than other layers, except lamina I, and is chiefly characterized by the somata of stellate cells, with occasional small pyramidal cells. The cells are densely aggregated and the lamina is traversed by a concentration of horizontally arranged fibres, long known collectively as the *external band of Baillarger*. As in the case of other laminae, the layer also contains large numbers of vertically orientated neurites derived from nerve cells in other parts of the cortex, in subcortical regions, and in adjoining layers.

V. **The ganglionic lamina** contains the largest pyramidal cell somata, but smaller elements of the same type also occur, the actual dimensions of these cells varying in different cortical areas. In any particular area, however, the largest pyramidal cells are in lamina V. Small numbers of stellate cells may also occur. The layer is, of course, permeated by a dense neuropil of dendrites and axons derived both from its intrinsic elements and cells in other laminae. It is also traversed by ascending and descending projection fibres and by association fibres. A considerable complement of horizontally deployed fibres is apparent in lamina V, corresponding, in sections stained to display myeloarchitectural details, to the *internal band of Baillarger*.

VI. **The multiform lamina** contains a considerable range of cell types, as judged by their somata and processes, the variable shape of the former reflecting to some extent the variations in their dendritic arrays. Most of the cells are small and are considered to be modified pyramidal elements, despite the fusiform, triangular, ovoid and other profiles of their somata. The small, multipolar Martinotti cells are often prominent in this lamina. Lamina VI is not always well demarcated from the subjacent cortical zone of fibres approaching or departing from the cortex itself.

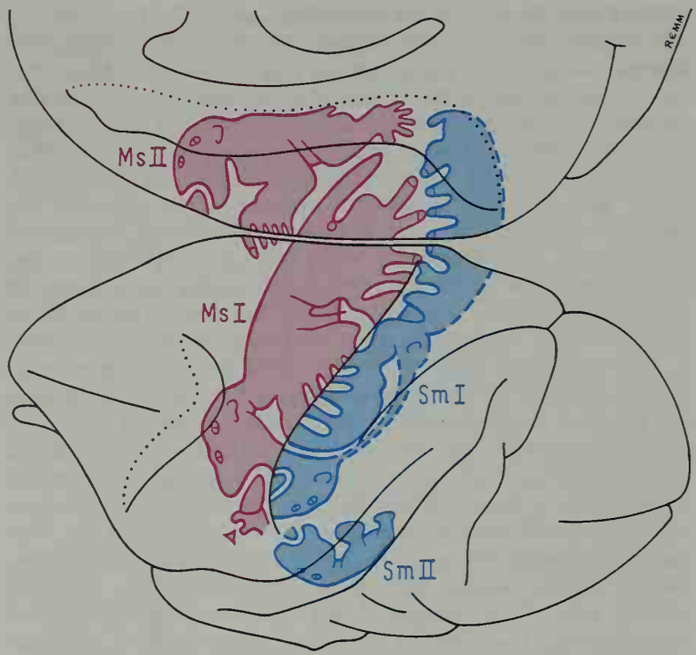
The numbering and nomenclature of cortical laminae set out briefly above is in the style of Brodmann. Many synonyms for their names are in circulation, derived from the work of such investigators as Campbell and Cajal; the Vogts also introduced another, somewhat more awkward nomenclature, based on myeloarchitectonic studies, in which the fibre structure is emphasized. Views as to the number of layers have varied widely, and much subdivision has been suggested. For example, lamina VI has been divided into VIa and VIb on the distribution of triangular and fusiform cells, and into no less than four sublaminae (VIa^1, VIa^2, VIb^1 and VIb^2) in material stained to show fibre structure. All layers except lamina II have been further analysed in this manner, as many as sixteen laminae in total being recognized by the Vogts. The usefulness of such minute dissection has been severely criticized, and these details are only mentioned here as examples. Similar remarks are applicable to much of the work in the field of cortical architectonics. Here again the Brodmann maps have achieved most attention. Their early

transference (in a form elaborated further by the Vogts but still not worked out in man) to the human cortex by Foerster has overshadowed the contribution of von Economo and Koskinas. In one respect this is fortunate, because the latter chose to designate areas by letters, as has Conel (1939), and these, and other nomenclatures, would have proved much less manageable than Brodmann's simple numbers. However, in recent years, new views on the extent of the major sensory and motor areas of the cortex have generated the need for a more appropriate terminology than Brodmann's (*see* Woolsey 1964). The new series of symbols suggested will be referred to in connexion with cortical areas involved; many of them are already in wide use in experimental studies, but since a lack of uniformity persists in this, and since such terms are only beginning to penetrate into clinical neurology, the customary numerical designation of cortical areas must be retained for the present.

REPRESENTATIVE VARIANTS OF CORTICAL STRUCTURE

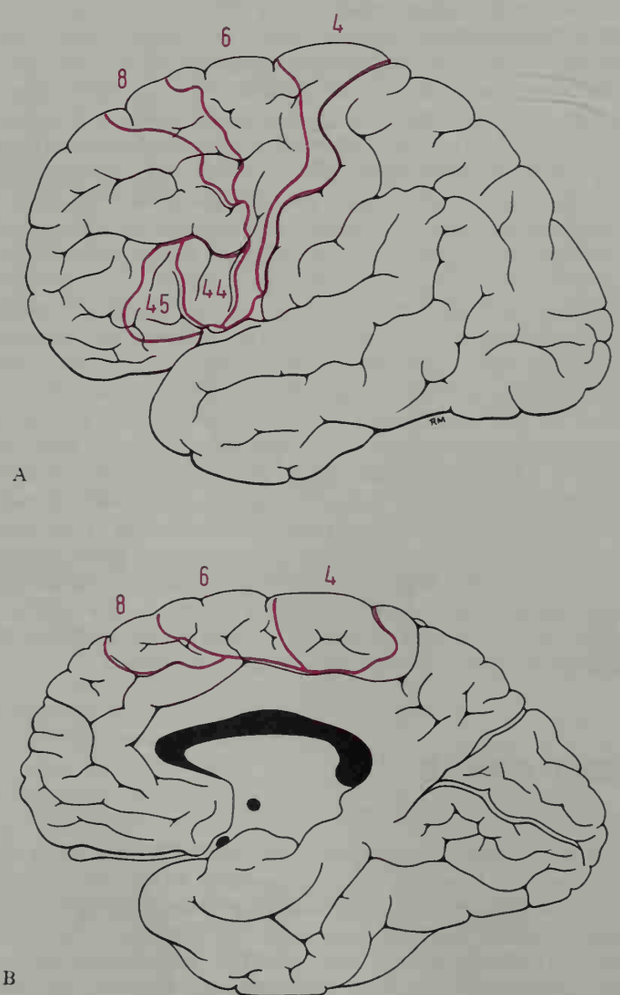
While it is obviously impossible, and probably unprofitable, to detail and discusss here the almost endless nuances of cortical structure in full-blown architectonics, it is necessary to allude to a smaller number of basic variant types of cortex. These were recognized in the classical pioneer studies of Campbell (1905) and consolidated by Economo and Koskinas (1929). *Five* fundamental types are described (7.126) in the neocortex, and while all are considered to develop from the same six-layered or *sesquilaminar pattern*, two of them are regarded as lacking certain laminae when fully differentiated, and are hence described as *heterotypical*; these are the *granular* and *agranular* types. The *homotypical* variants, in which all six laminae are discernible, are called *frontal* (premotor), *parietal* (postcentral), and *polar* (visuopsychic)—names which link them with specific regions in a somewhat misleading manner, as illustration 7.126 shows. For example, the frontal type occurs in the parietal and temporal lobes.

The agranular type of cortex is considered to be lacking in the granular laminae (II and IV), but it does usually display scattered stellate nerve cells. The predominant neuronal type is, however, pyramidal, and it is in this form of cortex that the greatest densities and largest sizes of pyramidal cells occur. Originally identified in the precentral gyrus (area 4), it also occupies areas 6, 8 and 44 (7.125) and occurs in other regions, including parts of the limbic system (p. 990). It is characterized by the projection of large concentrations of efferent fibres from the pyramidal cells, and agranular cortex can thus be equated with the 'motor' areas—with the proviso that such areas are now known to receive afferent projections in addition, as will be detailed in connection with the individual areas.



The granular type of cortex (koniocortex) may be regarded as at the opposite extreme of the main categories of cortical structure. The granular layers are maximally developed in such areas and contain densely packed stellate cells, amongst which are nevertheless a variable but small number of pyramidal cells. Laminae III and IV are poorly developed or unidentifiable. This type of cortex is associated with afferent projections but, here again, there is evidence of a lesser number of efferent fibres, derived from the few pyramidal cells usually to be found in this otherwise 'granular' cortex. Despite the relative lack of different laminae, the granular and agranular types of cortex exhibit little qualitative distinction, being rather at the opposite extremes of a gradation, in which the pyramidal and stellate series of cell types are reciprocally developed. Typical granular cortex is formed in the postcentral gyrus, striate area, and in the superior temporal gyrus (acoustic area); it also occurs in small parts of the hippocampal gyrus (p. 992). Despite the very large number of stellate cells packed into this form of cortex, especially in the striate area, it is almost the thinnest of the five main types. In the striate cortex the external band of Baillarger (lamina IV) is particularly well defined, as the *stria of Gennari* (or Vicq d'Azyr).

The remaining three types of cortex may be regarded as intermediate forms. In the **frontal type** large numbers of small and medium-sized pyramidal cells occur in laminae III and V, the granular layers (II and IV) being less prominent. The relative numbers of these two major forms of nerve cell vary reciprocally in the different areas in which this form of cortex exists. It is not confined to the frontal region of the cerebrum (7.126). The **parietal type** of cortex contains less pyramidal cells, which are mostly smaller in size than in the frontal type; the granular laminae are, on the contrary, wider and contain more abundant stellate cells. This kind of cortex occupies large areas in the parietal and temporal lobes (7.126). The **polar type** is classically identified with small areas near the frontal and occipital poles of the hemisphere, and hence its name. It is the thinnest form of the five types (7.126). All six laminae are represented in it, but the pyramidal layer (III) is reduced in width, and is not so extensively invaded by stellate cells as in the granular type of cortex. As in the latter, the multiform layer (VI) is more highly organized than in other forms of cortical structure.



While further subdivision of the above five basic types of cortical 'organization' may be useful for specific experimental purposes, it must be emphasized again that in the microscopic sections in which they are customarily distinguished—whether stained to show cell somata or their processes—the finer and more significant details of true organization are not apparent in studies of the whole thickness of the cortex. The functional organization is naturally linked to the spatial distribution of the cells, but it is in their actual patterns of connexion that any real enlightenment as to cortical mechanisms must be sought. Golgi preparations in particular have yielded an immense amount of information indicating the probable designs of neuronal interaction. Functional hypotheses deduced from such merely structural data, however intricate, require confirmation in terms of the precise nature of synapses both in their distribution and mode of action. Details of this kind depend upon electron microscopy and unit recording. Unfortunately, such techniques deal only with much smaller volumes of cortical tissue, but most exciting results are apparent in the research in this field in the last two decades or so, as will be seen in various sections of this account of the central nervous system. The cytoarchitectural approach to the problems of cortical activity was a necessary prelude, and the resultant definition of various forms of organization in structural terms remains as a necessary scheme of orientation to which the finer ultrastructural details must be constantly referred.

THE MAIN CORTICAL AREAS

Before describing the major areas customarily distinguished, on functional and structural data, in the human cerebral cortex—such as the somatomotor, somatosensory, visual and auditory areas—some preliminary general remarks are necessary. As has already been emphasized, the somewhat extreme parcellation of the cortex deriving from the studies of Brodmann has a limited usefulness and is frankly misleading if regarded as more than a reference grid in defining parts of the cortex. Even the simpler differentiation of the cortex into *sensory* areas receiving afferent projection fibres and *motor* areas projecting efferents—the remainder being regarded as 'silent' or *associational*—can no longer be considered appropriate, being itself an inaccurate over-simplification. Evidence has accumulated during the last three decades to show that the areas receiving or originating projection fibres are much more extensive than the initial classical studies indicated. Furthermore, the division into 'receiving' and 'originating' projection areas is by no means so distinct as at first appeared. Thus, the postcentral gyrus is not the only area to which a somatosensory thalamic projection is directed; at least two other areas of cortex are similarly involved, as will be detailed later in this section. In the same way, the precentral gyrus is supplemented by a second 'motor' area. It is necessary to qualify

7.129 The main sensorimotor areas projected diagrammatically upon the superolateral surface of the simian cerebral hemisphere. Note the somatotopic arrangement in all four areas. (Adapted from C. N. Woolsey, 1964—see text for details and references.)

7.130A and B Superolateral (A) and medial (B) surfaces of the cerebral hemispheres, showing approximate correspondence of the Brodmann areas to the main motor area (4) or MsI, the premotor area (6, 8) and motor speech area of Broca (44, 45). See text for details and compare with 7.125, 134, 135A and B.

the term 'motor' because the distinction of motor and sensory areas still customary in simpler accounts of the cerebral cortex is erroneous, and has indeed been known to be so for many years. As long ago as 1933 motor responses to stimulation of the 'sensory' areas were demonstrated (Dusser de Barenne 1933), and projection of efferent ('pyramidal') fibres from the same postcentral area was established shortly afterwards (Levin and Bradford 1938). Since these pioneer studies a mass of confirmatory evidence in various experimental animals has extended these findings to other areas. Moreover, clinical and experimental observations in mankind suggest that similar arrangements obtain. It is hence more appropriate to speak of the pre- and post-central areas as being *sensorimotor*; and since a mixture of afferent and efferent connexions has been shown to exist also in respect to the projection fibres of the acoustic and visual 'sensory' areas, they also are more accurately described as sensorimotor in character.

The recognition that the corticospinal or 'pyramidal' pathway is derived from nerve cells in a much larger area than the precentral gyrus is paralleled by similar findings in regard to the various thalamic and geniculate projections upon the cortex; these terminate in considerably wider regions of the cortex than originally described. For example, the classical somatosensory area in the postcentral gyrus is supplemented by a second area, inferior to it, and by a third, on the medial aspect of the hemisphere, which is also a motor area (*vide infra*). Similarly, the lateral and medial geniculate bodies are now known to project to other regions of the cortex beyond the visual and auditory areas of conventional description. Not only the striate cortex (area 17, visuosensory area), but also the para- and peri-striate areas around it (areas 18 and 19—the 'visuopsychic' cortex) receive projection fibres; and in cats the acoustic radiation has been shown to terminate not only in the *first acoustic area* (41), but also in several other regions in the temporal cortex.

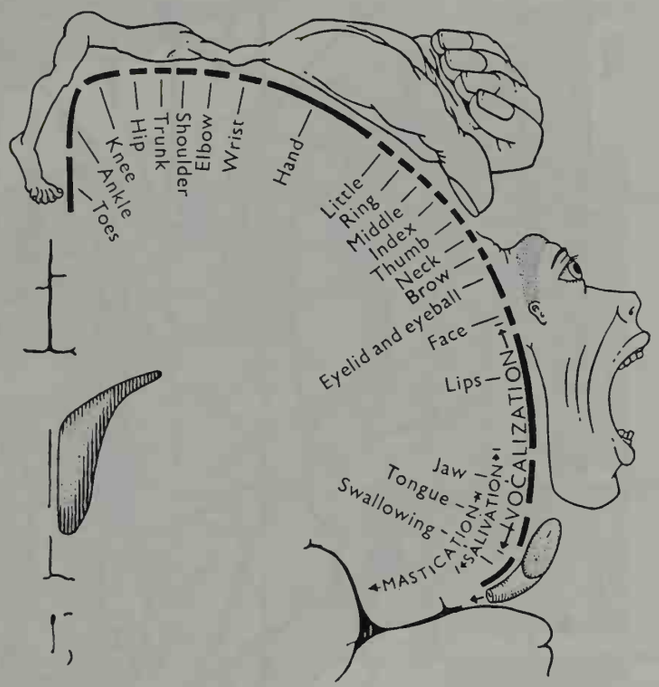
These modifications of the originally simple motor and sensory areas require a revision of terminology. One commonly used (Woolsey 1964), although not entirely satisfactory or as yet accurately adapted to the human cortex, divides the main sensorimotor area into a part in the precentral gyrus termed MsI, because it is the main or *first* predominantly *M*otor area but to a lesser extent also *s*ensory (7.129). Conversely, in the postcentral gyrus, SmI is the primary *S*ensory area, though also partly *m*otor. On the medial surface of the cerebrum is a further sensorimotor area, which, being largely motor, is called the *supplementary motor area*, MsII. Unfortunately, MsII is sometimes known as the *third* somatomotor area, because there is a second sensorimotor area, SmII (7.129), inferior to SmI. It would, of course, have been easier to regard MsII as the second somatomotor area and SmII the third, as some authorities do, but this merely shifts the numerical confusion. Some authors surmount the difficulty by disregarding the useful abbreviations and speaking of first, second and third motor or sensory areas. This terminology is admittedly a little perplexing, but its shortcomings are merely incidental to the important fact that the frontoparietal sensorimotor region is a complex of areas, each with its own degree of somatotopic organization. It should, however, be emphasized that none of these 'areas' is exclusively motor or sensory, though one or the other quality always predominates. In the text which follows ambiguity has been avoided by the use of synonyms wherever necessary.

In the occipital lobe the striate, parastriate and peristriate regions of the cortex (areas 17, 18 and 19) are likewise termed the *first*, *second* and *third visual areas*, or visual areas I, II and III.

A more complex array of terms applied in particular to the feline cerebrum (Rose and Woolsey 1958) is current to describe the *four* temporal areas considered to receive auditory projection fibres in cats. These are the *first acoustic area* (AI)—the auditory area of usual description—the *second acoustic area* (AII), and the *anterior* and *posterior ectosylvian areas* (Ea and Ep). The accessory acoustic areas can only be indicated in a tentative manner in the human cortex (7.138), partly because the acoustic parts of the temporal lobe are entirely superficial in the cat, whereas they are partly folded into the inferior lip of the lateral sulcus in mankind. All the sensory areas named above not only receive projection

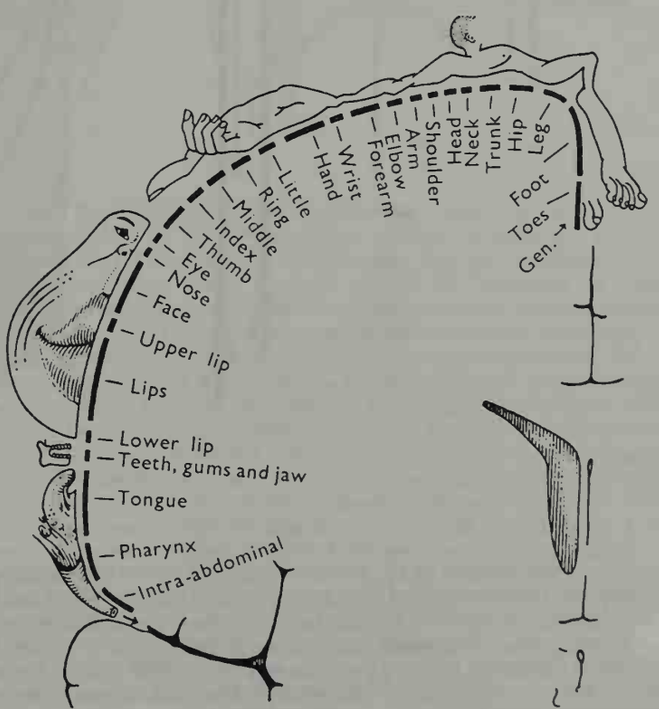
fibres from particular nuclei of the thalamic complex (though this is not completely established with respect to the ectosylvian acoustic areas), they also project back to the same regions, and perhaps in some instances to other nuclei at lower levels in the central nervous system—connexions which in each modality are probably concerned with inhibitory and sometimes facilitatory effects in their own sensory pathway. It is this afferent-efferent character of most, and probably all, the sensorimotor areas which makes the concept of distinguishable motor and sensory parts of the cortex anatomically invalid and functionally misleading.

It is clear from the above remarks that much less of the cerebral cortex remains to be dubbed as 'associational', in the vague but well-established meaning of the term. Nevertheless, large regions in all the lobes of the cerebrum are not accounted for by the sensorimotor areas. In regard to the human brain, much clinical evidence strongly suggests that such so-called 'silent' areas are indeed concerned in the further elaboration and interpretation of sensory information, and in the combination of its different modalities. Much less is known of the connexions of these parts of the cortex, whether by association or commissural fibres. For these reasons, less can be said of these areas than the sensorimotor domains of the cortex. Nevertheless, ablation experiments coupled with tracing of degenerating axons and with observation of disturbed behaviour, and similar deductions in human patients affected by damage, disease or surgical intervention, are beginning to provide more coherent concepts of the activities of the association areas, as will become apparent below.



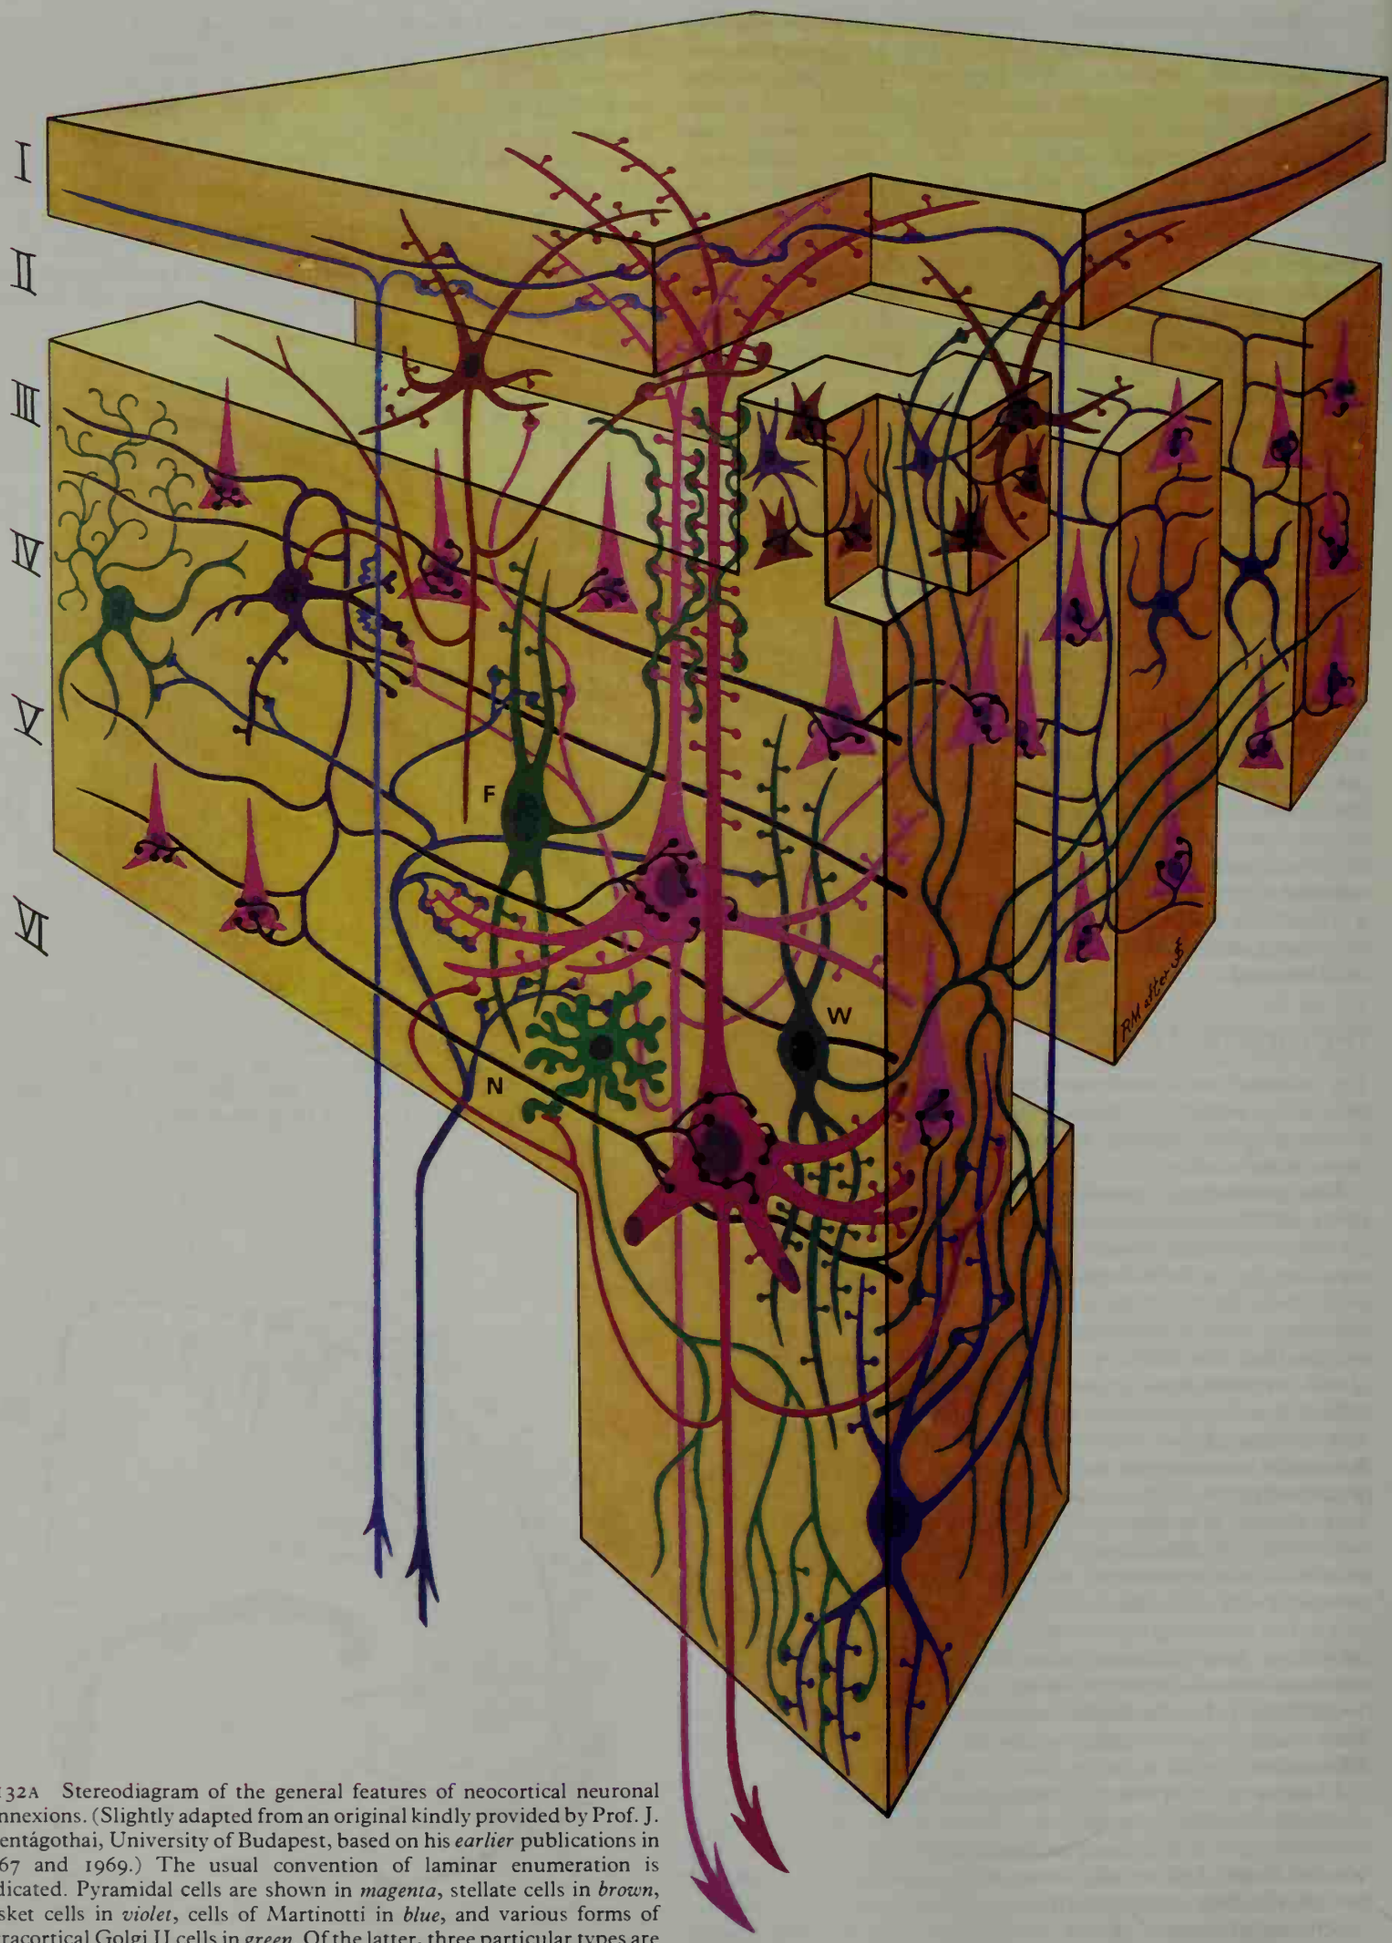
Though it might be regarded as functionally appropriate to consider first the predominantly sensory areas of the cortex and then those which are mainly motor, the widespread involvement of many parts of the cortex in even the simplest of activities and the sensorimotor nature of the areas concerned render any such considerations of priority almost meaningless. The main areas will therefore be described on the basis of the lobes in which they are located, and in the arbitrary order—frontal, parietal, occipital and temporal.

THE FRONTAL LOBE



The cortex of the frontal lobe may be divided for convenience into two main regions, *precentral* and the unfortunately named *prefrontal*. The former is largely sensorimotor, the latter 'association' cortex.

The precentral area includes the whole of the precentral gyrus and the posterior (caudal) parts of the superior, middle and inferior frontal gyri (Brodmann areas 4 and 6). The whole of this region (7.130) is characterized by the almost complete absence of the granular layers. Intracortical fibres are very numerous and the plexiform layer is particularly densely packed. The precentral area has been divided into posterior and anterior parts, *motor* (area 4) and *premotor* (area 6), but the distinction between these areas differs, according to whether cytoarchitectural or physiological data are applied. As comparison of illustrations 7.125 and 7.130A shows, the boundary between areas 4 and 6 descends through the precentral gyrus, whereas the entire gyrus is regarded as the *motor area*. Hence it is less confusing to disregard the Brodmann numeration of areas, or to use it as a merely approximate indication of the situation of areas. Thus, the premotor area occupies parts of the three frontal gyri, corresponding largely to area 6, but including parts of areas 8, 44 and 45 (7.130A). For the present, it is simpler and more direct to designate the whole precentral area as the *first* or leading **somatomotor area** (MsI), remembering that functional variations occur within it and that these may to some extent coincide with cytoarchitectonic differences.



A feature of the whole precentral area (MsI) is the prominence of pyramidal nerve cells of all sizes. The largest of these, the *giant pyramidal cells of Betz*, vary in height from 30 to 120 μm and in breadth from 15 to 70 μm, being most numerous in the medial part of the first somatomotor area, where it extends over the superomedial border of the hemisphere into the paracentral lobule (7.130B). They become progressively less frequent as the precentral gyrus is followed downwards towards the lateral fissure. They also extend less and less forwards in the gyrus in the same direction, following the boundary of area 4, to which they are largely limited, being absent from the premotor or anterior part of the first somatomotor area. In view of the mode of somatotopical arrangement now to be described in this region, it is tempting to suppose that the size of the larger pyramidal cells is associated with the length of their axons. The number of giant pyramidal cells in the human motor cortex has been estimated as between 25,000 and 30,000, (Campbell 1905; Lassek 1940), a figure which conflicts with the million or so fibres in the medullary pyramid (Lassek and Rasmussen 1939; Lassek 1942). It is clear that the huge majority of corticospinal and probably

7.132A Stereodiagram of the general features of neocortical neuronal connexions. (Slightly adapted from an original kindly provided by Prof. J. Szentágothai, University of Budapest, based on his *earlier* publications in 1967 and 1969.) The usual convention of laminar enumeration is indicated. Pyramidal cells are shown in *magenta*, stellate cells in *brown*, basket cells in *violet*, cells of Martinotti in *blue*, and various forms of intracortical Golgi II cells in *green*. Of the latter, three particular types are identified—fusiform (F), neurogliaform (N), and 'wide-field' (W). The connexions indicated were in general considered fairly well established, but they were, of course, subject to revision and extension, *see* 7.132B.

corticobulbar fibres are derived from smaller pyramidal cells. As is now known, many such fibres do not originate in area 4 at all, and it is interesting to note here that ablation of this area in monkeys reduces the fibres in the pyramid by a mere 25 per cent (Lassek 1942). Obviously the majority of 'pyramidal' fibres have other origins, as will be detailed below.

The recognition that *contralateral movements*, simple in type, can be elicited in different parts of the body by electrical stimulation of separate loci in the region of the central sulcus dates from the pioneer study of Fritsch and Hitzig (1870) in dogs. This discovery has been confirmed in innumerable subsequent studies in primates (e.g. Leyton and Sherrington 1917) including man (Ferrier 1874; Penfield and Rasmussen 1950), and it has become a tenet of neurology that the area involved is intimately concerned in the mediation of voluntary movements. The order of loci, starting from the paracentral lobule, is associated with the lower limb, the trunk (in the upper part of the precentral gyrus), the upper limb, neck, and head (7.131A). Much greater detail of this bodily 'representation' has accumulated, of course, and it has been established that the amount of cortex mediating movement in any particular region of the body is proportional *not* to the bulk of muscle involved but to the skill with which it is customarily used. All these details can be better appreciated by consulting 7.131A. It is perhaps more important to emphasize that even in the earliest studies of the excitability of the 'motor cortex', it was recognized that movements could be elicited from the postcentral gyrus, as well as from the precentral, and that the same movement could be excited in the same experimental animal's brain from different loci at different times. More careful control of the parameters of stimulation in later investigations has confirmed this apparent 'plasticity' (Liddell and Phillips 1950) which is, of course, difficult to represent in textbook illustrations. This and other factors have obscured to some extent these early findings, and the polemics associated with the great volume of reports on cerebral motor function, especially regarding discrepancies between clinical observations and experimental findings, were only useful insofar as they refocused attention on facts rather than theories (Bucy 1944).

As a result of much painstaking work it is well established that while the whole first somatomotor cortex (MsI—areas 4 *and* 6) is a source of corticospinal fibres, it is not the only one. Both in monkeys (Levin and Bradford 1938) and man (Kuypers 1958) the first somatosensory area (SmI—areas 3, 1 and 2) in the parietal lobe is also a source of corticospinal fibres, and there is some evidence that the second somatosensory area (SmII, approximately equal to areas 40 and 43—*see* p. 1015), below the first area and just above the lateral fissure (posterior limb), also contributes 'pyramidal' fibres. Smaller contributions from the occipital and temporal lobes have also been described in the cat (Walberg and Brodal 1953). Physiological evidence is largely in accord with these anatomical findings. The fibres descending from this extensive origin vary much in calibre. In the human pyramid 90 per cent were estimated to be 1–4 μm in diameter, while only about 2 per cent were 11–22 μm, a fraction corresponding closely with the number of giant pyramidal cells (Lassek 1942). Up to 94 per cent of the fibres are myelinated in man (De Meyer 1959).

The primary, first somatomotor area or MsI receives fibres from the cerebellum, which relay in the nucleus ventralis lateralis of the thalamus (p. 958), and these are distributed particularly to its anterior region (area 6), and to the prefrontal area (area 8). It also receives afferents concerned in other *sensory* modalities, probably via the thalamus also, but in addition from the hypothalamus and from other parts of the cortex. Physiological studies suggest that the corticospinal neurons are influenced not only by somatosensory impulses but also by visual, acoustic and 'nonspecific' thalamic afferents (p. 960). The interactions of all these influences on the pyramidal neurons inevitably demands a most intricate deployment of axons, dendrites and their synapses in the cortex. Illustration 7.132A was an earlier tentative epitomization of the kind of structure involved, provided by Professor J. Szentágothai. It is basically *columnar* in arrangement as in other parts of the cerebral cortex, the pyramidal neurons being extended vertically through the cortex and making abundant vertical associations with afferents and also horizontal connexions with intracortical interneurons (see also p. 1019). This concept tallies to some extent with recent studies of individual motor neurons by microelectrode techniques in the monkey (Landgren *et al.* 1962) and cat (Asanuma and Sakata 1967). These indicate that some motor neurons at least, though excitable from a considerable area, can be most easily stimulated within a cylindrical section of cortex about 1 mm in diameter. Illustration 7.132B is a more recent and refined summary of the '*module-concept*' in cerebral cortex architecture (Szentágothai 1975). In it: 'An attempt is made to bring earlier circuit models of *primary sensory* cortical areas into better line with recent observations on (1) the distribution of excitatory feedback connexions in cortical tissue volume, (2) putative inhibitory

7.132B A stereoscopic view of the elementary neuron circuit in sensory cortical areas. The horizontal planes are entirely arbitrary and are included to aid stereoscopic visualization; they are unrelated to the cortical lamination (arabic numerals on the left, indicating the 'non-absolute' character of the lamination in such a diagram). Specific sensory afferents (heavy black vertical lines on the right) terminate (separately) on the spiny stellate neurons (S1) and the so-called star pyramids (S2) of upper lamina IV, and in lower lamina IV on another type of spiny stellate neurons (S3) as well as on neurogliaform non-spiny stellate neurons (NS). Ascending relay of sensory afferent impulses is twofold: (1) within *narrow* cylindrical spaces (indicated with dashed outlines) by horsetail-shaped axon arborizations of S1 and S2 type neurons and primarily to selected individual (or small groups of) pyramidal cells, and (2) within *wider* cylindrical spaces (heavier dashed outline) from ascending S3 type neurons, probably mainly to basal dendrites of a much larger group of pyramidal cells. Descending relay is more widely and more indiscriminately distributed by descending branches of the spiny stellate neurons and star pyramidal neurons, and occurs in narrow columns by the vertically orientated axonal lacework of neurogliaform non-spiny stellate neurons (NS). The vertical plane on the left shows the strictly orientated axonal arborization of a large basket cell; the vertical plane on the right, orientated at right angles to the basket cell plane, shows a large stellate neuron with vertically orientated dendrites and part of its extended axonal arborization which is strictly confined to this plane. (From Professor Janos Szentágothai and *Brain Research* (1975), by kind permission.)

7.133 Superolateral surface of left cerebral hemisphere showing the frontal motor eye field, corresponding to parts of Brodmann areas 6, 8 and 9 (compare with 7.125). The perimeter of this area is delineated by an interrupted line to indicate uncertainty as to its precise extent.

interneurons and the distribution of inhibition in well defined space modules, and (3) the direct (monosynaptic) cortical target cells of the specific sensory afferents, and the modes of relay to secondary neurons. Even though the concept of cortical circuitry on larger "integrative units" containing smaller modules (or fields) of specific (excitatory and inhibitory) neuronal actions, proposed in 1967 and 1969, had gross deficiencies in the light of newly emerging data, the basic idea of how to look at the functional organization of the cortical neuron network may still be useful as a conceptual framework for the functional interpretation of structural data.'

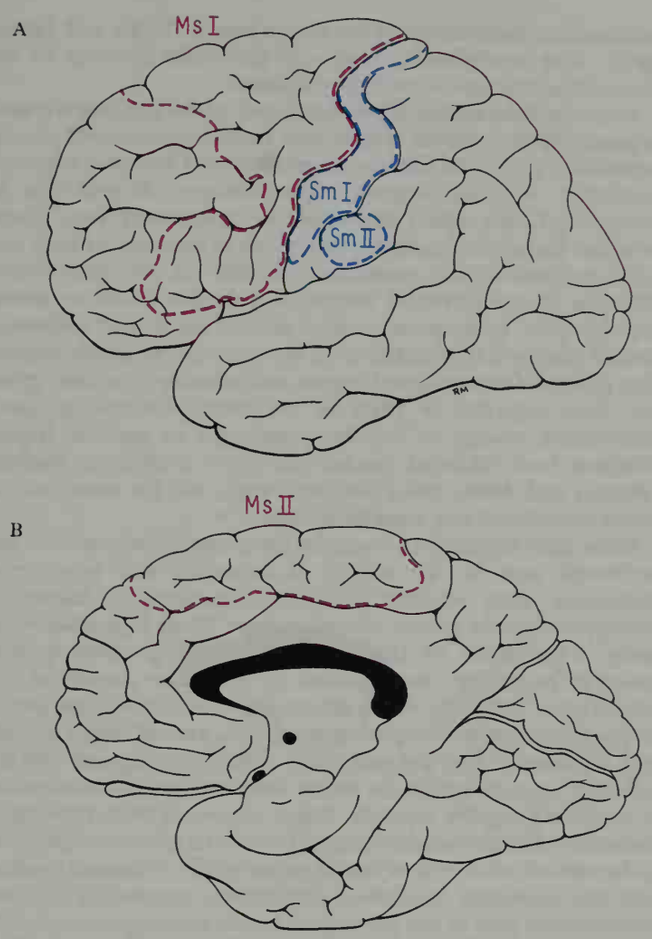
However the so-called *plasticitity* of the 'motor' cortex may be explained, the anatomical evidence favours a fixed and specific relation between the pyramidal cells and the effectors which they influence. At all levels of the corticospinal pathway a highly specific somatotopical arrangement has been demonstrated. In this connexion it should be emphasized that stimulation of cortical areas is an artificial method, which does not distinguish between direct excitation of pyramidal cells, or even their axons, and of the innumerable intracortical elements which interconnect with them. It is all the more interesting to note that studies employing microelectrode techniques are nevertheless beginning to point in the same direction.

Before dealing with certain specific regions of the somatomotor cortex, it is necessary to point out that stimulation of the cortex in experiment never produces elaborate coordinated movements, but only simple combined activities between synergists and antagonists. The movements elicited bear no relation to the particular skills or motor experience of the individual. This is to be expected, because such stimulation leaves out of account not only other efferent pathways but also the wide range of afferents from the cerebellum, corpus striatum, thalamus, hyothalamus, and other cortical areas mentioned above.

Extending forwards into the middle frontal gyrus from the part of the precentral gyrus concerned with facial movements is the **frontal eye field**; it occupies a considerable part of the Brodmann area 8, invading area 6 behind and probably area 9 in front (7.133). Stimulation, which is most effective in area 8, elicits conjugate or binocular movements of the eyes, especially towards the contralateral side, but perhaps also in other directions. Movements of the head and pupillary dilation may also be elicited from the frontal eye field. For a review of work on these responses *see* Crosby (1953). Little is known with certainty concerning the efferent projection from this area; degenerating fibres have been traced from it in monkeys as far as the midbrain, but their ultimate destination is not established. None have been traced with certainty to the nuclei of the motor nerves of the extrinsic ocular muscles, and it has been hypothecated that they influence these through intermediary cell masses or 'centres' in the brainstem. There is, however, no doubt that voluntary and reflex eye movements are mediated by the frontal eye field and its projection. Like the rest of the first somatomotor area, this region of it also receives association fibres, probably from the occipital cortex, and in addition thalamic afferents from the juxtalaminar part of the dorsomedial nucleus (Scollo-Lavizzari and Akert 1963) to which the central zone of the frontal eye field (area 8) reciprocally projects (Rinvik 1968). A **second frontal eye field**, roughly anterior to the above has been demonstrated in monkeys, and hypothecated in man (Crosby *et al.* 1952).

The motor speech area of Broca is an extension of the primary somatomotor cortex into the inferior frontal gyrus, coinciding approximately with area 44 and part of 45 (7.134). Little reliable knowledge is available concerning its anatomical connexions, although subjacent to it are large concentrations of association fibres effecting interconnexions between many other parts of the cortex. Most information as to its functional significance is derived from the results of ablation or stimulation in experimental animals and man (Penfield and Roberts 1959). Ablation may abolish vocalization and usually produces a motor or expressive *aphasia*, or paralysis *of speech* in man, if carried out in the left or '*dominant*' hemisphere. In some individuals the leading speech area is, however, on the right, and it is considered that in some there is no such dominance. (See also p. 1024.)

It is to be emphasized that damage to the motor speech area does not entail *paralysis* of the *musculature* involved, all of which is in any case also amenable to stimulation of appropriate parts of the primary motor area in the precentral gyrus. Stimulation of the area may lead to a variety of effects, according to the parameters employed; speech in conscious patients may be actually inhibited, or simple acts of vocalization, such as the utterance of a vowel sound, may ensue. The response in experimental animals consists of simple movements of the face, lips and larynx and perhaps vocalization. Stimulation of the area in macaques has been shown to produce contractions in individual laryngeal muscles (cricothyroid and thyroarytenoid) and in combinations of them (Hast *et al.* 1974). In man also it is to be emphasized that the responses are, as in the case of the somatomotor cortex, always simple, In stimulation studies of the human cortex very similar effects can be elicited from two other areas, one in the frontal lobe, the supplementary motor area (MsII), and another curving round the posterior extremity of the lateral sulcus and occupying a large region in the parietal and, more extensively, temporal lobes. This latter area is sometimes known as the **second motor speech area of Wernicke.** All three regions, which may be named the *anterior*, *posterior* and *superior motor speech areas*, develop in the dominant hemisphere in each individual; and while the corresponding parts of the cortex in the opposite hemisphere have in some human patients apparently taken over the functions of a damaged area in the dominant hemisphere, they are perhaps in ordinary circumstances uncommitted in the activities of speech.



7.134 The superolateral surface of the left cerebral hemisphere showing the motor speech areas of Broca (44, 45) and Wernicke. The latter is variously depicted by different authorities, and is tentatively indicated by the large parieto-temporal area enclosed in an interrupted outline, which itself includes areas 39 and 40. Areas 22 and 37 are considered by some to be respectively auditory and visuo-auditory areas associated with speech and language.

Illustration 7.134 shows the positions of these areas, but it must be said at once that other and often far more complex 'maps' of the cortical areas reputed to be concerned in speech have been propounded. Language, in all its permutations of speaking, listening, reading and writing, is obviously a most intricate activity, and it would be surprising if this, the major form of human communication and perhaps the main distinction of mankind, did not in fact involve widespread and voluminous parts of the brain and central nervous system. In view of the lack of information concerning the connexions of the various cortical areas believed to mediate these activities, it is hardly to be expected that other, subcortical mechanisms will have yet been implicated, despite the intensely active speculation prompted by study of the various forms of aphasia; but the pulvinar of the thalamus has fairly recently been associated with the speech 'centres' (Ojemann *et al.* 1968). However, the inconclusive nature of the evidence in this highly interesting field must limit further pursuit of the subject here, and the reader should consult the excellent reviews available (Brain 1961; Penfield 1966; Millikan and Darley 1967). (See also p. 1024.)

The supplementary motor area (MsII) must now be briefly considered, before passing on to the remainder, the 'prefrontal' region of the frontal lobe. This is, like other projection areas, sensorimotor in nature, but being predominantly motor and in the frontal lobe it is most conveniently described here; its sensory activities, about which less is known, will be merely alluded to in connection with the somatosensory cortex. The situation of this supplementary motor area, on the medial surface of the hemisphere has already been stated (p. 988); it is anterior to, and probably confluent with, the medial extension of the first somatomotor area into the paracentral lobule which mediates leg and perineal movement. It is thus in the medial frontal gyrus in man (area 6 and probably in part area 8). Movements of the contralateral limbs can be elicited from the supplementary motor area in monkeys and in man (Penfield and Welch 1951), but higher thresholds obtain than in the primary somatomotor cortex, as in the case of other accessory areas, and the movements are sometimes ipsilateral or bilateral. A somatotopic pattern (7.129) has been established in monkeys (Woolsey *et al.* 1952), but has not as yet been demonstrated in man. Efferent fibres from this area have been traced into the spinal cord in cats (Nyberg-Hansen 1969), most of these ending contralaterally. There is also a *bilateral* projection to the thalamus, and to the gracile, cuneate and pontine nuclei, contrasting with the similar but unilateral projections from the primary somatomotor cortex. In accord with these variations the contributions of these two areas to the integration of movement are probably different, but the details are not yet sufficiently well defined to warrant discussion here (Travis 1955).

The second somatosensory area (SmII), being preponderantly sensory, will be considered in more detail with the primary sensory cortex in the parietal lobe. Since, however, it is also a *somatomotor area*, its less well-established motor characteristics are included here to complete the picture of the 'motor cortex'. Movements of most parts of the body can be elicited from it and the loci of stimulation show a somatotopic organization both in subhuman primates and in man (Adrian 1941). Its projection fibres have been followed as far as cervical spinal segments in monkeys (Brodal and Angaut 1967), and to the thalamus and dorsal column and pontine nuclei in cats, in which features it resembles the other somatomotor areas. Little can yet be added with regard to its significance in motor function.

The prefrontal area corresponds approximately to all parts of the frontal lobe which have not so far been particularized. It hence includes much of the three frontal gyri, the orbital gyri (orbitofrontal area), most of the medial frontal gyrus, and anterior half, approximately, of the cingulate gyrus, etc. It has been said that the great development of the frontal lobe in particular distinguishes the human from other brains. The so-called *silent areas* have long been regarded as a specially notable feature of the human cortex—at least, in their degree of expansion; and the prefrontal area is usually assigned to this category. If, however, silent or association areas are to be regarded as those parts of the cortex whose connexions are predominantly or exclusively

7.135A and B Superolateral (A) and medial (B) surfaces of the cerebral hemispheres showing the sensorimotor areas. See text for details and compare with 7.125, 130. These areas can only be applied tentatively to the human cortex, and they are hence delineated with interrupted outlines.

mediated by association fibres, the prefrontal region would not qualify. In addition to elaborate afferent and efferent interconnexions with areas of cortex in all lobes of the cerebrum, it also has abundant links with the *thalamus*, *corpus striatum* and *hypothalamus*, and it projects in addition to the *cerebellum* via the nuclei pontis and perhaps to certain *cranial motor nuclei*.

Through the *superior* and *inferior fronto-occipital fasciculi* the frontal lobe appears to be connected not only with the occipital but also the parietal and temporal lobes. *Commissural* connexions also link corresponding parts of the frontal lobes through the corpus callosum, and there is some evidence that frontal commissural fibres may pass to other lobes. These connexions are said to be largely afferent, but in fact little is known of them in reliable detail, though it is suggested that efferent commissural contralateral fibres may also link the frontal lobe to many other parts of the cortex.

Massive *anterior* and *frontal thalamic radiations*, principally derived from the nucleus medialis dorsalis (MD) of the medial nuclear group of the thalamus (p. 962) pass to the lateral (areas 9 and 10) and orbital regions of the frontal lobe, both of which in turn project back to the same parts of the thalamus. The anterior thalamic nuclei also contribute to these radiations establishing reciprocal connexions with the medial frontal and anterior cingulate cortex. These thalamic nuclei receive many afferents from the mamillary body and thus from the hippocampus (p. 957), which also connects directly with the anterior thalamus. Connexions of the anterior and medial thalamus with the hypothalamus (p. 962) therefore bring this, in addition, into afferent relation with the prefrontal cortex, from which corticohypothalamic projections have also been described. The *prefrontal corticopontine projection*, though less massive than that from the motor areas of the frontal lobe (4 and 6), is equally well established; both relay with considerable specificity in the

paramedian components of the nuclei pontis (Nyby and Jansen 1951). The orbitofrontal region in particular projects to the paramedian nucleus of the hypothalamus.

Even this brief survey of the connexions of the prefrontal region suggests highly complex interactions in both *somatic* and *visceral activities*. The orbital surface, or orbitofrontal area, has attracted particular attention among experimenters. Stimulation in monkeys (Kaada 1960) depresses the respiratory rate, blood pressure and gastric motility; inhibition of induced cortical and reflex movements and emotional reactions has also been noted. Ablation of orbitofrontal cortex in primates leads to motor hyperactivity, restlessness, loss of attentiveness; and somewhat similar results follow ablation of the anterior cingulate region. The posterior orbitofrontal cortex and anterior cingulate gyrus are often regarded as parts of the limbic system (p. 990). Behavioural studies of monkeys subjected to *anterior* frontal ablations have adduced similar but often conflicting findings (Warren and Akert 1964; Sanides 1964), but the sum total of firmly established fact remains slender.

Some light has been shed on the functional significance of the prefrontal area by the results of lobotomy and leucotomy, performed until recently on human patients in efforts to ameliorate certain mental disorders now treated pharmacologically. The effects of these operations, which were usually bilateral, resembled those caused by extensive disease of the frontal lobes. Abolition of the distressing aspect of illusions and of severe somatic pain were prominent effects, a result which accords with the concept that this part of the cortex is concerned with the 'affective tone' of sensations rather than with any discriminative or localizing aspects of them. Some observers have reported a diminution in intellectual capacity, but limitation of the operation to the orbitofrontal area or the cingulate gyrus is claimed to affect only the emotional balance of personality, suggesting that the superolateral part of the prefrontal area is more concerned with 'intellectual' processes (Lewin 1961). Patients with extensive frontal lobe damage, from whatever cause, almost always exhibit permanent and on the whole undesirable changes. Though perhaps more tractable and docile, they also show less initiative, untidiness, disregard for others and for general tenets of behaviour, and a marked lack of concentration, all of which can for the moment be summed up as a retrogression from the human condition—a somewhat vague statement but excusable and perhaps appropriate in our present dearth of precise information.

THE PARIETAL LOBE

Immediately posterior to the central sulcus, occupying most of the postcentral gyrus and also extending over on to the medial surface of the parietal cortex in the paracentral lobule, is the primary or *first somatosensory area* (SmI, areas 3, 1 and 2). Posterior to it is the large 'silent' area of the parietal lobe, taken up in part below by the second speech area (*vide infra*). Inferiorly, in the lowest part of the postcentral gyrus (and extending forwards a little into the precentral gyrus) is the *second somatosensory area* (SmII).

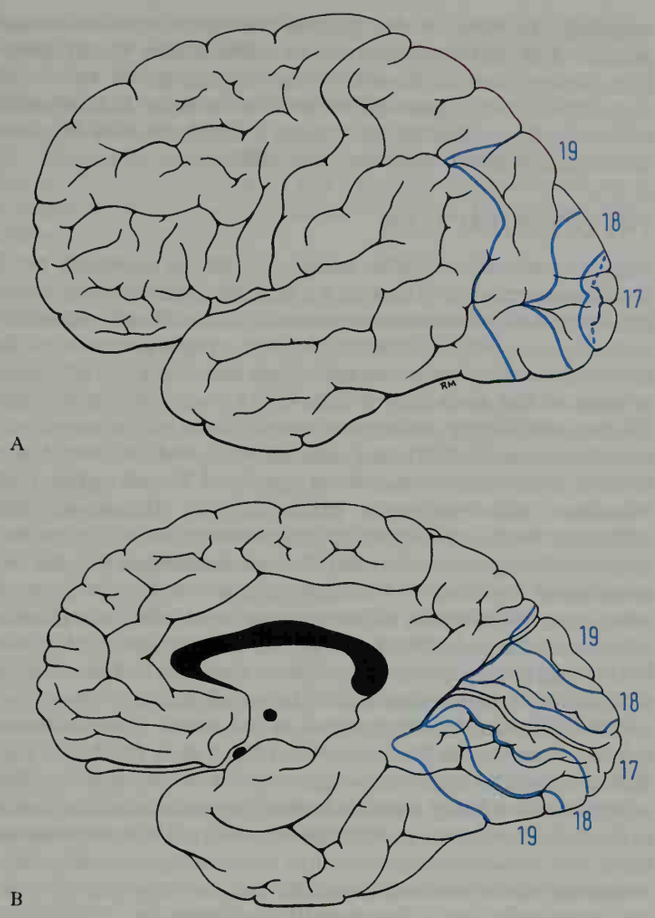
Anterior to its medial extension is the *third somatosensory area*, the supplementary 'motor' area (MsII). It is appropriate here to note that the region of cortex, centrally situated in the cerebral hemisphere, which forms the great arrival station for somatic afferents and similarly for the departure of somatic efferents, consists of *four separate*, though *juxtaposed sensorimotor areas*. Of these, two, the primary and supplementary motor areas are chiefly efferent projection cortex, MsI and II, while two are preponderantly recipients of afferent projection fibres—the primary and secondary somatosensory areas, SmI and II. As 7.129, 135A, B show, all these four areas evince a somatotopic pattern in cats and monkeys, and evidence that this is largely so in man has already been quoted (p. 1013). The motor aspects of all four areas have been dealt with above, and it remains to consider their involvement in sensory functions.

The first somatosensory area shows interesting cytoarchitectonic variations. Its anterior part (area 3), bordering the central sulcus and extending into its depths to meet the agranular cortex of area 4, is of the granular type but also contains numbers of scattered medium and small pyramidal cells; it is in many respects similar to the striate cortex, the outer band of Baillarger, for example, being broad but not so prominent as the visual stria. The posterior part of the postcentral gyrus (areas 1 and 2) differs particularly in its smaller content of less densely packed granular or stellate cells (for further details see p. 1002). The precise boundary, if such exists, between the pre- and post-central areas in the central sulcus has been a matter of dispute, and may be of some importance in the interpretation of experimental results (Rinvik 1968).

The projection from the *nuclei ventralis posterior lateralis* and *medialis of the thalamus* (VPL and VPM), to the primary somatosensory area is well attested, and it is through this radiation that a wide range of exteroceptive and proprioceptive modalities of sensation are mediated. Unit recording techniques and retrograde degeneration experiments have established that there is a highly specific pattern of localization between the cortex and the thalamus; and this is associated with a somatotopic form of organization in the postcentral gyrus like that in the adjoining first somatomotor area, including an apportioning of cortex in proportion to skill rather than size in the representation of bodily segments. This pattern has been studied in the human cortex by noting the type of sensation and the region to which it is referred when individual loci are stimulated in the exposed cortex at operations (Penfield and Jasper 1954). With carefully moderated stimulation very sharp localization can be established. By such means the localization of vesical, rectal and genital sensations to the lowest part of the medial region of the postcentral area has been established in man. The sensations aroused are for the majority of the body *contralateral*, but may sometimes be solely *ipsilateral* (oral region), or they may be *bilateral* (larynx, pharynx and perineum).

Experimental studies in animals have largely confirmed the localization demonstrated in the human somatosensory cortex. Responses to natural or artificial stimulation of peripheral receptors have also been shown to evoke potentials in the precentral area (Albe-Fessard and Liebeskind 1966) and by ablation of the somatosensory cortex it is established that there is a *direct* thalamic radiation to the 'motor' area (p. 1013), an elegant demonstration of the latter's sensorimotor nature. Degeneration studies (see, for example, Le Gros Clark and Powell 1953) have provided more refined data as to the specificity of the thalamocortical projection; the nucleus ventralis posterior lateralis exhibits a fairly discrete localizational pattern of connexion with areas 3, 1 and 2, suggesting a functional significance in the structural differences between them, as mentioned earlier in this section (p. 1015). Unit recording observations have confirmed this, revealing that area 3 is activated only by cutaneous stimuli, whereas area 2 is concerned with impulses from proprioceptors (Albe-Fessard and Liebeskind 1966). This implies a transverse deployment of modalities across the long axis of the precentral gyrus (Mountcastle and Powell 1959). To this is to be added a segmental or dermatomic projection to such transverse strips of cortex, as a further refinement of the somatotopic localization in this area (Powell and Mountcastle 1959). Morever, each modality-specific locus appears to be associated with a column of cells vertically arranged through the thickness of the cortex, like the columns described in the visual area (p. 1019). Evidence from anatomical studies in monkeys has demonstrated a cortico-cortical connexion from the first somatosensory area (Brodmann 3, 1, 2) to area 5 in the parietal lobe (Pandya and Kuypers 1969). This connexion has been analysed further (Pearson and Powell 1978); the connexion is isotopological, but reversed in the anteroposterior axis, so that area 3 projects to cells posterior to those receiving fibres from areas 1 and 2. There is some anatomical evidence of modality convergence in area 5, which accords with previous physiological investigations (Mountcastle *et al.* 1975), and provides a basis for the concept of 'association'.

The specificity of the somatosensory neurons concerned with joint receptors appears to be particularly marked, as in the thalamus. Some cortical units respond only to displacement in one direction, and these may continue to discharge even during a statically maintained position of the joint. Such arrangements, if



applicable to man, would provide the neuronal basis for the 'joint sense' hypothecated in much earlier studies (Stopford 1922). Fast adapting units activated by the bending of hairs and others adapting slowly to cutaneous deformation have also been identified. Similar studies suggest that afferents from receptors in striated muscle terminate in units sited in the somato*motor* cortex, and that impulses may reach them by pathways independent of the cerebellum, constituting the mediating basis, in part, for consciousness of stretch in muscles. These experimental findings imply a considerable difference in the sensory properties of the pre- and post-central parts of the main sensorimotor area. The two gyri are, however, linked by numerous short association fibres, conducting in both directions (Pandya and Kupyers 1969). As is so in most, if not all, the sensorimotor areas, primary or accessory, the first somatosensory area has abundant reciprocal connexions with the thalamus (p. 962), the corticothalamic projection comparing in its specificity of point-to-point linkage with the thalamocortical radiation (Rinvik 1968). In connexion with this specific and apparently unvarying nature, in the spatial sense, of the cerebral level of some modalities in their pathways, a recent study of the cortex in mice is particularly interesting (Woolsey and van der Loos 1970). Barrel-shaped architectonic groupings of nerve cells were detected in the somatosensory area (SmI) and in the part of this related to the head and muzzle. There is some evidence that these 'barrels' may be units equated with the individual vibrissae of the animal's muzzle (see also Waite 1977). Both this and a study of the spatial distribution of synapses in the same cortical area in neonatal dogs (Molliver and van der Loos 1970), though of course not immediately applicable to the human cortex, illustrate the intricate and quantitative kind of analysis of the cortex being made in current investigations.

The commissural connexions of the primary somatosensory areas of the two sides are restricted to representation of the face, trunk, and proximal parts of the limbs (Pandya and Vignolo 1969; Jones and Powell 1969). These commissural projections, in the monkey, terminate in bands (Jones *et al.* 1975; Shanks *et al.* 1975), as in the visual and motor cortical areas. Shanks *et al.* (1978) have shown that within these bands short intrinsic connexions propagate repeated representations of bodily regions, comparable to the retinotopic repetitions in the visual cortex (p. 1018).

Much less is known of the **second** and **third somatosensory areas** (SmII and MsII). The former is in the superior lip of the posterior limb of the lateral fissure, adjoining the insula in monkeys (7.129), and it occupies a similar position in man. Evoked potentials indicate a somatotopic organization in SmII, with the face area most anterior and the leg at the posterior or caudal end of the area. Single units associated with tactile and vibration senses have been identified in the area, and stimulation of Pacinian corpuscles evokes higher potentials than in the primary somatosensory area (McIntyre *et al.* 1967). The second somatosensory area projects to the thalamus, but its connexions and their reciprocal nature have not yet been studied in detail. It also projects to the dorsal column nuclei, like the other somatosensory areas. The details of such descending projections in monkeys have been studied by many workers (*see* Weisberg and Rustioni 1977), and are of particular interest as an inhibitory modulating influence upon the dorsal column nuclei.

The third somatosensory area, which is the equivalent of the supplementary motor area, is in its sensory functions as yet little understood. It is known to receive thalamocortical fibres and projection fibres leave it, some of which are not motor, but details of these connexions are yet to be worked out. Stimulation in conscious human patients is said to evoke generalized sensations referred to the head and abdominal region, but no exact somatotopic pattern can be ascribed to it, as regards its sensory activities.

The second speech area of Wernicke (7.134), because it is partly in the parietal lobe, must be mentioned here. It occupies a small parietal area, extending more extensively into the temporal lobe (p. 1020). The rest of the parietal lobe, between the main somatosensory and visual areas, is 'silent' cortex. This region corresponds more or less to the inferior parietal gyrus, 'areas' 39 and 40 (Critchley 1953). The connexions of this region, as far as they are known, are indeed in part association and commissural,

7.136A and B Superolateral (A) and medial (B) surfaces of the cerebral hemispheres showing the visual areas in the occipital lobe. The striate (17), parastriate (18) and peristriate (19) areas correspond approximately to the Brodmann areas as indicated, and also to visual areas I, II and III. See text for details.

but little clear detail of them has been established; but there is also a reciprocal interconnexion with all the parts of the lateral nuclear group of the thalamus (p. 891). Corticospinal and corticotegmental projections have also been suggested, the latter influencing motor nuclei in the brainstem, and more particularly those of the nerves to the eye muscles, either directly or through intermediary nerve cells. These latter connexions are specially interesting in conjunction with description of a supplementary motor area in areas 5 and 7 in the macaque monkey (Crosby *et al.* 1959). The strategic position of the parietal association area close to all the cortical regions concerned with general and special modalities of sensation, coupled with its multifarious connexions, is in itself highly suggestive of complex and integrated activities. Most of the evidence in this regard is derived in man from clinical observations of behavioural defects and distortions consequent upon pathological lesions or surgical ablations, and upon extrapolation of similar results in primates submitted to deliberate experimental damage. The reports available and their results are confusingly numerous and varied. Muscular debility, slowing of reflex activity, disorders of speech (aphasias), loss of awareness of bodily parts and of spatial relation to the environment, and other forms of *agnosia* (a state of absent or defective recognition of the significance of objects and situations), have all been observed. A particular form of agnosia, which has long been associated with parietal lobe damage, is *astereognosis*, a failure to interpret the three-dimensional nature of objects when examined by the hand without the help of vision. *Interpretation* has, indeed, been strongly advocated as the prime parietal activity in man (Penfield 1966); in connexion particularly with language on the dominant (left) side of the cerebrum and in a more generalized sense on the other side. The parietal lobe is thus perhaps to be regarded as a region of high activity in learning processes, and of uniquely high development in this respect in

mankind. In view of the general nature of the evolutionary process it is perhaps unwise and unnecessary to attribute a qualitatively unique nature to the operations of the human parietal area, but its great importance in our behaviour, especially in discrimination and interpretation, is amply attested by clinical evidence and animal experimentation. (See also p. 1024.)

THE OCCIPITAL LOBE

Almost the whole of the occipital lobe is occupied by the Brodmann areas 17, 18 and 19 (7.136A, B). Although only area 17, the **striate** or **visuosensory cortex**, was originally regarded as containing the terminations of the optic radiation, there is now firm evidence that the lateral geniculate body (p. 977) radiates also to areas 18 and 19 in the cat (Glickstein *et al.* 1967) and monkey (Wilson and Cragg 1967), and that in these, as in area 17, the spatial arrangement of optic radiation terminals is related to the retinae in an orderly manner (Garey and Powell 1967; 1968). Moreover, all three areas project to the thalamus (lateral geniculate body or pulvinar) or brainstem motor nuclei, or both. Short and long association and commissural fibres link the *three visual areas* together, and to their contralateral equivalents and other parts of the cortex in both hemispheres. (For an exhaustive critique of this and other aspects of visual neuroanatomy consult Polyak 1957.) Occipitopontine fibres have been described, but their status in man is uncertain. The actual extent of area 17 is, of course, identified by the presence of the visual stria of Gennari, but the demarcation between areas 18 and 19 is much less easily definable by the usual techniques of cytoarchitectonics. Braak (1977) has introduced a method which depends upon the staining of lipofuscin granules, and this shows a sharp distinction between these two areas and, furthermore, permits the identification of structural subdivisions within them. It is, however, not clear how far such subdivision is functionally significant.

The striate cortex (area 17), or **first visual area**, occupies the upper and lower lips and the depths of the posterior part of the calcarine sulcus (7.136), extending into much of the cuneus and lingual gyrus. As a cytoarchitectonic area it can easily be defined, both macro- and micro-scopically, by the visual stria and by the thinness of the cortex. Posteriorly the area is limited by the lunate sulcus (and by the polar sulci above and below this), and it thus does not extend beyond the occipital pole in man, though it reaches the lateral aspect of the lobe in other primates. Anteriorly the striate area is bounded by the medial parieto-occipital sulcus, but its lower part, below the calcarine sulcus, may extend somewhat further. The stria becomes less obvious as it is followed posteriorly towards the occipital pole, and this change can be correlated with the retinotopical organization of the area (*vide infra*), its prominence being inversely related to proximity to the central retinal area.

Histologically the area is of the *granular* type, or *koniocortex* (p. 1009), in which densely packed stellate cells greatly outnumber the few pyramidal cells present. For full details the reader should consult Polyak (1957); Crosby (1960); Colonnier (1964, 1967, 1968, 1974); only salient features will be mentioned here. (*a*) The deeper stratum of the pyramidal layer (III) contains *large stellate cells*, which almost replace the large pyramidal cells present here in other types of cortex. (*b*) The outer band of Baillarger in lamina IV is accentuated as the *visual stria*, consisting of large numbers of terminations of optic radiation and probably association fibres. (*c*) The ganglionic layer (V), which commonly consists largely of pyramidal cells, including the largest, here contains a few large, scattered *solitary cells* (*of Meynert*); these are of a modified pyramidal shape, about 30 μm in diameter, and distributed in a single row. Their dendrites extend widely through the cortex and their axons form the projection element of the visual cortex, passing through the optic radiation to reach the superior colliculus and possibly the motor nuclei of the extraocular muscles. A study of Meynert's cells in the striate cortex (area 17) of the rhesus monkey (Chan-Palay *et al.* 1974) showed the potential of these neurons for widespread and intricate connexions. It was estimated that each cell's dendrites may display 36,000 spines, and that the apical dendritic field in lamina I is about 400 μm for each cell, being 800 μm for the basal dendrites in lamina V. The density of distribution of Meynert cells varies in different parts of the striate cortex, reaching its greatest (8000/cm^2) in the macular region. (*d*) The external and internal granular layers (II and IV)—especially the latter—contain larger numbers and more densely packed small stellate cells than any other part of the cerebral cortex.

The laminar pattern described above is based upon Brodmann's; other patterns, particularly that of Cajal, have considerable vogue, but a recent review by Billings-Gagliardi *et al.* (1974) advocates a return to the Brodmann scheme.

Although the striate cortex contains only about 3 per cent of the cerebral surface area, approximately one-tenth of all the cortical neurons are said to be concentrated in it. In their cytoarchitectural details, areas 18 and 19 approximate respectively to the polar and parietal types of cortex (p. 1009), in which stellate cells are less prominent and pyramidal cells more so. Myelin and axonal stains have been used to investigate the fibre structure of the visual area, especially the striate cortex (Sholl 1955; Colonnier 1964). In general this resembles arrangements in other cortical areas (p. 1009), but dendritic fields in their quantitative aspects have been studied more intensively in this part of the cortex than perhaps any other excepting the postcentral gyrus. The stimulus to this has been in part the physiological demonstration of a species of columnar organization in the somatosensory area and thereafter in the striate cortex (*vide infra*). So far the physiological techniques in use are providing more illuminating evidence.

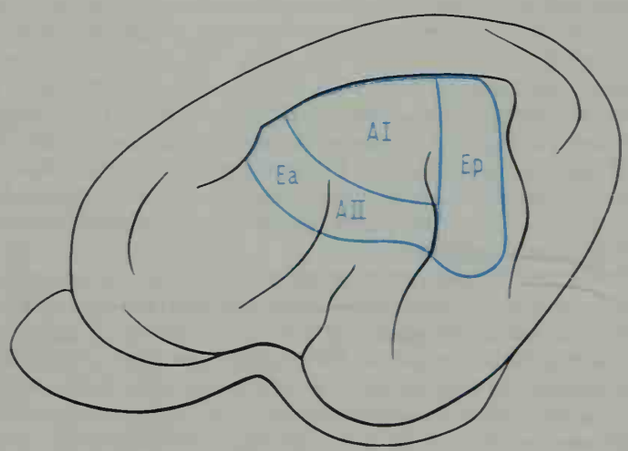
The status of area 17 as the primary visual cortical area has long been established, both by electrical stimulation in man and by its connexions with the lateral geniculate body, and through this with the retinae (p. 977). The *retinotopical organization* which exists in the lower parts of the visual pathway has also been shown to be carried through to the cortical level. Each striate area receives impulses from the two ipsilateral half retinae, representing the *contralateral* half of the binocular visual field. As has already been described (p. 977), the patterns of impulses from the retinae do not undergo a simple relay in the geniculate body, where some degree of processing has been shown to occur, excluding any interaction of a biretinal nature (for a more detailed discussion *see* p. 981). These activities have been studied even more intensively in the striate cortex, especially by single unit recording technique. The *geniculate radiation* spreads out as it swerves through the white substance of the occipital lobe, its fibres terminating in a strict point-to-point deployment in the striate area, such that the peripheral parts of the retinae activate the most anterior parts of the area, the macular regions activating a relatively large part of the striate cortex adjoining its posterior extremity. Moreover, the superior and inferior retinal quadrants are thus connected with corresponding divisions of the striate area. In the classical studies of the effects of injuries of the occipital lobe in warfare, similar retinotopic results were obtained. (Holmes and Lister 1916; Teuber *et al.* 1960).

These experimental findings, established in a wide range of mammals and especially primates (*see* p. 977 for references), have been corroborated by stimulation of the human cortex (Penfield and Jasper 1954). The visual impressions thus elicited are simple, such as flashes of light, but they are referred to a specific part of the visual field according to the location of the cortical stimulus. Eye movements are also produced by such stimulation. When similar stimuli are applied to areas 18 and 19 more complex images are reported by the patient, indicating that these regions are concerned in further elaboration of the visual information reaching area 17.

In recent years most interesting results have been obtained by recording the response of single nerve cells to various forms of retinal stimulus; and while the earlier studies have been chiefly pursued in cats (Hubel and Wiesel 1962, 1963, 1965, 1971; Wiesel and Hubel 1963*a* and *b*), there was little reason to doubt that in principle they were applicable to the human striate cortex, especially since the cytoarchitectonic areas involved in the cat could be equated with those in primates (Otsuka and Hassler 1962), in which unit cortical recording has also been studied more recently (Hubel and Wiesel 1977). Briefly, each unit from which recordings are made corresponds to a definite receptive field in the retina, and can presumably be excited only from that area. Units

responding to a range of modes of stimulation have been identified; some react to white light, especially in the form of stripes or edges between light and dark. This contrasts with the more or less circular receptive fields of excitation demonstrated in the lateral geniculate body. Excitatory units surrounded by inhibitory zones have also been described, but these also evince a strip-like character as well as the circular receptive areas recorded in the geniculate body. Many units are sensitive to the orientation of the stimulus, responding only to vertical, horizontal or intermediate forms of linear stimulation of the retina. More complex units occur, for example, some responding to the particular direction of a moving stimulus. It is possible that these represent the integration of information from the simpler units mentioned above. Further studies by Hubel and Wiesel (1968) have clearly demonstrated the existence of striate cortical neurons, in cats and especially monkeys, which respond preferentially to stimuli from the right or left eye, a phenomenon somewhat misleadingly termed *ocular dominance*. Vertical exploration of the cortex by unit-recording techniques has also shown that these neurons are deployed in vertical columns, extending through all layers of striate cortex, as described below. Certain of these columns may be binocular in response in cats, but in monkeys it is doubtful whether such columns occur, all being right or left orientated. A further evidence of perhaps a greater degree of development of such 'dominance' in the simian cortex resides in the greater facility with which they can be discovered and explored. These workers consider that the columns are of greater diameter in monkeys. It has been possible to refer the majority of the neurons involved to particular laminae of the striate cortex and to equate this distribution with that of termination of the lateral geniculate projection. The full significance of these findings is not yet entirely clear, except that they confirm the segregation of 'information' from each retina to be maintained at least as far as the striate cortex. There is, however, no doubt of the validity of these observations, which have been confirmed by other techniques, such as autoradiographic identification of labelled substances (for example 3H-proline) injected directly into the feline eyeball (LeVay *et al.* 1978). By transneuronal transport in the lateral geniculate body such substances reach the striate cortex, and particularly lamina IV, where they correspond in distribution most clearly with the columnar arrangement identified by other methods. Studies in both cats (LeVay *et al.* 1978) and monkeys (Hubel *et al.* 1977) suggest that these neuronal arrays are subject to some degree of plasticity, since they can be altered by monocular deprivation during early postnatal life.

Further work in this field has led to the identification of columnar unitary loci in the striate cortex which respond to stimulation from one retina, although, as indicated above, some appear to be excited simultaneously from both; a columnar organization of cells coded according to colour responses has also been advanced. Some of these later results have been obtained in monkeys, with an increased likelihood that they correspond to human visual activities.



These studies, carried out with meticulous reference to the laminar pattern of the striate cortex, suggest a *columnar* form of anatomical arrangement corresponding to the vertical physiological organization in 'units' for which there is such undoubted evidence. The concept of 'chains' of neurons linked by synapses through the vertical dimensions of the cortex is comparatively old (p. 1004), and much more recent work, with the advantages of improved staining techniques and electron microscopy, has confirmed and elaborated this view, not only with regard to the striate cortex but also in the case of other areas. Synaptological studies and the results of degeneration experiments indicate clearly that the afferents of such an area as the striate cortex feed their impulses into a limited columnar group of neurons of internuncial type, the resultant of their interactions, excitatory and inhibitory, reaching a pyramidal cell and being thus translated to subcortical neurons or to some other part of the cortex. Such *columnar units* are not, of course, completely independent, being linked to others by recurrent axons, by the tangential fibres in the superficial lamina of the cortex (I), and by actual spatial overlap. (For a survey of the development of concepts concerning the columnar architecture of neocortex compare the publications of Szentágothai in 1967, 1969 and 7.132A with his later, more refined 'module concept' published in 1975 and summarized in 7.132B. The latter relates in particular to the visual cortex. See also below.) It is perhaps appropriate to mention here that within each cortical unit, cells in laminae II and III project to other cortical areas (such as 18 and 19), while lamina V projects to the superior colliculus and lamina VI to the lateral geniculate nucleus.

The effects of lesions of the lateral geniculate body in cats provide particularly detailed patterns of the termination of geniculocortical fibres in all three visual areas (Rossignol and Colonnier 1971). In area 17 degenerating terminals are mainly in lamina IV, but a few fine vertical axons reach lamina I to spread tangentially in it. In area 18 the main termination is in lamina IV, while in area 19 the afferent terminations are much less numerous but are spread through layers IV, V and VI. These results not only confirm earlier findings on the wide region of afferent projection in the occipital lobe, but also accord with the divergence of activity in the three parts of the visual cortex. The above experiments entail the infliction of very large, almost total lesions of the lateral geniculate body. Restricted lesions are naturally required to demonstrate the specific point-to-point relationship between the geniculate projection fibres and the visual areas. The specificity can also be shown by making cortical lesions and observing the resultant retrograde degeneration in the geniculate body, where a columnar series of groups of cells in all six layers are affected (p. 977). It is of special interest here that this effect is only achieved when the cortical lesions involve the whole thickness of the cortex (Rose and Malis 1965). By a similar combined 'attack' the functional details of visual *areas* II and III are being gradually clarified. In both areas evidence of columnar units is accruing, with the difference that the units respond to more complex stimulation and are almost all bi-retinal in respect to their receptive fields.

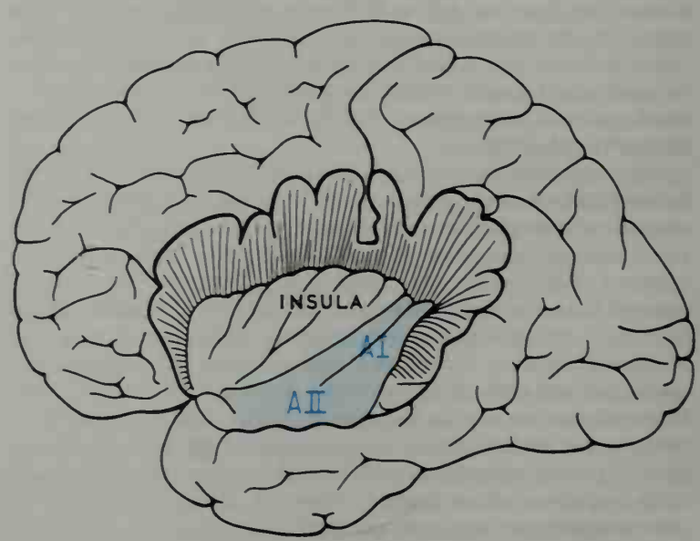
Hubel and Wiesel (1978), working on the macaque monkey, have been able to carry the above concepts further and to provide at least an initial integration in our understanding of the *modus operandi* of the striate cortex. Briefly, they have been able to show (by transport of radioactively labelled amino-acids from a single eye via the lateral geniculate bodies to the striate cortices) the existence not only of neuronal columns correlated with ocular dominance but also a particular pattern of arrangement of these columns throughout the striate cortex, area 17 (see also LeVay *et al.* 1978). This pattern is based in lamina IV of the cortex, which receives the major part of the geniculate projection and which contains so-called 'simple' neurons responsive to circularly symmetrical retinal stimuli in a strictly uni-ocular manner. The pattern consists of curving and branching stripes, about 0.5 mm in width in the macaque. The stripes are separated by unreactive intervals of similar width and, naturally, identical pattern. The reactive (radioactively labelled) stripes correspond to the cortical 'columns' associated with the injected eye, the intervening, non-reactive, stripes to the unaffected eye. It can be concluded, therefore, that interaction between signals from corresponding areas of both retinae must occur elsewhere in the striate cortex, perhaps in association with the 'complex' cells (in laminae II, III, V or VI), some of which respond to binocular stimuli. A second type of columnar pattern has also been demonstrated in the striate cortex by a combination of unit recording and a radioactive technique revealing sites of high utilization of glucose, the stimulus in both situations being the orientation of linear objects in the visual field. The columns associated with varying angles of object-orientation display a pattern of arrangement of whorled or 'swirling' 0·5 mm wide stripes similar to those concerned in uni-ocular reception. However, the 'stripes' of the two patterns do not correspond but intersect at frequent points. On the basis of these findings Hubel and Wiesel have hypothecated a cortical arrangement of repeated unitary columns, through the whole thickness of the striate cortex, each unit being able to respond to a stimulus in terms of position and orientation in the visual field, each columnar group of neurons being, however, concerned purely with a uni-ocular input. The theory has not yet been extended to attempt to explain cortical mechanisms concerned in

the colour, kinetic, or spatial (stereoscopic) aspects of stimuli. Nevertheless, these studies have provided the most detailed ideas of the manipulation of signals received by any part of the cerebral cortex, though they do not, as the workers cited admit, approach the integratory process which we call perception.

Parts, at least, of the occipital visual area must be considered as sensorimotor, inasmuch as eye movements can be elicited from them. In monkeys this (third) *occipital eye field* (7.136) is confined to visual areas I and II (17 and 18), stimulation of which produces conjugate deviations in various directions, especially to the opposite side. Head turning, facial movements, and sometimes responses in the upper limbs may occur (Rieck 1959; Bender 1964). This occipital motor eye field (III) is connected reciprocally with the *frontal eye fields* I and II. Such connexions are considered to be involved in the mediation of vision in the voluntary ocular movements which are held to characterize the frontal eye fields. The motor responses from area 18, which include accommodation, are on the contrary thought to be, in natural activities, reflex in nature and involved in following and fixation movements. This area may project to the pulvinar, in which connexion a controversial linkage between the lateral geniculate body and the same part of the thalamus should be noted; projection from the pulvinar to areas 18 and 19 is established in principle, but there is disagreement over details

7.137 Lateral aspect of the feline cerebral hemisphere showing the main auditory areas, AI and AII, and accessory areas Ea and Ep. These areas cannot yet be extrapolated with confidence to the human cortex. See text for details. (Adapted from *The Auditory Pathway*, by I. C. Whitfield—see Bibliography.)

(Locke 1961). Efferent projection fibres descend from the occipital motor eye field, particularly from area 19, to the superior colliculus and to the nuclei of the motor nerves of the ocular muscles; but the latter connexion is probably through intermediary nerve cells, such as the para-abducens nucleus (p. 1069), interstitial nucleus of Cajal, nucleus of Darkschewitsch, and the posterior commissural nuclear complex (Carpenter and Peter 1971). These descending fibres are to be distinguished from the corticogeniculate projection (pp. 978 and 1174), the evidence for which is chiefly physiological (Widén and Marsan 1961). A number of workers have now shown in some detail corticofugal connexions from areas 17, 18 and 19 projecting upon the thalamus, tectum, and pretectal region particularly in the cat. In this animal a degree of retinal representation has been demonstrated (Updyke 1977) in the projection from area 19 to the pulvinar.



The three visual areas are intimately linked by short association pathways, which are probably especially specific in the spatial sense between areas 17 and 18. The topographical relation preserved in the connexions between all three visual areas has been demonstrated in monkeys by Cragg (1969) and Zeki (1969, 1974); according to Zeki (1977) the spatial representation displays a 'mirror-image' reversal between adjoining visual areas, as apparently occurs in connexions between other adjacent 'sensory' areas (*see* Somatosensory Area, p. 1016).

In his most recent reviews of the organization of the primate visual cortex, Zeki emphasizes the propagation of '*mosaics*' of retinal representation from the striate to the 'pre-striate' cortex—the latter term including not only peri- and para-striate areas (Brodmann 18 and 19) but perhaps other more remote cortical regions. The latter include in particular the so-called fourth visual area (V4 and V4a), which extends between area 19 and the occipital end of the superior temporal gyrus (7.136A). Zeki's mosaic concept of retinal spatial representation involves the projection of each unitary retinal area at repeated points in all the visual areas, the responsiveness of the cortical loci showing variation in modality, different loci responding to orientation, contour, depth, different colours, and movement. In this concept there appears a possibility of equating such responsive loci with the columnar form of architectonics, already well established, with the results of unit recording. There is considerable evidence that the retinally-linked loci in the major visual areas subserve different modalities of the visual function; for example, area 17 appears to emphasize orientation, whereas columnar loci in area 18 are more concerned with stereoscopic depth. Beyond this, in areas 19 and V4, retinal representation is extended into the modalities of colour and movement. Picturesquely, one may imagine the total pattern of excitation from the retinae as propagated from area to area, the cortical units of each adding its particular modality to the total sensory pattern. Association and commissural fibres connect all visual areas, but more particularly 18 and 19, to many parts of the ipsi- and contra-lateral hemispheres. Vision and ocular movements may therefore be affected by lesions remote from the visual cortex, or from the recognized motor fields. For example, the course of the optic radiation as it swerves through the temporal lobe (Meyer's 'loop') entails that temporal lesions, such as tumours, may lead to homonymous field defects (Falconer and Wilson 1958).

THE TEMPORAL LOBE

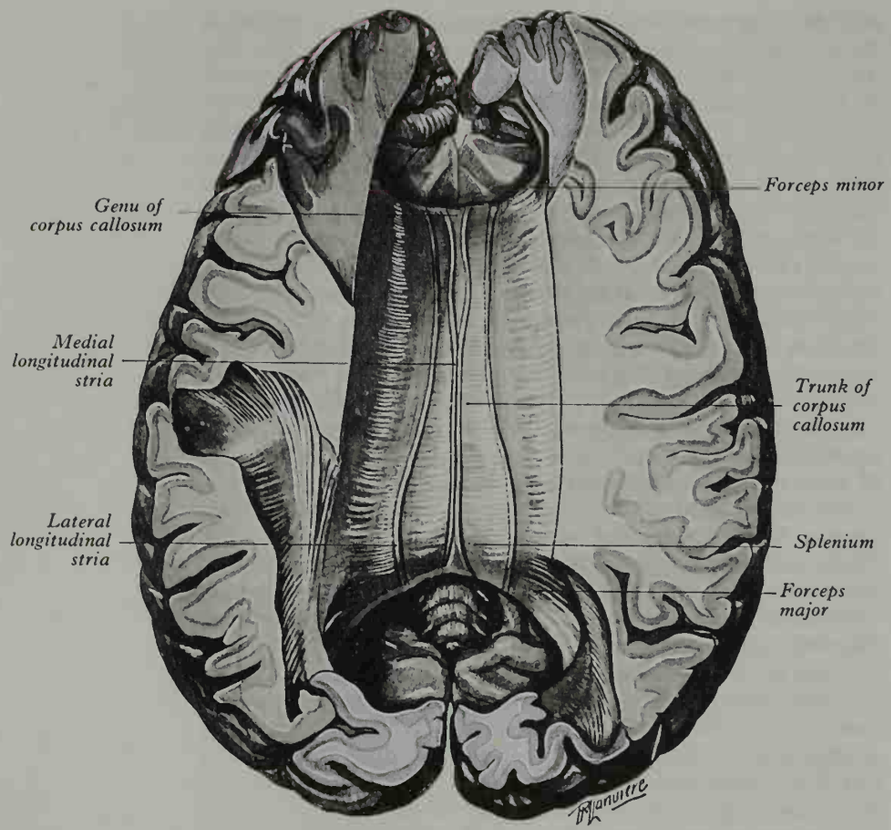
The temporal lobe has lateral and inferomedial surfaces, the former presenting superior, middle and inferior temporal gyri, the latter including the medial and lateral occipitotemporal gyri (sometimes regarded collectively as the fusiform gyrus), which are separated from the parahippocampal gyrus by the collateral fissure (7.114 and 119). The temporal lobe is regarded as highly evolved in man and of relatively recent phylogenetic development. In a general way it may be regarded as particularly involved in hearing, language and perception.

Part of the superior temporal gyrus is 'rolled' into the posterior limb of the lateral fissue during human fetal development, and

7.138 Superolateral surface of left cerebral hemisphere from which the opercula have been cut away to expose the insula and the adjoining anterior and posterior transverse temporal gyri and their continuity with the superior temporal gyrus. The area shown in blue contains the classical acoustic area, AI (equal to Brodmann area 41 and parts of areas 42 and 52), and the secondary acoustic area, AII (extending into area 22).

this buries two short gyri which ascend obliquely backwards posterior to the limiting sulcus of the insula. These are the anterior and posterior *transverse temporal gyri* (of Heschl), which correspond to areas 52, 41 and 42 approximately (7.112). A large number of other cytoarchitectonic localities have been described in the temporal lobe; but only those areas just mentioned, together with 22, which adjoins them on the lateral aspect of the superior temporal gyrus, can be reliably equated in man. In the original description of Campbell in 1905 the *acoustic area* of the cortex covered rather more than area 41, to which subsequent observers narrowed it down, thus defining what might be called the classical acoustic area, a leading feature of the temporal gyrus (7.126A). As will become apparent, Campbell's view has been revived by more recent experimental work.

Area 41 is histologically a variant of the granular type of cortex, but it is thicker than the cortex in the visual and somatosensory areas (Bailey and von Bonin 1951). Its immediate surroundings, such as area 22 (7.125), are of the parietal type, and beyond this much of the temporal lobe is frontal in type, like the main areas of the parietal and frontal lobes. Both the latter types of cortex show a considerable admixture of pyramidal cells and a diminution in granular elements (stellate cells). For further details consult the authorities referred to on p. 1002, and consult Braak (1978) for an extensive study of temporal areas in the human brain containing large pyramidal cells.



The acoustic area, as classically defined, is approximately equivalent to area 41; for reasons shortly to be related it is now more properly called the **first acoustic area** (AI). It extends a little into the superior temporal gyrus, but is largely obscured in the lateral fissure, forming the anterior transverse temporal gyrus. The earlier evidence on which the acoustic nature of this area was based may be sought in suitable reviews (*see* Whitfield 1967). The cytoarchitecture of the area has been described in detail by Sousa-Pinto (1973), who claims that the area AI thus defined corresponds exactly to the projection of the lateral part of the ventral nucleus of the medial geniculate body (in the cat). Attempts to define more accurately the area in which projection fibres from the medial geniculate body terminate have extended the area (Rose and Woolsey 1949), and the results of cortical stimulation (evoking head and ear movements) and cortical recording of potentials excited by localized stimulation of the cochlea and the cochlear nerve (Woolsey and Walzl 1942) have provided similar evidence. Much of this experimental work has been carried out on cats, and less often on monkeys (consult Sousa-Pinto 1973). Consequently the details of these accessory areas apply primarily to the feline temporal lobe and cannot be confidently translated in their entirety to man (7.138). The **second acoustic area** is often abbreviated to AII and lies inferior to AI in the equivalent of the superior temporal gyrus, in the cat the ectosylvian gyrus. Flanking AII are the *anterior* and *posterior ectosylvian areas*, Ea and Ep (7.137), and even further areas have been advanced. There is some evidence that all the areas named, except Ea, receive projection fibres from the medial geniculate body. Ablation of the first acoustic area, AI, leads to degeneration of cells only in the anterior part of the medial geniculate body, which receives fibres from the inferior colliculus (p. 941); but other parts of the complex of nuclei which make up the body project to all the other areas, except perhaps Ea, but including also part of the insula (Morest 1964). It has been suggested that some of the fibres in the acoustic radiation divide and terminate in more than one area, and that this may be in part the cause of the equivocal results of some experimenters. Short association fibres have been shown to link AI to AII and Ep, but not Ea. (For detailed development *see* Krmpotić-Nemanić *et al.* 1979.)

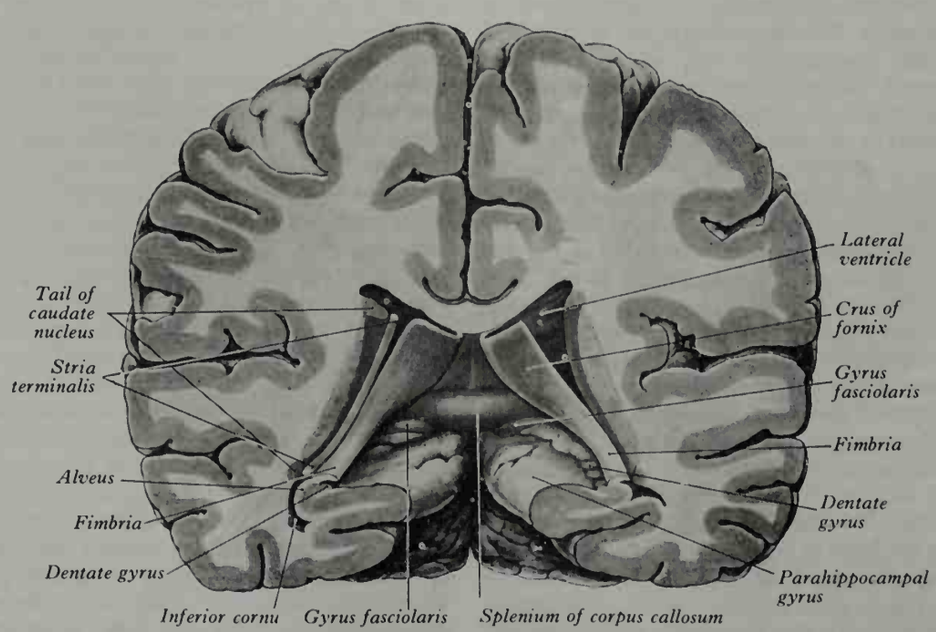
The geniculocortical projection has been 'mapped' in the first acoustic area in the chimpanzee (Walker and Fulton 1938), and a topical representation in this (Woolsey and Walzl 1942) was considered at an early date to be *tonotopical*, that is, to indicate a localization pattern on the basis of frequency of sound. This has been strongly denied as a feature of the human first acoustic area (Penfield and Jasper 1954), and remains a major controversy (Evans 1968). Stimulation in the conscious patient merely produced poorly localized patterns of sound or noise of simple nature, such as buzzing, humming, or ringing, but in the neighbouring areas (which may correspond to those identified in the cat), more complex acoustic phenomena were elicited. The topological relationship between the acoustic areas and the various divisions of the medial geniculate nucleus have been investigated in detail by retrograde transport of horseradish peroxidase from small cortical lesions (Winer *et al.* 1977). These observations suggest that only the laminated part of the ventral medial geniculate nucleus projects to a single acoustic area (AI), all other parts of the medial geniculate complex projecting to several of the cortical acoustic areas. It was also noted that the pulvinar projects to acoustic areas. Despite numerous studies of unit recording from the primary acoustic area, this problem has not been settled, but it seems highly likely that there are in fact units which respond to specific frequencies, even if they are not arranged in any particular pattern. Other units which can be excited by *variation* of frequency with time or direction have been described (Whitfield and Evans 1965), and in these specific arrays of units, the acoustic area resembles the visual cortex.

The existence of *efferent fibres* descending from the acoustic areas to the brainstem has been alluded to elsewhere (p. 941). These may not only modulate activities in the medial geniculate body but may also mediate various reflexes by forming connexions with motor nuclei of cranial nerves. Some of the fibres probably influence contraction of the stapedius and tensor tympani in the middle ear cavity; experiments suggest that this is increased in association with high-frequency sounds (Carmel and Starr 1963). *Association fibres*, in addition to the short ones alluded to above, link the acoustic areas to the other lobes in their own hemisphere, and perhaps particularly to the frontal pole and the cortex deep in the superior temporal sulcus, which recent work suggests may be special loci of convergence of association fibres from all the sensory areas. Little is known of commissural fibres, but it should be remembered that the lateral lemniscus is a bilateral tract. As a result of this, lesions in man of the medial geniculate body or the acoustic cortex do not lead to noticeable deafness unless they are bilateral—an unusual occurrence. Quite extensive temporal tumours are associated with only minimal effects on hearing, though they may interfere with the acoustic aspects of interpretation of language, especially if in the 'dominant' hemisphere. In connexion with this it is apposite to note that the posterior motor speech area mentioned in the section on the parietal lobe (p. 1017) extends markedly into the temporal lobe posterior to the acoustic region, practically surrounding the latter according to some authorities (7.134). This proximity doubtless has its implications in the complex cortical organization of speech, hearing and language, but further comment would be at the present juncture mere speculation.

The vestibular area is a matter of uncertainty and disagreement as regards its site, but in the monkey it is said to be located close to the part of the somatosensory area (SmI) concerned with the face in the postcentral gyrus (area 2)—*see* Jones and Powell (1970). Area 2 is a cortical region particularly involved in sensations from deep tissues and joints, and the spatial proximity of a vestibular area to this appears interesting. The area is believed to receive a projection from the vestibular nuclei, but this rests more upon the results of natural or electrical stimulation of the vestibular nerve or its receptors than upon any anatomical demonstration. Unlike the acoustic pathway, the vestibular projection appears to be almost entirely crossed. Indications of some degree of somatotopical specificity in the connexions of the vestibular cortex with parts of the vestibular nuclear complex have been reported (Massopust and Daigle 1960), but in view of the lack of anatomical evidence and the conflicting nature of the physiological data, little more can be said until better evidence is available. Another view of the position of the vestibular area must be mentioned; this depends on the recording of equilibratory responses in man, and implicates part of the superior temporal gyrus, anterior to the acoustic areas (Penfield 1957).

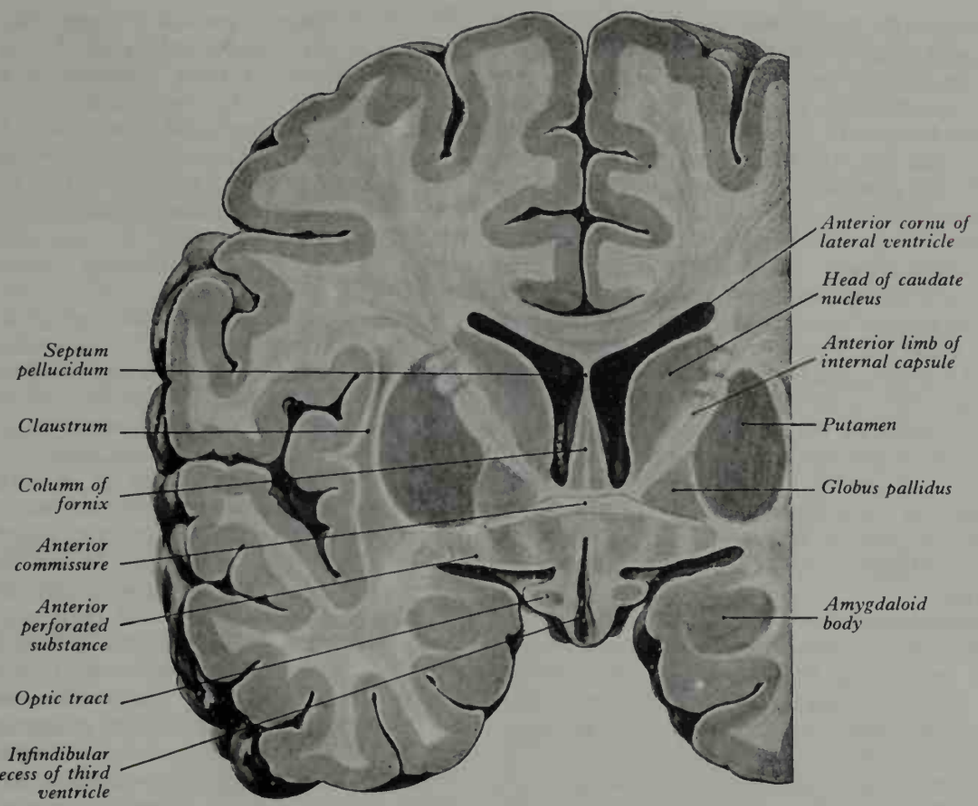
Apart from the acoustic areas, a possible vestibular area, and the extension into it of the posterior motor speech area (of Wernicke), the temporal lobe contains no other functionally designated neocortical areas, but it is not therefore to be assumed that all the remainder can be regarded as association cortex. The existence of large numbers of association fibres connecting parts

7.139 The corpus callosum, superior aspect, revealed by partial removal and dissection of the cerebral hemispheres.



of the temporal lobe to each other and to areas in other lobes is well established, although precise definitions are often lacking. Such connexions with the visual areas—between areas 18 and 19 and 37—and with the parietal lobe—between areas 7 and 40 and 22—are likely to be involved in complex integration between the sensorimotor areas in the temporal, occipital and parietal lobes. Thus, the more posterior region of the temporal lobe is perhaps more concerned with somatic activities, and especially with linguistic communication in its auditory and visual forms. The results of stimulation studies in man naturally provide the chief basis for such views (Blum *et al.* 1950). The anterior region of the temporal lobe appears to be more multiform still in its association with somatic and visceral activities. Apart from intrinsic association connexions, it is linked to the limbic system (p. 990) through the connexions of the parahippocampal gyrus with the hippocampus, through connexions with the piriform lobe (p. 995) and with the amygdala (p. 996), and the temporal pole, area 38, is also involved in these interrelationships (p. 1001). Effects on blood pressure, respiration, and gastric motility—usually depression—have been elicited by stimulation of this part of the anterior temporal lobe; but the major source of evidence in mankind depends on the defects following limited temporal lobe ablations to relieve epileptiform attacks invading this region.

Stimulation prior to temporal lobectomy, which usually does not involve removal of either acoustic or motor speech cortex, may elicit complex memories of auditory, visual or combined content. After actual lobectomy a somewhat confusing plethora of manifestations have been described in the extensive clinical literature on this topic, for which the appropriate textbooks should be consulted. Effects on speech, auditory memory, and the interpretation of both auditory and visual phenomena have been noted (Milner 1967; Falconer 1967). A form of visual agnosia, sometimes called 'psychic blindness', in which patients or experimental animals are unable to recognize the visual significance of objects, coupled with a change in dietary habits, a tendency to examine objects with the oral region, hypersexual behaviour, and loss of emotional responses, together constitute a syndrome named after Klüver and Bucy (1937)—see also Terzian and Ore (1955). But in these instances the lobectomy involved the amygdaloid body, hippocampus, and part of the parahippocampal gyrus, and subsequent experiments have shown that these phenomena are only in part due to temporal lobectomy involving neocortex alone.



In recent years the temporal lobe has been loosely associated with the activities of memory; but except for the possible participation of the parahippocampal gyrus in what has been ascribed to the hippocampus and other associated structures as 'short term' memory, there is little firm evidence of any anatomical entities in the temporal lobe or elsewhere which can be regarded as sites of 'long term' memory.

OTHER CORTICAL AREAS

The insula (7.113A–D) has already been described (p. 987). It is a matter of choice to which lobe it is assigned, since it adjoins and is overlapped by all lobes save the occipital. Histologically it exhibits in its posterior part a type of cortex resembling the parietal (p. 1009), whereas its anterior region is variously described as agranular or like the piriform cortex (Bailey and von Bonin 1951). The fibre connexions of the insula are still largely

7.140A Anterior aspect of a coronal section of the cerebrum from which the posterior parts of the thalami have been removed to reveal the splenium and parts of the limbic system. (Note that the dentate gyrus is not equally exposed on the two sides.)

7.140B A coronal section of the cerebrum immediately caudal to the optic chiasma and passing through the anterior commissure.

obscure; short association axons between it and all its opercula have been described, and it is said to be connected to the lateral olfactory gyrus and the piriform lobe (p. 995). Thalamic connexions (to the centromedian nucleus) have also been suggested (Le Gros Clark and Russell 1939; Locke 1967). Contralateral motor responses in the face and limbs have been elicited by insular stimulation in macaques and gibbons, and a somatotopic pattern may exist in this possible supplementary field (Showers and Lauer 1961). Stimulation in man excites visceral motor and sensory effects, such as belching, gastric movements, nausea and abdominal 'sensations' (Penfield and Rasmussen 1950). Increased salivation in man and experimental animals has also been elicited, and vasomotor effects in the latter. The insula has also been regarded as a gustatory area by some experimentalists. (For a review *see* Kaada 1960.)

The 'suppressor areas' reported by earlier experimenters in various parts of the cortex, particularly a vertical strip anterior to area 4, have been the subject of much controversy and adverse criticism (Druckman 1952). It is now considered that the suppression of motor activities from such areas is due to a generalized phenomenon of 'spreading depression' which is not associated with any particular areas of cortex. This phenomenon, which has not yet been completely explained, is characterized by a relatively long depression of neuronal activity, which may last several minutes, during which all responses may be suspended or distorted. It has no special anatomical correlates (Leao 1944).

The cingulate gyrus is discussed elsewhere in connexion with the limbic system (p. 990), but certain aspects of its anterior part, corresponding roughly to area 24, must be mentioned here. In its microscopic structure this area has features in common with the pre- and post-central areas. It receives a projection from the anterior nuclear complex of the thalamus which is reciprocated, and it may have connexions with the corpus striatum, hypothalamus and midbrain tegmentum. Commissural fibres through the corpus callosum have been described, and association fibres appear to link it with the frontal and parietal cortex anterior and posterior to the main sensorimotor region (Showers 1959).

Stimulation in macaques has been held to evoke bodily movements, both contralateral and bilateral, with some form of somatotopic pattern (Showers and Crosby 1958). This supplementary motor area extends into the posterior part of the cingulate gyrus, but the finding requires confirmation. In human patients stimulation of the anterior cingulate area may elicit changes in pulse, respiration and blood pressure, but the most reliable information has come from the results of surgical division or removal of the anterior cingulate gyrus, which is often involved in frontal leucotomy, performed to alleviate certain mental abnormalities. Cingulectomy alone appears to relieve abnormal aggressiveness and obsessional states, resulting in a milder and more placid personality (Tow and Whitty 1953). Similar effects have been recorded in monkeys subjected to ablations of the anterior cingulate gyrus (Glees *et al.* 1950). More recently, cingulate gyrus ablation has been claimed as a useful manœuvre in relieving intractable pain (Folty and White 1962). This mixture of somatic motor and sensory, emotional and visceral activities is at least in accord with the intermediate position of the anterior cingulate gyrus between the limbic system and the neocortex proper.

The Corpus Callosum

The corpus callosum is the great transverse commissure which connects the cerebral hemispheres and incidentally roofs in the lateral ventricles. Its development in mammals is proportional to the relative volume of the neocortex and is maximal in man (Rakic and Yakovlev 1968). A good conception of its position and size is obtained by examining it in median sections of the brain (7.110, 114). It forms an arched structure about 10 cm in length, its anterior end being about 4 cm from the frontal poles and its posterior end about 6 cm from the occipital poles of the hemispheres.

The *genu*, which forms the anterior end, inclines postero-inferiorly in front of the septum pellucidum and, diminishing rapidly in thickness, is prolonged posteriorly to the upper end of the lamina terminalis as the *rostrum*. The trunk arches back, convex above, to terminate posteriorly in the *splenium*, which is the thickest part of the corpus callosum.

The superior surface of the *trunk* of the corpus callosum (7.139) is covered by a thin grey layer, the *indusium griseum* which extends round the genu to the inferior surface of the rostrum to become continuous with the paraterminal gyrus, and in it are embedded two fine longitudinal bundles of fibres on each side, which are termed the medial and lateral longitudinal striae (p. 998); posteriorly the indusium griseum is continuous with the dentate gyrus and the hippocampus through the gyrus fasciolaris (7.140).

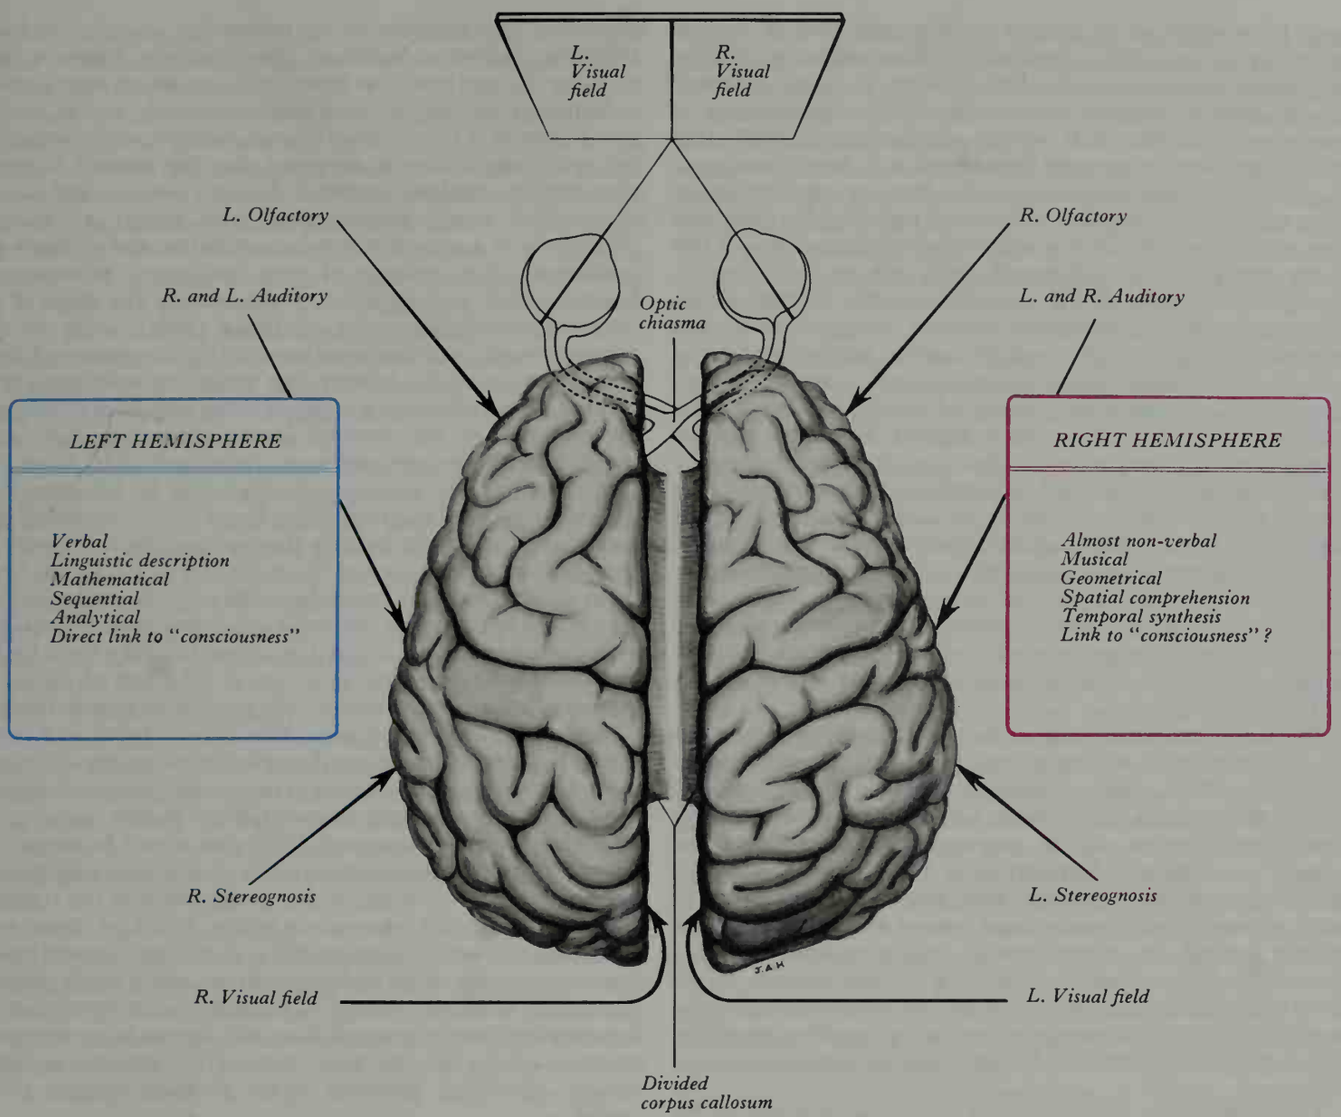
In the median plane the trunk of the corpus callosum forms the floor of the longitudinal fissure, and is related to the anterior cerebral vessels and to the lower border of the falx cerebri, which may come into actual contact with it posteriorly (8.31). On each side of the median plane the trunk is overlapped by the gyrus cinguli, from which it is separated by the slit-like callosal sulcus.

The inferior surface of the trunk is concave in its long axis and convex from side to side. In the median plane, the septum pellucidum is attached to it anteriorly, to an extent which depends on the length of the septum (7.110). Posteriorly it is fused with the body of the fornix and the commissure of the fornix. On each side of the median plane, the inferior surface of the trunk forms the roof of the lateral ventricle (7.141) and is covered with the ventricular ependyma.

The *genu* is continuous above with the trunk and below with the rostrum. Its anterior surface, which is related to the anterior cerebral vessels, is covered with the indusium griseum and the longitudinal striae. To its posterior surface is attached the septum pellucidum in the median plane, and on each side it forms the anterior wall of the anterior horn of the lateral ventricle.

The *rostrum* connects the genu to the upper end of the lamina terminalis. In the median plane its superior surface is attached to the septum pellucidum and, on each side, forms the narrow floor of the anterior horn of the lateral ventricle (7.155). On the inferior surface of the rostrum the indusium griseum and the longitudinal striae are carried backwards to the upper end of the paraterminal gyrus.

The *splenium* overhangs the posterior ends of the thalami, the pineal gland and the tectum of the midbrain. It is, however, separated from them by a number of structures. On each side of the median plane the crus of the fornix and the gyrus fasciolaris (7.140) curve upwards to reach the splenium. The crus of the fornix continues forwards on the inferior surface of the trunk, but the gyrus fasciolaris passes round the splenium, rapidly tapering off and fading away into the indusium griseum. In the median plane, the tela choroidea of the third ventricle passes forwards below the splenium through the transverse fissure, and the internal cerebral veins emerge from between its two layers and unite to form the great cerebral vein. Above, the splenium is covered with the indusium griseum and is related to the falx cerebri and the inferior sagittal sinus in the median plane, and to the cingulate gyrus on each side. Posteriorly the splenium is related to the free margin of the tentorium cerebelli, the great cerebral vein and the beginning of the straight sinus.



The nerve fibres of the corpus callosum radiate into the white core of the hemisphere on each side and disperse to various parts of the cerebral cortex. The rostral fibres extend laterally below the anterior cornua of the lateral ventricles, and connect the orbital surfaces of the two frontal lobes. The fibres of the genu curve forwards and connect the lateral and medial surfaces of the two frontal lobes, as the *forceps minor*. The fibres of the trunk pass laterally and intersect the projection fibres of the corona radiata (7.98). They connect wide cortical areas of the two hemispheres to one another. Those fibres of the trunk and of the splenium which together form the roof and lateral wall of the posterior horn and the lateral wall of the inferior horn of the ventricle constitute the *tapetum* (p. 1029). The remaining fibres of the splenium curve backwards and medially into the occipital lobes as the *forceps major*. This large bundle of fibres bulges into the superior part of the medial wall of the posterior horn of the ventricle and forms a curved elevation which is termed the *bulb of the posterior horn*.

Despite the great size of the corpus callosum and the enormous number of commissural fibres that it contains, limited information is available concerning its functional significance, apart from the obvious inference that it links the two hemispheres together and appears to ensure that they act as a single entity. The number of fibres is unknown in man, but in the cat there are 700,000 in each square millimetre (Myers 1959). The precise linkages effected by these commissural fibres have not been defined, except in the visual area (Zeki 1970, 1974) and the postcentral gyrus (Jones and Powell 1969). In the somatic sensory areas (SmI and SmII) the connexions are limited to the same area on the opposite side, but the right and left loci concerned with the hand and foot appear to lack such commissural connexion. Where commissural linkages occur they are considered to be highly specific, associating 'corresponding' columnar cortical units in bilateral functions.

Cases of complete congenital absence of the corpus callosum are recorded from time to time—the condition is a rare one—but the defect is usually found at autopsy, and the clinical history does not show any characteristic feature which can lead to certain diagnosis during life (Unterharnscheidt *et al.* 1968). In recent decades large portions, and in some cases the whole, of the corpus callosum have been divided as a surgical approach with apparently surprisingly little disturbance of function (Akelaitis 1942). Nevertheless, the accumulated experience of the results of brain damage (*see*, for example, Milner 1974), especially to the temporal lobe and corpus callosum, of experimental studies of commissurotomized cats (Butler 1966) and chimpanzees (Myers and Henson 1960), and particularly from the studies of Sperry (*vide infra* for references) on the effects of division of the human corpus callosum—all this evidence has not only illumined the function of this great commissure in the transfer of information, including memorized data, across the midline of the cerebrum, but has also confirmed a long-suspected asymmetry of function, which has led to a concept of 'dominance', usually by the left hemisphere. This has become a major arena of cerebral research which requires a short section to itself. Though it is impossible in this brief account even to survey more than superficially the profuse, and even at times prolix, literature recorded by clinicians, experimenters (anatomical and physiological), psychologists, behaviourists, and others, it is hoped that the references to major contributions will enable the interested reader to enlarge his knowledge elsewhere.

CEREBRAL ASYMMETRY OR HEMISPHERIC DOMINANCE

The concept of asymmetry of function, and structure, in the cerebrum is by no means modern, although it has attracted intensive study only in recent decades. It arose during the nineteenth century in company with developing views on functional localization in the cerebral cortex. Early protagonists of such asymmetry were Bouillard (1825) and Dax (1834), both concerned with speech, and Weber (1834), who believed he could detect asymmetry in various sensory functions. But it was the observations of Broca (1861), upon a single case of motor aphasia, which not only formed perhaps the first clear indication of cortical localization but also provided the first convincing evidence of *unilateral* representation of function in the cortex. Correlation between pathological changes in the region now known classically as Broca's area (p. 1014), and the observed almost complete defect in speech, clearly pointed to a close association between the initiation of speech and, in this case, the left cerebral hemisphere. Further patients, and similar examples of clinico-pathological deduction from the patients of other clinical observers, confirmed this finding. Moreover, the view was further elaborated into a concept of the left hemisphere as *dominant* and the right as in some, rather vague manner a *minor* hemisphere. This was perhaps partly prompted by an exaggerated identification of language with cognitive processes in general; perhaps also the known high incidence of right-handedness was also a corroborating factor, the more skilful hand being under the command of the apparently more intelligent hemisphere. Others were less dogmatic; Hughlings Jackson (1868), while confirming Broca's clinical findings, was wary of extending the undoubted presence of a unilateral motor speech 'centre' in the left hemisphere (in patients afflicted with vascular lesions of Broca's area) into the concept of left cerebral dominance or an exclusively 'verbal' hemisphere. He considered that the somewhat neglected right or 'minor'

7.141 This diagram is an adaptation (with the author's permission) of the original 'split-brain' schema published by Professor R. W. Sperry in 1964, of hemispheric attributes as revealed by complete division of the corpus callosum. The right and left halves of the total visual field are projected into the contralateral hemispheres and are completely isolated, the right hand being 'controlled' from the left hemisphere. The olfactory and auditory inputs also project to separated hemispheres, but in the former case ipsilaterally and in the latter bilaterally with a contralateral bias. On each side of the diagram the abilities listed refer to the adjoining hemisphere; they are to be taken as extremely generalized attributes, which are likely to be modified as research in this field progresses. The diagram represents, of course, arrangements in an individual with left cerebral dominance or preference.

hemisphere might be of equal functional importance in somewhat vaguely expressed terms, such as an involvement in ideational, non-verbal cognitive activities. As will become apparent, he was closer to modern concepts than his contemporaries, in this as in other matters. However, the idea of dominance persisted with little change into the twentieth century, although it did not become a part of general neurological teaching until much more recent times. Perhaps this stagnation was due to the comparative dearth of further data, especially of an experimental type. Many further studies of cases of motor aphasia were, of course, added in confirmation of Broca's speech 'centre', and the defects consequent upon damage to other cerebral regions in some instances suggested, somewhat vaguely, asymmetry of cortical function and sometimes the reverse. Inevitably the role of the corpus callosum demanded attention—a commissure of such size, containing an estimated 200 million nerve fibres in mankind, cannot be ignored. But, as stated earlier, the observed effects of agenesis or occasional extensive injury proved difficult to assess, and it was easy for many observers to accept that even severe damage to the corpus callosum produced little change in the patient's cerebral performance. Retrospectively it is now easy to appreciate that this was the consequence of the relatively crude and inappropriate tests available. As will be seen, the introduction of adequate testing transformed the scene; but before passing to this it is appropriate to turn briefly to the subject of '*handedness*', the preference for use of the right or left hand characteristic of mankind.

The close association of cortical areas concerned with the motor 'control' of speech and the right hand in the same, left hemisphere has inevitably evoked much statistical examination of the incidence of right and left hand-preference, a most fascinating problem in itself. A large literature of recorded data, and even more speculation, surrounds this subject (*see* Hicks and Kinsbourne 1978, for a recent brief review). Forelimb preference in mammals other than man is not easy to assess, and while such preferences are considered to exist, they are never so clear and apparently universal as they are in human beings, nor is there the same high frequency of a 'dominant' right hand. This is 'preferred' in about 90 per cent in all races and cultures, however diverse (Chamberlain 1928; Komai and Fukoka 1934; Hécaen and Ajuriaguerra 1964; Annett 1967; Hicks and Kinsbourne 1978). A genetic basis for hand-preference has been confidently postulated for mankind alone (Nagylaki and Levy 1973), but this is still an issue of some but diminishing disagreement. Such a genetic lateralization factor has naturally been extended to the development of the individual's dominant (verbal) cerebral hemisphere, and this influence is widely accepted. Single gene (Annett 1964) and double gene (Levy and Nagylaki 1972) models

have been advanced to explain the observed data of familial incidence of hemispheric dominance (often coupled with those regarding hand-preference); but neither of these proposed genetic models accounts completely for the distribution of variants. However, such studies have demonstrated that hemispheric asymmetry is far from simple in its lateral incidence. If one individual is encountered who does not conform to the large majority of left-sided 'verbal' and right-handed people, it does not follow that he is automatically the reverse of this. A few (2 per cent according to Zangwill 1967), who are right-handed, nevertheless display clinical evidence of right cerebral dominance, and similar discordance between hand-preference and cerebral dominance occurs more frequently among left-handed subjects. Occasionally, lateralization of function may be difficult to establish, especially in respect of hand-preference. True ambidexterity may occur, and a limited degree of bilateral hemispheric function is more often suggested but less easily established. In the case of hand-preference in particular, the genetic influence may, of course, be complicated by cultural imitation of a largely right-handed population. How far this may, in childhood, produce secondary effects on cerebral dominance is uncertain; but it is certainly unwise to adopt a dogmatic or inflexible attitude of mind in regard to manual or cerebral asymmetry; and the apparent anomalies in their distributions renders theorization upon the genesis of asymmetry at present highly speculative.

Studies of cerebral dominance have been greatly amplified by the introduction of sodium amytal injections into the cerebral circulation (Wada 1949). Unilateral injection, despite cerebral arterial anastomoses, temporarily suspends or, at least greatly diminishes, function in the corresponding hemisphere; the 'speech' or dominant hemisphere is thus easily deduced in patients or normal volunteers, who may then be observed in much greater detail by appropriate testing techniques. The use of this method has complemented and sometimes extended the opportunities already afforded by injured patients in the investigation of the peculiarities of the two hemispheres; and the recorded data have become almost confusingly profuse, especially with the widespread interest of experimental psychologists in this field.

The contribution, to the study of cerebral asymmetry, of the assessment of functional defects following cerebral lesions, by injury or deliberate surgery, has been collectively large, though scattered through a large number of necessarily limited observations. Historically, of course, this is the oldest mode of study (cf. Broca) and also the newest (cf. Sperry, below), as has been pointed out by Milner (1974), who has herself made a large contribution in this field, particularly upon patients submitted to frontal lobectomies and patients with temporal lobe epilepsy, for which unilateral or bilateral ablations were carried out. The association of the temporal lobes, and more deeply situated hippocampi, with the function of memory has been established for many years; and a particular interest in the effects of unilateral temporal lobectomies resides in the revelation of asymmetrical memory defects (Milner 1958; Milner *et al.* 1964; Blakemore and Falconer 1967; Milner and Teuber 1968). Removal of the left temporal lobe impairs learning and memorization of verbal material, whether visual or auditory, whereas the right temporal lobe appears to be concerned with the acquisition and retention of visual and auditory experience of a non-verbal nature. Right lobectomy damages the ability to follow mazes, both in terms of vision and proprioception. Some of these lobectomies involve more than cortex, and they may include hippocampal and amygdaloid tissue. The localization of function is therefore sometimes crude and uncertain, but there is no doubt of the asymmetry which is observed.

Although all the avenues of enquiry mentioned above have contributed substantially to unmasking asymmetry of cerebral function, by temporary or permanent partial blockage of function in one hemisphere, the most fruitful approach to the problem has undoubtedly been the *isolation* of otherwise intact hemispheres from each other, though not from the external environment, by division of the corpus callosum for therapeutic purposes in human patients, and to a lesser extent by performing the same procedure for experiment in laboratory animals, including monkeys. Before considering this evidence, however, it is necessary to turn briefly to the strictly anatomical contribution.

Although anatomical observation inevitably enters into the interpretation of the effects of disease, injuries, and experimental lesions, it might also be supposed that the marked functional asymmetries, gradually exposed during a century and more of observation, would be associated with clearly ascertainable differences of a structural type, quantitative and perhaps even qualitative. The evidence of such anatomical asymmetry is, however, small and equivocal. Stimulated by the views of Dax (1834) and the discoveries of Broca (1861), some of their contemporaries, and also Broca himself (1875), considered the left hemisphere to be the heavier, but others recorded the reverse opinion. None of the long series of those who have investigated the structure of the cerebral cortex appears to have noted significant differences between right and left sides, and Braitenberg (1977) has re-emphasized this by his own observations. Because of its proximity to Broca's area (on the left side), and its association with hearing, the superior temporal gyrus (and the adjoining speech area of Wernicke (*see* p. 1014)) has been a focus of attention in the search for asymmetry. A predominance in size of the left superior temporal gyrus has been described by several observers (such as Geschwind and Levitsky 1968; Le May and Culebras 1972; Hyde *et al.* 1973). The first of those cited claimed a left areal superiority in 80 per cent of human brains. A decade earlier two authorities, Von Bonin (1962) and Bodian (1962) had already pronounced opposite views on the significance of such structural asymmetries in respect of cerebral dominance, even when convincingly demonstrated, Bodian opining that searching for such anatomical differences would be sterile. The general lack of observations in this field, and their uncertainties, corroborates this view so far; but it may be that the structural asymmetries are of a more subtle nature. Di Chiro (1962) noted reciprocal differences in calibre between the superior and inferior anastomotic veins of the two hemispheres, which might denote, if confirmed, some divergence of vascular requirement; but this comparatively crude angiographic study has not been repeated. It must be concluded, therefore, that for the present, at least, a strictly anatomical approach to the problem has not proved useful.

Although the nineteenth-century interest in asymmetric control of speech continued, if somewhat sporadically, into the twentieth (*see*, for example, the work of Penfield and Roberts 1959), it is not unjust to suggest that the work of Sperry and his collaborators, in the sixties and beyond, has proved the outstanding contribution and stimulus in this field (Sperry *et al.* 1969; Gazzaniga 1970; Sperry 1970, 1974, 1977). The fact that he was already investigating 'split-brain' preparations in experimental animals and could collaborate with the pioneers (Bogen and Gazzaniga 1965) in complete division of the corpus callosum to alleviate severe, bilateral epilepsy, proved most productive. Sperry (1961) had elaborated, during his work on monkeys, an array of ingenious testing techniques, which could be applied, extended and further refined in observation upon these human patients, with the great advantage of verbal communication, allowing access to subjective phenomena which could merely be hypothecated in monkeys from their motor behaviour. The essence of such techniques is the isolated presentation of a wide variety of sensory cues, visual, auditory, or tactile, to the right or left hemisphere, and also the isolation from each other of such stimuli or cues presented simultaneously or sequentially in these different modes. The most commonly employed stimuli are visual cues, projected with great care in either the right or left half of the total visual field of the two eyes; but auditory and even olfactory cues have been extensively used, and the hands are frequently included, though in the performance of motor tasks, in which tactile and proprioceptive stimuli are significant.

Although corpus callosal division, or *commissurotomy*, is not a frequent operation, many patients have now been studied postoperatively, and a large array of experimental results has been recorded in such patients, and also in considerable numbers of patients and normal volunteers subjected to amytal injection, both by Sperry and his team and by other workers. Sperry's

original findings have been largely corroborated, with some further extensions and modifications, often of a semantic nature (*see* Dimond and Beaumont 1973). They are shown in 7.141. There has, in fact, been so much corroboration of the functional asymmetry of the cerebrum and such detailed analysis of the peculiarities of the two hemispheres, that there is a distinct danger of over-statement. As in any fruitful field of discovery the original impetus is necessarily towards *analysis*, to establish differences and details. As will be emphasized further, below, it is necessary, as a corrective, to preserve also an impulse towards *synthesis*. The two hemispheres are, despite their differences, *complementary*, and they are in normal circumstances undeniably in continuity. The phenomena revealed by their artificial separation have now been studied by a host of workers in much detail, and only examples of those asymmetric qualities which are best established can be summarily recounted here.

In the surgically 'split' brain a suitably brief signal presented in the left half of the binocular visual field is received only by the right hemisphere, with no possibility of transfer of information to the left. (The stimulus must be brief enough, usually about 0·1 second in duration, to counteract momentary ocular movement from midline fixation.) If the right is the 'minor' hemisphere as it usually is, no verbal response can be obtained, and the patient is unaware (so he says) of the occurrence of the signal when he is questioned. (He may, in fact, volunteer statements, but the content of these is unrelated to the experimental situation.) Nevertheless, the patient (or experimentee if sodium amytal is used) must in some manner, apparently outside the consciousness associated with his left hemisphere, recognize signals, especially actual objects, with his right hemisphere. This is shown, for example, by his ability to *remember* an object displayed to him momentarily, and to pick it out subsequently with his *left* hand, unaided by vision, from a small array of dissimilar things presented to his searching hand. Whatever comments his isolated left hemisphere likes to make on his performance, of which he has no experience in this verbalizing, talkative hemisphere, these phenomena demonstrate that the right hemisphere is able to carry out much that is characteristic of a conscious brain: he 'sees', recognizes, employs memory, and directs successfully the corresponding hand. A large series of such experiments, employing a wide variety of visual, auditory, and tactile cues, and recorded by many observers, demonstrates beyond doubt that each hemisphere can, when separated, act to a marked extent as an independent unit, with its own ability for perception, learning, memorization, and motor control; hence, of course, the expression 'split brain' and the assumption that two separate consciousnesses can co-exist in the single individual. However, it is only the verbally skilful hemisphere, usually left, sometimes right, which can communicate directly, explicitly, and intelligently with other consciousnesses by the medium of language, thus uniting its own conscious world with the exterior. The other, the so-called 'minor' hemisphere, is severed from such communication and, moreover, from communication with the 'dominant' hemisphere. Nevertheless, this isolated right hemisphere is even able to recognize the meaning of the names of objects, presented either visually or aurally, and to correlate this recognition with memories of similar experiences and to carry out appropriate motor behaviour, though this half-brain, apparently conscious, is out of touch with any observer, who has no access to its activities except through its motor responses (excluding those of speech). These astonishing findings have persuaded some interpreters to an even firmer belief in the dominance of the verbal hemisphere; and to assign to it a major, if not exclusive role in a supposed brain-consciousness linkage. Some workers have even been led to question the need for two such 'brains' (e.g. Teuber 1974). The enthusiasm for analysis has undoubtedly led to an over-emphasis of the peculiarities of each hemisphere, tending to obscure the normal unity of the two halves of the cerebrum. Whatever may be hypothecated with respect to consciousness, it is clear that in some of the attributes of consciousness, such as spatial conception, geometrical perception, and perhaps 'musicality', the minor hemisphere is the more able partner and must participate in the conscious activities of the united hemispheres. It is easy, of course, to overlook the fact that in the diencephalic region and caudal to this, the unity persists even after commissurotomy. As Young (1978) has picturesquely stated, the split personality of the commissurotomized patient, dual though it may seem, falls asleep as one, though his two eyes appear to take different views of his environment, when he is questioned on awakening. It is not surprising, perhaps, that such patients exhibit so little deficiency or duality in the ordinary activities of life, in which circumstances they are also able to explore the visual field freely with both eyes, to use both hands, and to rotate the head, thus duplicating in each hemisphere a representative array of signals from the entire sensory field, and not merely from one side or the other. It is only by the careful techniques initially evolved by Sperry and his co-workers that the defects are clearly unmasked. The specialization of the hemispheres in an asymmetrical, unilateral manner, so that in the total cerebrum certain abilities are sufficiently correlated with one hemisphere as to be assignable to it, is at present beyond explanation, despite some interesting theorization. Such arrangements are not, however, wholly unexpected. The existence of two central mechanisms, bilaterally related, for any generalized function is not easy to understand or even accept, without evidence of some linking or coordinating locus. The operation of two such central mechanisms, each dealing with half of what is continuously appreciated as an unbroken visual field has always posed such a problem, and appears to evoke some unitary integrating activity, although Sherrington (1906) was prepared to regard the simultaneous occurrence of the dual sets of neuronal events as a sufficient explanation. But the evidence for the transference of visual and other information across the midline of the cerebrum is impressive, and the memory stores of each hemisphere appear to be accessible to the other and to be probably bilateral to a considerable extent. All such phenomena would in hypothesis demand a large connexion between the two hemispheres, and this of course exists and must provide the anatomical matrix for extensive communication and presumably integration between right and left activities. Although so much of the research in this field has been focused upon functional differentiation of the hemispheres, with a special emphasis at first upon a unilateral mediation of speech, thus leading to the concept of dominance, it is becoming clearer in later investigations that the laterality of many functions is merely greater on one side, and not exclusive to one or other hemisphere. Even in the case of verbalization, some ability has long been assigned to the 'minor' hemisphere (consult Albert and Obler 1978). Moreover, our concepts of what constitutes a discrete 'function' may be in themselves misleading. Though I may *describe* a complex three-dimensional structure to another individual through a symbolic series of sounds called language, which are chiefly organized into an intelligible sequence by left hemispheric activity, it seems equally probable that I am *conceiving* an image or idea of the object I wish to describe in my right hemisphere, and that in the absence of linguistic description the concept may remain largely limited to the 'minor' brain. The too facile ascription of labelled functions or abilities to one or other side has been criticized by Milner (1974), who has redirected attention to the 'parallelism' of right and left activities. Broadbent (1974) has also emphasized the integrative action of the two hemispheres (an interesting reminder of the title of Sherrington's classic text!), regarding speech, for example, as a combined production of both. Such considerations favour the growing tendency to abandon the terms 'dominant' and 'minor'; and it is clearly preferable to think rather of a complex but complementary asymmetry of distribution of ability within the whole cerebrum. Inevitably this will entail a degree of right and left predominance, though perhaps only in so far as we impress our own semantics upon the complete organization. Eccles (1973, and in Popper and Eccles 1977) has professed a preference for the term 'dominance', on the basis of his own interpretation of the dominant, verbalizing hemisphere as the mediator between the external universe and the internal consciousness of the individual. He has resuscitated an old postulate due to Sherrington, whose student he was, that some part of the cerebrum would prove to be a site of what Eccles calls a *liaison* between brain and consciousness, but the latter goes further by designating the *dominant* hemisphere as a particularly *self-conscious* cerebral

region. Although we are here being returned to the nineteenth-century association of speech and cognitive processes in a common locus, the evidence derived from Sperry's patients and other sources does also support such a view. But the apparent inaccessibility to verbal communication of the 'minor' hemisphere, and its apparent oblivion in regard to its own activities, are both revealed by the artificial separation. However useful this isolation may be in analysis of cerebral abilities, it may also mislead; for it must be followed by a re-synthesis in accounting for the operations of a normally united and singular brain.

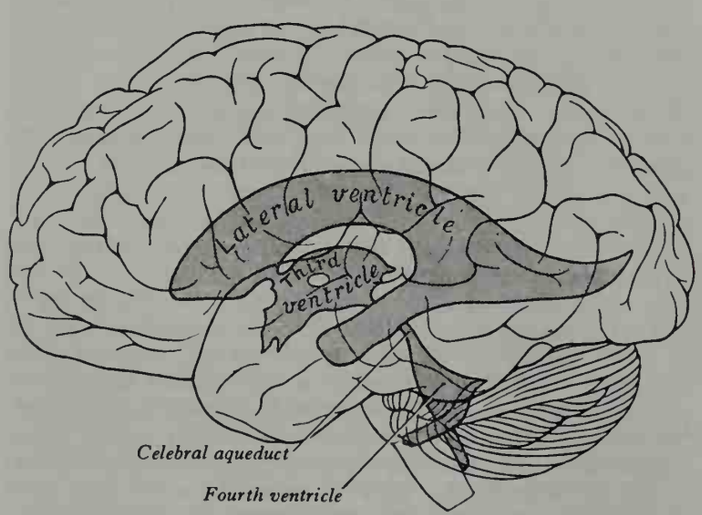
These fascinating studies are currently providing the most fertile common ground between neuroanatomists, neurophysiologists, experimental psychologists, and even philosophers, in a general endeavour towards an understanding of the human brain and hence of what we call ourselves. It is an exciting prospect, particularly because it centres around the great problems of communication between the private world of the individual and his external environment of countless similar individuals, each locked in a private prison except insofar as communication succeeds. Perhaps, as understanding increases, we shall dissolve our differences and disperse our doubts, and then perhaps, in the happily optimistic words of Young (1978) 'a new form of laughter will echo through the system'. However that may be, it is pertinent to conclude with a statement by Braitenberg (1973), another distinguished student of man's brain: 'The *neuroanatomy* of neuronal networks will be for quite some time, and perhaps forever, the context that relates the *physiology* of single neurons and synapses to the macroscopic events of *psychology*.' (Editors' italics.) After analysis must come synthesis.

THE SEPTUM PELLUCIDUM

The septum pellucidum is a thin vertical partition (7.110, 114), consisting of two laminae, separated throughout a greater or lesser part of their extent by a narrow interval, termed the *cavity of the septum pellucidum*, which does not communicate with the ventricles of the brain. The septum is triangular in form, with its base in front and its apex behind. It is attached above to the inferior surface of the trunk of the corpus callosum; below and behind, to the anterior part of the fornix; below and in front to the upper surface of the rostrum of the corpus callosum; anteriorly to the posterior aspect of the callosal genu. The lateral surface of each lamina takes part in the formation of the medial wall of the anterior horn and central part of the lateral ventricle (7.141), and is therefore covered with ependyma.

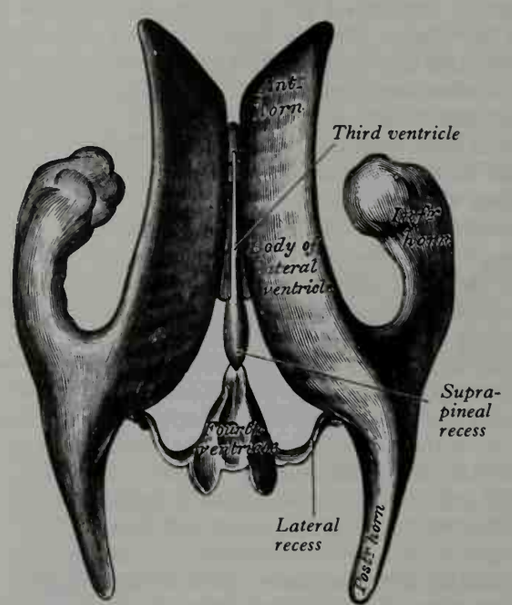
The laminae contain both grey and white matter, and for what is known of their connexions see the account of the *septal areas* (p. 997) and the *dorsal fornix* (p. 1002). The development of the septum pellucidum is referred to on p. 171.

The anterior commissure is described on p. 997, and the *commissure of the fornix* (hippocampal commissure) on p. 1001.



INTERNAL STRUCTURE OF THE CEREBRAL HEMISPHERES

In the interior of the hemispheres are the lateral ventricles, the basal nuclei and many fibre tracts, both projection and intrinsic.



The Lateral Ventricles

The two lateral ventricles (7.142, 143, 144) are irregular cavities situated in the lower and medial parts of the cerebral hemispheres, one on each side of the median plane. They are almost completely separated from each other by the *septum pellucidum*, but each communicates with the third ventricle and indirectly with the other through the *interventricular foramen* (p. 981). They are lined with ependyma and contain cerebrospinal fluid, which, even in health, is secreted in considerable amounts. Each lateral ventricle consists of a *central part* and three *cornua* or *horns*, anterior, posterior and inferior (7.143, 144, 145).

The central part (7.144) of the lateral ventricle extends from the interventricular foramen to the splenium of the corpus callosum. It is a curved cavity with a roof, floor and medial wall; on transverse section it is triangular anteriorly and rectangular

7.142 Projection of the ventricles on to the left surface of the brain.

7.143A A drawing of a cast of the ventricular cavities. Superior aspect. (Retzius.) Note that where the lateral recess joins the fourth ventricle, the lateral dorsal recesses of the roof of the ventricle project dorsally on each side beyond the posterior margin of the median dorsal recess. The superior angle of the fourth ventricle and the aqueduct of the midbrain are hidden by the suprapineal recess.

posteriorly. The *roof* is the inferior surface of the corpus callosum; the *floor*, which is concave superomedially, is formed by the following in lateromedial order: the caudate nucleus, the stria terminalis, the thalamostriate vein, and the lateral portion of the upper surface of the thalamus. The caudate nucleus becomes rapidly narrower as it is traced backwards in the floor, and its long axis is directed laterally as well as posteriorly. The stria terminalis, a small bundle of white fibres (p. 996), and the thalamostriate vein occupy a narrow groove which follows the medial border of the caudate nucleus and separates it from the lateral margin of the superior surface of the thalamus. The latter may be almost entirely hidden by the choroid plexus, which invaginates the ependyma into the cavity through the slit-like

interval between the edge of the fornix and the upper surface of the thalamus, the ependymal invagination occupying this *choroid fissure*. The body of the fornix becomes wider as it is traced backwards, and its thin, lateral margin lies parallel with the groove for the stria terminalis.

The *medial wall* is formed by the posterior part of the septum pellucidum with the body of the fornix in its lower margin. Posteriorly, where the septum pellucidum ends, the roof and the floor meet one another on the medial wall.

The anterior cornu (7.141, 142) passes forwards, laterally and slightly downwards, into the frontal lobe. It is continuous behind with the central part at the interventricular foramen. In a coronal section it appears as a triangular slit below the anterior part of the corpus callosum, and it is bounded anteriorly by the posterior surface of the genu and rostrum of the corpus callosum. The *roof* is formed by the anterior part of the trunk of the corpus callosum. The greater part of the *floor* is formed by the rounded head of the caudate nucleus, but, in its medial portion, a small part is formed by the upper surface of the rostrum of the corpus callosum (7.155). The *medial boundary* is formed by the septum pellucidum containing the column of the fornix in its posterior edge.

The posterior cornu curves backwards and medially into the occipital lobe. Its development is very variable and frequently asymmetrical; it may be absent. Its *roof* and *lateral wall* are formed by fibres of the tapetum of the corpus callosum, which separate them from the optic radiation (p. 1031). The splenial fibres which constitute the forceps major pass medial to the posterior horn as they sweep backwards into the occipital lobe. In this part of their course they produce a rounded ridge, the *bulb* of the posterior cornu, in the upper part of the *medial wall*. Below the bulb, a second elevation may be identified on the medial wall. It is the *calcar avis*, and it corresponds to the infolded cortex of the anterior part of the calcarine sulcus (7.146). Posteriorly the lateral and medial walls meet each other. Kier (1977) has shown that the posterior cornu is phylogenetically the most recent extension of the lateral ventricle, being present only in the Anthropoidea. It is symmetrical in the human fetus, but in adults the two cornua are usually unequal in size, a peri-natal change which Kier ascribes to unequal folding of the calcarine fissure.

The inferior cornu (7.144, 147), the largest of the three, traverses the temporal lobe, forming in its course a curve round the posterior end of the thalamus. At first it descends posterolaterally and then curves anteriorly to within 2·5 cm of the temporal pole close to the uncus, its position being usually indicated on the surface of the brain by the superior temporal sulcus. A needle introduced at a trephine hole, the centre of which is placed 3 cm behind and 3 cm above the centre of the external acoustic meatus, and passed in the direction of the tip of the opposite auricle, enters the inferior cornu at a depth of some 5 cm from the surface.

The *roof* of the inferior cornu is formed chiefly by the inferior surface of the tapetum of the corpus callosum, but the tail of the caudate nucleus and the stria terminalis also extend forwards in the roof, at the extremity of which they are continuous with the amygdaloid body. Its *floor* consists of the collateral eminence laterally and the hippocampus medially; the surface of the latter is covered by the alveus, continuing as the fimbria of the hippocampus, which becomes continuous posteriorly with the crus of the fornix (p. 1001). Between the stria terminalis and the fimbria is the inferior, or temporal, part of the choroid fissure, through which the lower part of the choroid plexus of the lateral ventricle invaginates the ependyma closing the fissure. The choroid plexus covers the upper surface of the hippocampus.

The fimbria and the hippocampus have already been considered (pp. 1001 and 997), and a full description of the choroid plexus will be found on p. 1037.

The *collateral eminence* (7.147) is an elongated swelling lying lateral to and parallel with the hippocampus. It corresponds with the middle part of the collateral sulcus, and its size reflects the depth and direction of this sulcus. It is continuous behind with a flattened triangular area, named the *collateral trigone*, which forms the floor of the ventricle between the posterior and inferior cornua. The capacity of the lateral ventricles (and the other chambers of the system) can be estimated by anatomical and radiological techniques (Weintraub 1953). Levinger and Kedern (1974) have devised a technique for estimation of the surface area of cerebral ventricles from casts of them, but have applied this so far only to cats.

The Nerve Fascicles of the Cerebrum

If the hemisphere is sliced horizontally about 1·25 cm above the corpus callosum, the central white substance of the hemisphere is seen as an oval area surrounded by a narrow convoluted margin of grey matter, and studded with red dots (puncta vasculosa) produced by the escape of blood from divided blood vessels. If the hemispheres be sliced off at the level of the corpus callosum, its nerve fibres will be seen in continuity with the white matter of the hemisphere on each side. The white matter contains many myelinated fibres, of varying size, supported by neuroglia. These fibres may be described according to their course and connexions, as belonging to one of three vast fibre systems: (1) The *commissural fibres* connect the two hemispheres to each other, linking corresponding or *homotopic* loci, and also *heterotopic* loci. (2) The *arcuate (association) fibres* connect different cortical areas of the same hemisphere to one another; some of them are collaterals of the projection and commissural fibres, but the majority are independent axons. (3) The *projection fibres* connect the cerebral cortex with the grey matter of the brainstem and the spinal cord in both directions.

(1) **The commissural fibres** have already been considered (pp. 963, 997, 1001, 1023).

(2) **The arcuate (association) fibres** (7.148, 149), which are all ipsilateral, are of two kinds: short arcuate fibres, connecting adjacent gyri to one another; long arcuate fibres, connecting more widely separated gyri to one another. Details of many individual association pathways have already been given in the section on cortical areas.

7.143B and C Resin casts of the ventricular system of the human brain prepared by Dr. D. H. Tompsett of the Royal College of Surgeons of England. B Ventral view; C Left lateral view. Compare with the superior aspect shown in 7.143A.

7.144 Horizontal section of the cerebrum dissected to remove the roofs of the lateral ventricles.

The *short arcuate fibres* may be entirely intracortical or they may pass immediately below the cortex to connect adjacent gyri, some merely passing from one wall of a sulcus to the other.

The *long arcuate fibres* group themselves, somewhat indistinctly, into bundles, which can be dissected in the formalin-hardened brain after the cortex and the subjacent short arcuate fibres have been removed. The fibres in each fasciculus show considerable variation in length, and the longest are always situated in the deepest part of the bundle. Concerning the precise connexions of these fibre bundles very little accurate information is at present available, for histological methods are unable to demonstrate them throughout the whole of their length. The following fasciculi can be distinguished: (*a*) the uncinate fasciculus; (*b*) the cingulum; (*c*) the superior longitudinal fasciculus; (*d*) the inferior longitudinal fasciculus; (*e*) the fronto-occipital fasciculus.

(*a*) The *uncinate fasciculus* connects the first motor speech area (p. 1014) and the gyri on the orbital surface of the frontal lobe with the cortex of the temporal pole and the area immediately adjoining. The fibres follow a sharply curved course and cross the floor of the stem of the lateral sulcus. They are related to the antero-inferior part of the insular area (7.148, 149).

(*b*) The *cingulum* is a long, curved bundle which commences on the medial surface of the hemisphere below the rostrum of the corpus callosum. It lies within the gyrus cinguli and so follows the curve of that gyrus. Inferiorly it enters the parahippocampal gyrus and spreads out so as to reach the adjoining parts of the temporal lobe. Along its convexity fibres enter and leave it in groups, giving it a spiked irregular appearance when dissected.

(*c*) The *superior longitudinal fasciculus* is the largest of all the arcuate fibre bundles. It commences in the anterior part of the frontal region and arches backwards above the insular area and lateral to the lower part of the corona radiata (*v. infra*). After giving off a number of fibres to the occipital cortex (areas 18 and 19), it curves downwards and forwards behind the insular area and spreads out into the temporal lobe. Like the other long arcuate fasciculi, it constantly receives new fibres throughout its whole extent and gives off fibres to the adjoining cortex. Its constituent fibres are so intermingled that it is quite impossible to determine their precise connexions by gross methods (7.149), nor is the dissecting microscope of any real help for this purpose.

(*d*) The *inferior longitudinal fasciculus* commences near the occipital pole and its fibres are derived chiefly from areas 18 and 19. They sweep forwards, separated from the posterior horn of the lateral ventricle by the fibres of the optic radiation and the commissural fibres of the tapetum, and after being crossed by the superior longitudinal fasciculus, they are distributed throughout the temporal lobe.

(*e*) The *fronto-occipital fasciculus* commences at the frontal pole and passes backwards on a deeper plane than the superior longitudinal fasciculus and separated from it by the lower part of the corona radiata (*vide infra*). It associates itself with the lateral border of the caudate nucleus, and is therefore closely related to the central part of the lateral ventricle. Posteriorly its fibres radiate into the occipital and temporal lobes in a fan-shaped manner, passing lateral to the posterior and inferior horns, and intersecting and mingling with the fibres of the tapetum of the corpus callosum.

The above details are almost entirely based upon the appearances of blunt dissection of the white substance of the cerebrum. Accurate knowledge of the origins and terminations of association fibres can only be established by experimental studies, which have not been carried out for most regions of the cortex. Studies of the visual areas (Le Gros Clark 1941; Zeki 1970, 1974) and the main somatic sensory areas (SmI)—*see* Jones and Powell (1968)—suggest a high degree of specificity in such connexions.

(3) **The projection fibres** connect the cerebral cortex with the lower parts of the brain (including the diencephalon) and the spinal cord, and include both *corticofugal* and *corticopetal* fibres.

The projection fibres converge from all directions on the corpus striatum (7.150). For the most part they are internal to arcuate fibres, and they intersect the commissural fibres of the corpus callosum and the anterior commissure. At the periphery of the corpus striatum, they form the *corona radiata*. The medial aspect of the corona radiata is separated from the lateral ventricle by the fronto-occipital fasciculus, and its lateral aspect is covered by the superior longitudinal fasciculus. Below, the corona radiata is directly continuous with the internal capsule, a thick, curved zone of white matter which includes all the projection fibres, and which cuts into the corpus striatum, dividing it almost completely into two parts, the lentiform and the caudate nuclei.

The Internal Capsule

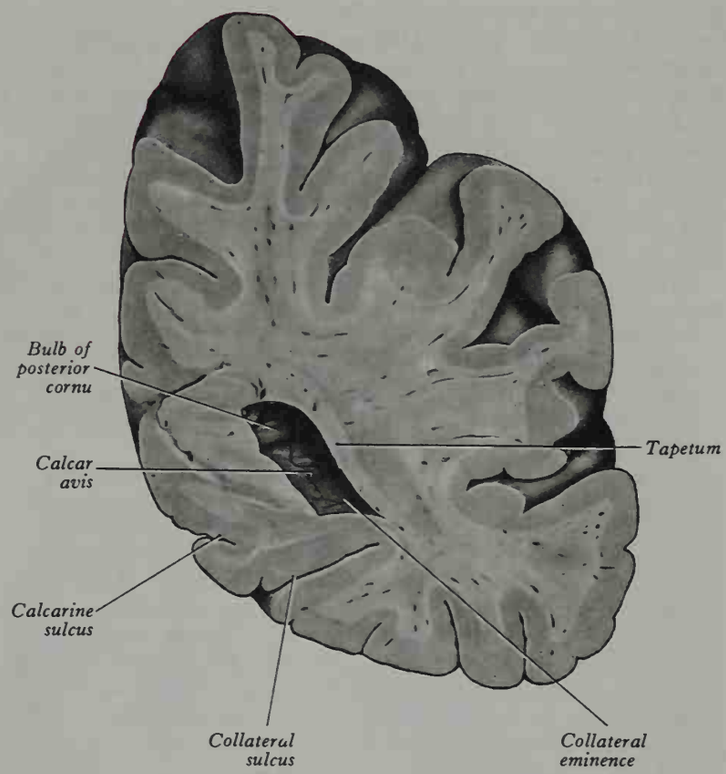
In horizontal section through the cerebral hemisphere the internal capsule is a broad band of white fibres, bent with a lateral concavity, which accommodates itself to the convex medial surface of the lentiform nucleus (7.151, 152, 153, 154). It can be divided into an *anterior limb*, a *genu*, a *posterior limb*, a *retrolentiform part* and a *sublentiform part*. The anterior limb is interposed between the lentiform nucleus on the lateral side and the head of the caudate nucleus on the medial side. The posterior limb has the thalamus on its medial side and the lentiform nucleus on its lateral side. The fibres of the internal capsule continue to converge as they pass downwards, and at the same time the frontal fibres tend to pass backwards and medially, while the temporal

and occipital fibres pass forwards and laterally. At the lower limit of the lentiform nucleus, they are crossed by the optic tract and enter the midbrain. The corticofugal fibres enter the crus cerebri, where the frontal fibres are placed to the medial side and the temporal, parietal and occipital fibres to the lateral side. What follows is a simplified account of the fibre constitution of the internal capsule. A number of other fibre 'systems' are described at points throughout the section on the telencephalon.

The *anterior limb* of the internal capsule contains *frontopontine fibres*, which arise in the cortex of the frontal lobe and synapse about the cells of the nuclei pontis, the axons of which pass to the cerebellar hemisphere of the opposite side. In addition there are the fibres of the anterior thalamic radiation which interconnect the medial and anterior nuclei of the thalamus and the cortex of the frontal lobe.

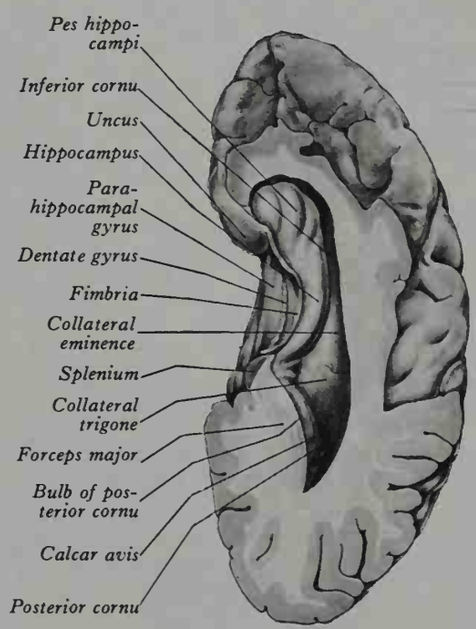
The *genu* is usually regarded as containing the *corticonuclear* fibres which arise mainly from area 4 of the cerebral cortex and terminate in the motor nuclei of the cranial nerves to the head, mostly of the opposite side. The most anterior fibres of the superior thalamic radiation interconnecting the thalamus and cerebral cortex also extend into the genu.

The *posterior limb* includes the *corticospinal tract* disposed in scattered bundles, with the fibres concerned with the innervation of the upper limb anteriorly followed by those to the trunk and lower limbs. The location of corticospinal fibres in the anterior part of the posterior limb has been widely accepted since the observations of Charcot (1883) and Déjerine (1901), but more recently evidence derived chiefly from stereotactic lesions in man has accumulated to suggest that these fibres are in fact situated in the *posterior* part of the posterior limb. This evidence has been reviewed by Smith (1967) and Hanaway and Young (1977). Other descending fibres here include frontopontine fibres from the frontal lobe, in particular areas 4 and 6, *corticorubral* fibres from the frontal lobe to the red nucleus and fibres from the globus pallidus contained in the subthalamic fasciculus. The majority of this portion of the internal capsule contains fibres of the superior thalamic radiation carrying general sensory impulses from the ventral thalamic nuclei to the postcentral gyrus. (For a survey of the posterior limb in the human brain consult Smith 1967.)



In the *retrolentiform part* are *parietopontine* and *occipitopontine* fibres and fibres from the occipital cortex to the superior colliculus and pretectal region. In addition there is the posterior thalamic radiation which includes the optic radiation, and interconnexions between the cortices of the occipital and parietal lobes and the caudal portions of the thalamus, especially the pulvinar.

The fibres of the *optic radiation* arise in the lateral geniculate body and sweep backwards in the angle between the central part and inferior horn of the lateral ventricle. In their course they are intimately related to the superior and lateral surfaces of the inferior horn and lateral surface of the posterior horn of the lateral ventricle, being separated from the latter by the tapetum.



The *sublentiform part* contains the *temporopontine* and some parietopontine fibres, and the acoustic radiation running from the medial geniculate body to the superior temporal and transverse temporal gyri (areas 41 and 42). There are also a few fibres interconnecting the thalamus with the cortex of the temporal lobe and insula.

7.145 Anteroposterior radiograph of the head after the introduction of air into the ventricular system of the brain. The outlines of the bodies and anterior horns of both ventricles are separated in the midline by the shadow of the septum pellucidum; directly inferior to the latter, the outline of the third ventricle can be seen. (Kindly provided by Dr. R. D. Hoare, Dept. of Diagnostic Radiology, Guy's Hospital.)

7.146 Anterior aspect of a coronal section through the posterior cornu of the left lateral ventricle.

7.147 The posterior and inferior cornua of the right lateral ventricle, exposed from above.

The fibres of the *acoustic radiation* sweep forwards and laterally below and behind the lentiform nucleus to reach the cortex.

The connexions between the cortex and the thalamus are discussed on p. 956; corticohypothalamic connexions on p. 957; corticostriate connexions on p. 1034.

The Basal Nuclei

Situated within each cerebral hemisphere is a series of subcortical nuclear masses of grey matter often loosely grouped under the general term *basal nuclei*. Unfortunately, the structures included vary between workers; but most commonly the term includes the amygdaloid complex, the claustrum, the caudate nucleus and the lentiform nucleus (7.141, 151, 152, 153). These topographical structures are a heterogeneous group with respect to their structural and functional associations and phylogenetic history. Accordingly, a large and often confusing terminology has been generated by different investigators, the various structures being subdivided and regrouped in many different ways. The array of terminologies will not be discussed at length, but some of the more commonly used alternatives are mentioned briefly here. (For critical reviews of the basal nuclei *see* Mettler 1968; Webster 1978.)

The *amygdaloid body* (amygdaloid nuclear complex, amygdala, or *archistriatum*) is discussed elsewhere in relation to the limbic system (p. 990).

The *claustrum*, a tenuous sheet of grey matter, surrounded by laminae of white matter which separate it from the deep surface of the insula and the external surface of the lentiform nucleus, is further mentioned on p. 1036.

The *caudate nucleus* and *lentiform nucleus* are commonly grouped together as the *corpus striatum*. The lentiform nucleus is divided into an internal *globus pallidus* and an external *putamen*, which are structurally distinct. The putamen resembles the caudate nucleus in its structure, and together they constitute the *neostriatum*, frequently termed simply the *striatum*. When used in this manner, therefore, striatofugal fibres are those which leave the caudate nucleus or putamen for other destinations, whilst afferents, denoted with the suffix -striate (e.g. thalamostriate), are those passing to the putamen or caudate nucleus, and not to the *corpus* striatum as a whole. (The terms will be used in the manner just described in this account, but it must be realized that some neuroanatomists refer to the whole corpus striatum when they use these terms, and in other cases, the intended meaning is by no means clear.)

The *globus pallidus* or *paleostriatum* is often referred to simply as the *pallidum*, and hence such terms as pallidal afferents or pallidofugal fibres.

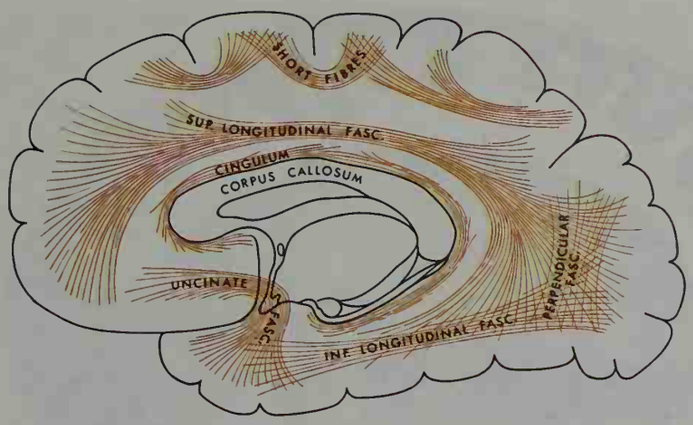
TOPOGRAPHY OF THE CORPUS STRIATUM

The caudate nucleus is an arcuate mass of grey matter, which has already been noted in the floor of the anterior cornu and central part of the lateral ventricle and the roof of its inferior cornu (7.141, 144, 151, 152, 153, 156). Its anterosuperior end is massive and termed the *head*. At the interventricular foramen this narrows into the *body* of the nucleus which tapers imperceptibly into the *tail*. As noted the nucleus projects into the *floor* of the anterior cornu and central part of the lateral ventricle and continues round into the roof of the inferior cornu, its tail merging at its anterior and lower extremity (tip) with the amygdaloid body. In all parts of the ventricle it is covered by ependyma. In the central part and inferior cornu of the lateral ventricle the stria terminalis lies along the medial border of the caudate nucleus. In the central part of the ventricle the stria terminalis lies with the thalamostriate vein in the groove between the caudate nucleus and the thalamus. In the inferior cornu it forms the upper border of the lower part of the choroid fissure.

In the anterior cornu and central part of the lateral ventricle the lateral margin of the caudate nucleus is related to the corpus callosum, being separated from it by the fronto-occipital arcuate bundle (p. 1030) and the subcallosal fasciculus (p. 1034). The lateral surface of the nucleus is flat and in contact with the internal capsule. At its anterior end the head of the caudate nucleus is fused below with the putamen of the lentiform nucleus just above the anterior perforated substance. Above this junction strands of grey matter traverse the anterior limb of the internal capsule and connect the putamen of the lentiform nucleus with the head of the caudate nucleus. The striped appearance which this region presents prompted the term corpus striatum.

In the inferior cornu of the lateral ventricle the tail curves forwards behind, below and then lateral to the fibres of the internal capsule entering the crus cerebri; these separate it from the thalamus which lies above and medially. Above, the sublentiform part of the internal capsule and fibres from the external capsule separate the tail from the globus pallidus.

The lentiform nucleus is shaped like a biconvex lens, but the



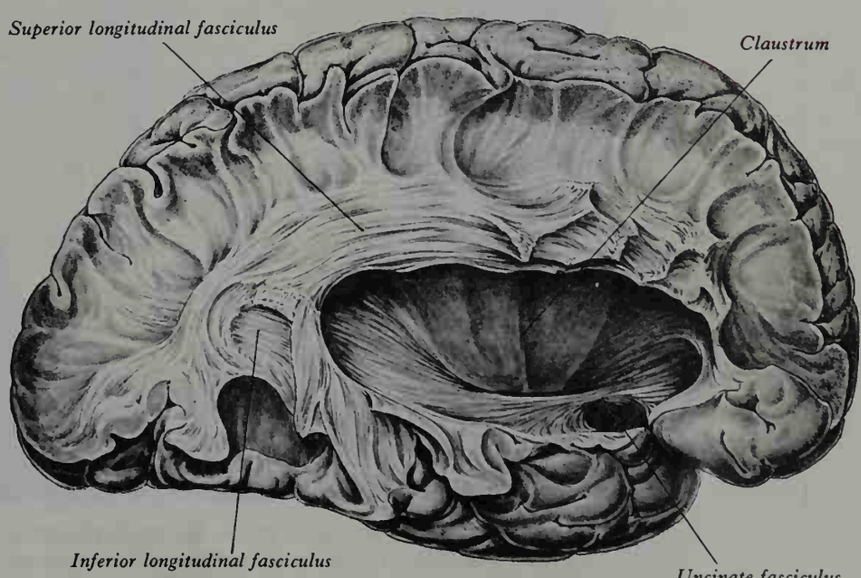
curvature of its medial surface is sharper than the curvature of its lateral surface (7.102, 141, 151, 152, 153, 156). Cut in section, it is seen to consist of two portions, which differ from each other in their colour. The larger, lateral part which is darker in colour, is termed the *putamen*; the smaller, medial portion is of a lighter tint, and is termed the *globus pallidus*.

The lentiform nucleus is completely buried in the substance of the hemisphere. Laterally it is covered by a thin layer of white matter which constitutes the *external capsule*. This sheet is covered on its lateral side by the *claustrum*, which intervenes between it and the subcortical white matter of the insula. Medially the lentiform nucleus is in relation to the internal capsule, which separates it from the thalamus behind, and from the head of the caudate nucleus in front. Round its anterior, superior and posterior margins the nucleus is related to the corona radiata. The inferior part of the lentiform nucleus is deeply grooved by the anterior commissure as it passes backwards and laterally into the temporal lobe (7.141), and anteriorly it is continuous with the head of the caudate nucleus. A little in front of the groove, the grey matter of the corpus striatum is continuous with that of the anterior perforated substance, and the lateral striate arteries, which enter the brain at this site, run laterally and then turn upwards in close contact with the lateral surface of the lentiform nucleus, before they pierce its substance. The lentiform nucleus lies above the inferior cornu of the lateral ventricle and is separated from it by the fibres of the external capsule as they pass medially towards the subthalamic region, the sublentiform part of the internal capsule (p. 1031), the tail of the caudate nucleus and the stria terminalis. More anteriorly, it is separated from the amygdaloid body by the ansa peduncularis.

STRUCTURE OF THE CORPUS STRIATUM

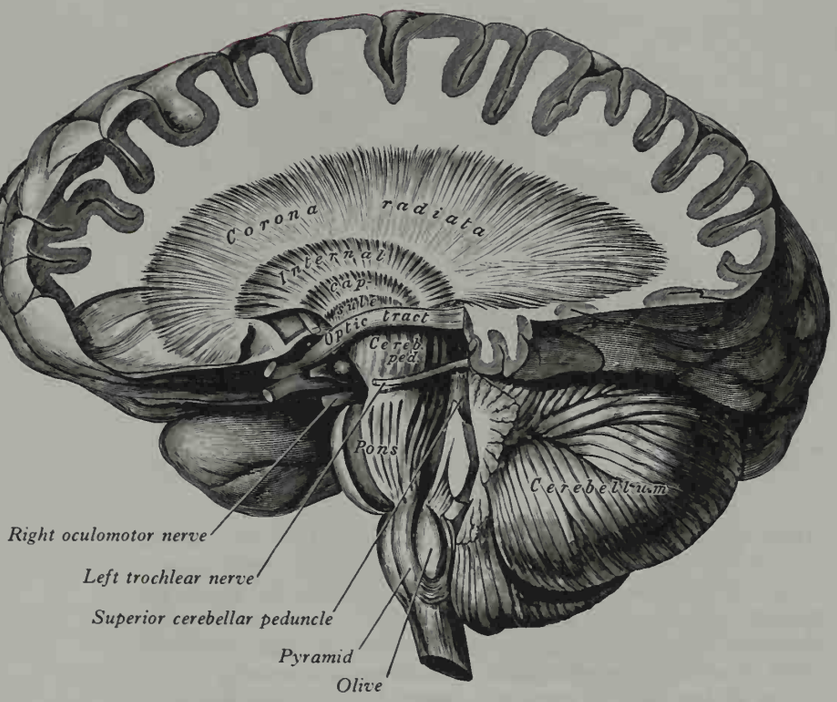
The caudate nucleus and putamen are similar in structure, being highly cellular, well-vascularized zones, permeated by delicate bundles of either finely myelinated or non-myelinated, small-diameter fibres. Hence the pinkish-grey colour of these regions when freshly sectioned, in contrast to the pale colour of the globus pallidus which is encapsulated and traversed by numerous, coarse, heavily myelinated fibres.

The neurons of the caudate nucleus and putamen are mainly small multipolar cells, with round, triangular, or spindle-shaped somata, admixed with a small proportion of large multipolar cells, the ratio of the two being roughly 20:1. The small neurons are considered to be receptive and associative interneurons, which receive the synaptic terminals of many of the striatal afferents. The large neurons possess large and roughly spherical or ovoid dendritic trees, and their principal axons are one source of striatal efferents (*vide infra*), but some of the smaller neurons probably also contribute to the striatal outflow. Although the general pattern of connexions of the striatum with extrinsic regions of the nervous region is becoming clearer (*vide infra*) we have, as yet, little knowledge of the detailed morphology of its neurons, intrinsic connexions, and synaptology. Some progress has, however, been made with both the Golgi technique and electron microscopy in various experimental animals (Fox *et al.* 1966; Kemp 1968*a* and *b*, 1970) but only some general features have emerged. The dendrites of striatal cells bear dendritic spines, and axodendritic synapses both related to spines and smooth interspine dendritic surfaces, and axosomatic synapses have also been identified. Further, both asymmetrical (Type I) and symmetrical (Type II) synapses are present. Lesions placed in the cerebral cortex, thalamus, or midbrain, result in degeneration of asymmetrical synapses, which are presumably excitatory, in relation to both dendrites and (after cortical lesions) to the cell somata as well. In contrast, lesions within the caudate nucleus itself cause degeneration in both type I and type II synapses. The latter, which are possibly inhibitory, are distributed on dendrites, somata and the initial segments of axons. In addition, it was shown that the axons of all striatal neurons studied possessed collateral branches and it was thought that the type II synaptic terminals might be derived not only from intrinsic interneurons, but also from the collaterals of neurons projecting to other regions. It is of considerable interest that histopharmacological



7.148 The principal arcuate (association) fibres in the cerebrum.

studies (Hökfelt 1968) have demonstrated that in the caudate nucleus of the rat many of the synaptic terminals contain dense-cored or 'granulated' vesicles which characterize aminergic neurons (7.19), and are thought, in this site, to represent stores of *dopamine*. The remaining synapses contain the clear spherical small presynaptic vesicles found in cholinergic terminals.

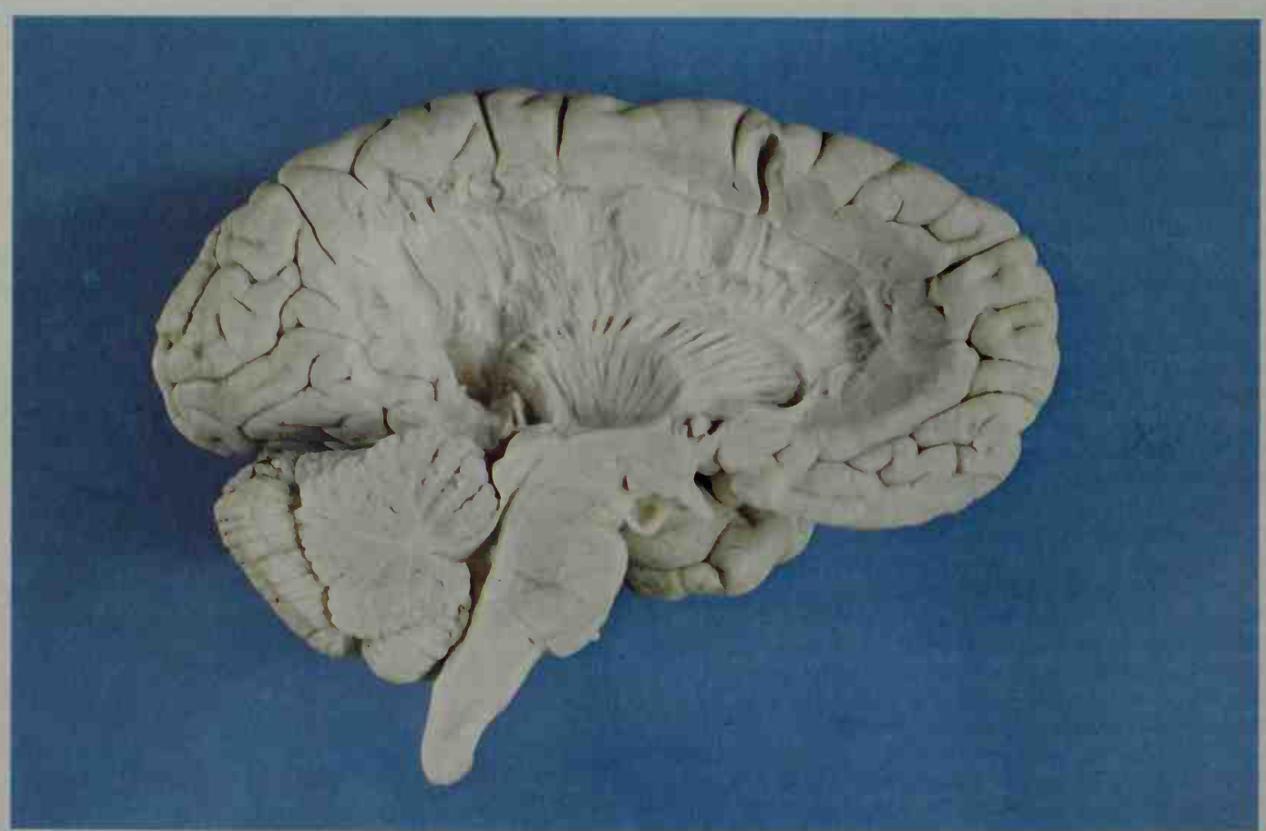


The globus pallidus contains a rather scattered population of large multipolar neurons which in their general cytology closely resemble the lower motor neurons in other situations and also the large cells of the substantia nigra. Their primary dendrites branch infrequently and possess only occasional small dendritic spines. Their synapses are mainly in relation to these dendrites and are of type II, but scattered between these are a small number of type I. The relatively sparse axosomatic synapses are also of both types. After experimental lesions in the caudate nucleus, numerous degenerating symmetrical (type II) terminals were found in relation to both dendrites and somata of neurons in the globus pallidus (and also in the substantia nigra). The axons of the large pallidal neurons give origin to the profuse, well-myelinated, pallidofugal system of fibres (*vide infra*). Topographically, the globus pallidus is separated by a layer of white matter, the *external medullary lamina* or *stria* from the medial aspect of the putamen, whilst an *internal medullary lamina* or *stria* divides it into a smaller, medial, and a larger, lateral part (*pallidum I and II* respectively).

CONNEXIONS OF THE CORPUS STRIATUM

In outline, the neostriatum (putamen and caudate nucleus) constitutes the main receiving station; this projects to the globus

7.149 A dissection showing some of the long arcuate fasciculi of the right cerebral hemisphere.



7.150A A dissection showing the convergence of cortical projection fibres through the corona radiata into the cerebral peduncle and pons.

pallidus, which in turn, gives rise to the main outflow pathways. However, in addition some efferent paths leave the striatum directly, whilst the pallidum also receives other afferent connexions.

Afferent connexions to the striatum are derived mainly from the cerebral cortex, thalamus and substantia nigra.

Although their existence was for long in doubt, *corticostriate fibres* have now been shown to constitute a widespread system which is *topically organized* and converges from almost *all parts of the cerebral cortex* on to the caudate nucleus and putamen. The experimental animals used in these studies included rats, rabbits, cats and monkeys to which the degeneration techniques of Glees, Nauta and more recently, ultrastructural methods, have been applied (Glees 1944; Whitlock and Nauta 1956; Webster 1965; Carman *et al.* 1963; Carman *et al.* 1965; Kemp and Powell 1970). Jones *et al.* (1977), using the retrograde horseradish peroxidase technique, have demonstrated that the corticostriate projection in monkeys is derived from the smaller pyramidal cells of lamina V, distributed sparsely, but widely, in the sensorimotor areas and elsewhere in the frontal and parietal regions in the case of ipsilateral fibres, but only in areas 4, 6 and 8 in the case of contralateral connexions. Yeterian and Hoesen (1978), however, in contrast, used autoradiographic techniques in rhesus monkeys and obtained somewhat differing results. Following the intracortical injection of tritiated leucine or proline they demonstrated the interesting phenomenon that areas having strong reciprocal corticocortical connexions, both projected to common areas of the caudate nucleus. Thus, each part of the cerebral cortex projects to a specific part of the caudate-putamen complex, although some overlap occurs. Most of the projections are derived from the ipsilateral cortex only, but some regions receive bilateral projections from restricted regions of the sensorimotor cortices of both hemispheres. Since the details of corticostriate projection in these different mammals vary somewhat they will not be pursued further here; obviously they should not be extrapolated directly to the human brain, but it is most probable that broadly similar connexions exist. The most profuse projections are from the sensorimotor cortex, whilst the least prominent are from the visual cortex. Corticofugal fibres reach the striatum through both the internal and external capsules, and from the temporal lobe via sublenticular routes, whilst some of the direct and crossed corticocaudate fibres run with the *subcallosal fasciculus* in association with the fronto-occipital arcuate bundle of fibres. It is at present not clear what proportion of corticostriate fibres have

7.150B After median sagittal section of the brain, the left cerebral hemisphere has been dissected from its *medial* aspect to display the fibre bundles of the corona radiata and internal capsule. This entailed the removal of the cingulate gyrus and subjacent white matter, much of the paramedian corpus callosum and fornix, the dorsal thalamus, and the head and body of the caudate nucleus. The oval depression previously occupied by the dorsal thalamus can clearly be seen within the curved depression left after removal of the caudate nucleus. (Dissection by Dr. Andrew Seal, Dept. of Anatomy, Guy's Hospital Medical School, London.)

their principal terminations in these nuclei, or whether substantial numbers of them are collateral branches of other corticofugal systems, for example, the corticospinal tract. As mentioned above, the corticostriate fibres form type I synapses upon the dendrites and somata of the striatal neurons and thus, on morphological grounds, are probably excitatory.

Thalamostriate fibres form another profuse afferent system to the striatum and are derived from the nucleus centromedianus, various other intralaminar and midline nuclei, and also from the nucleus medialis dorsalis. Some of these fibres pass directly to the caudate nucleus to terminate there; others traverse the caudate, or skirt it, to reach the internal capsule, where they pass between its fibres to reach the putamen. The details of many of these connexions have not been satisfactorily resolved. The nucleus centromedianus has been claimed to project to many parts of the corpus striatum. Studies in the monkey (Powell and Cowan 1956), however, suggested that its projection was topically organized and confined to the putamen, whilst other investigators (Mehler 1966) claimed that its projection was to a band which included the whole mediolateral extent of both putamen and caudate nucleus. The intralaminar and dorsomedial thalamic nuclei are thought to project largely to the caudate nucleus.

Nigrostriate fibres, for long considered by some authorities to provide an important afferent system to the striatum and globus pallidus, although doubted by others, have now gained considerable prominence in relation to theories of the genesis of Parkinsonian tremor (Calne 1970). An increasing body of evidence, derived from electrophysiology (Purpura *et al.* 1967; Feltz and Mackenzie 1969; Connor 1968), neuroanatomy (Adinolfi and Pappas 1968; Nauta and Mehler 1969), and neuropharmacology (Calne 1970), not only supports the existence of such a pathway, but strongly suggests that its neurons, at least in part, utilize *dopamine* as their neurochemical transmitter (*vide infra*).

The *nigrostriate fibres* take origin from cells in both the pars compacta and pars reticularis of the substantia nigra. They ascend through the caudal subthalamus and reach the internal capsule, where separate bundles of nigrostriate fibres interdigitate with the capsular fibres, giving in histological section an appearance like a hair comb, hence the term *comb bundle* for this tract. Some fibres pass to the caudate nucleus, whilst the remainder continue on to reach the putamen and globus pallidus. Carpenter and Peter (1972) have identified degenerating terminals in parts of the caudate nucleus and the putamen following lesions of the pars compacta of the substantia nigra in rhesus monkeys; they have described a topological nigro-caudate relationship.

For further details of the brainstem origins and routes of the monoaminergic pathways to the striatum consult pp. 943–953.

Further afferents may reach the striatum from the subthalamic nucleus and other neighbouring cell groups, but these cannot be regarded as established.

Striatofugal connexions are mainly to the *globus pallidus*, but *striatonigral* and *striatothalamic* fibres, which retrace the pathways just recounted to reach the substantia nigra and thalamus, have also been described. Both the caudate nucleus and the putamen project in a topically organized manner on to the cells of the globus pallidus. The lateral part of the putamen projects only to the external segment of the globus pallidus, whilst the more medial parts of the putamen and the caudate nucleus project to either both segments of the globus pallidus, or to the internal segment alone.

Other striatofugal connexions have been described, but their status is less certain; these include projections to the subthalamic nucleus and to restricted parts of the inferior olivary nucleus.

Afferent connexions to the globus pallidus are principally the topically organized *striatopallidal fibres* from both the putamen and caudate nucleus described above.

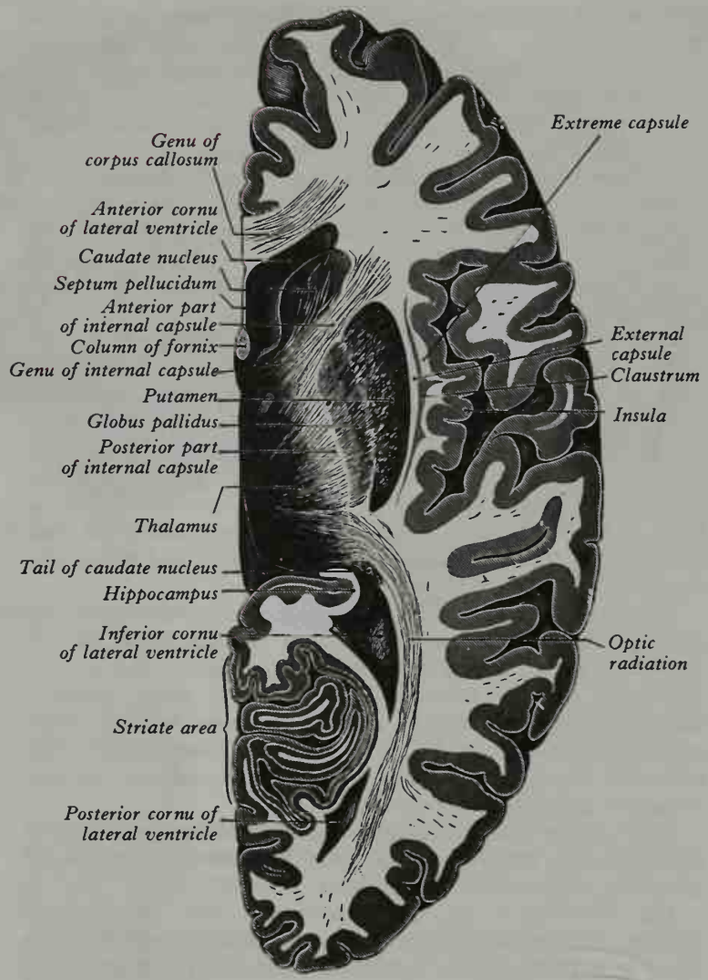
Other pallidal afferents include fibres from the subthalamic nucleus, substantia nigra, thalamus and cerebral cortex. The subthalamic fibres reach the globus pallidus (mainly pallidum I) as part of the *subthalamic fasciculus* (p. 965). *Nigropallidal fibres* have been described by a number of authors as part of the comb bundle mentioned above. The neurons forming this tract are dopaminergic, but it is uncertain whether nigrostriate or nigropallidal fibres predominate in the *human* brain. In addition to the extensive, well-organized corticostriate projection mentioned above, some investigators have described fibres which accompany these from many parts of the cerebral cortex, but terminate directly in the globus pallidus. *Thalamopallidal fibres* may also reach the pallidum from the intralaminar, centromedian and dorsomedial nuclei of the thalamus. It must be emphasized, however, that these somewhat variable results have been obtained with different methods in a number of experimental animals, and the existence of some pathways, and the destination to specific parts of the pallidum of others, have not yet been established in the human brain.

The pallidofugal system constitutes by far the quantitatively most important outflow from the corpus striatum. The fibres are thick and well myelinated, and they form a topographically complex series of pathways which diverge to a number of destinations. The main pathways involved include: (1) the *ansa lenticularis*; (2) the *fasciculus lenticularis*; (3) the *fasciculus thalamicus*; (4) the *fasciculus subthalamicus*; and (5) *descending fibres*. The topography of these tracts was described and illustrated (7.102) with the subthalamus (p. 963) and will not be repeated here.

The main destinations of the pallidofugal fibres are to: (1) the *thalamus*, mainly the *nucleus ventralis anterior*, with smaller contributions to the nuclei ventralis intermedius and centromedianus; (2) the *subthalamic nucleus* and other, smaller, subthalamic centres which include the zona incerta, entopeduncular nucleus and the nucleus of the prerubral field; (3) the *substantia nigra*; (4) the *red nucleus*; (5) the *midbrain reticular formation*; and (6) the *inferior olivary nucleus*.

Illustration 7.156 summarizes some of the main connexions of the basal nuclei based on an analysis by Webster (1975) which the interested reader should undoubtedly consult.

The following points should also be noted. The external segment of the pallidum projects on to the internal segment, from which most of the pallidofugal fibres originate. The fibres to the subthalamic nucleus, however, arise mainly from the external segment. For long, a *pallidohypothalamic tract* appeared in most accounts of the corpus striatum, but more recent studies using the newer degeneration techniques offered no conclusive evidence that fibres project directly from the globus pallidus to hypothalamic nuclei. The tract described pursues an aberrant course which curves around the column of the fornix; thereafter the majority of its fibres rejoin the main pallidal outflow.



SUMMARY AND FUNCTIONAL STUDIES

Clearly, the corpus striatum and its associated regions of the nervous system constitute an exceedingly complex set of interconnexions, but their details and our understanding of their function role is still elementary.

Broadly, information *converges* on the corpus striatum from most of the cerebral cortex, the thalamus, subthalamus and a number of brainstem centres. After integration within the corpus striatum, information *diverges* again to the thalamus, subthalamus and the various brainstem centres listed above.

For long it was held that the main outflow from the corpus striatum, as part of the classical 'extrapyramidal motor system', *descended*, through various indirect polysynaptic pathways, to the lower motor centres. Whilst such descending pathways as the reticulospinal and rubrospinal tracts undoubtedly carry information derived in part from the corpus striatum, it is increasingly clear that the most prominent outflow from the corpus striatum is to the *nucleus ventralis anterior* of the thalamus (p. 958), where, after integration with other channels, *ascending* pathways radiate to the *motor and premotor areas* (areas 4 and 6). Equally important reciprocal interconnexions are established with the *subthalamic nucleus* and *substantia nigra*.

An impressive list of organic nervous diseases has long been known to affect, in varying measure, the different parts of the corpus striatum and their associated nuclei and fibre pathways. These cannot be reviewed here, and the reader should consult texts devoted to clinical neurology and neuropathology. Briefly,

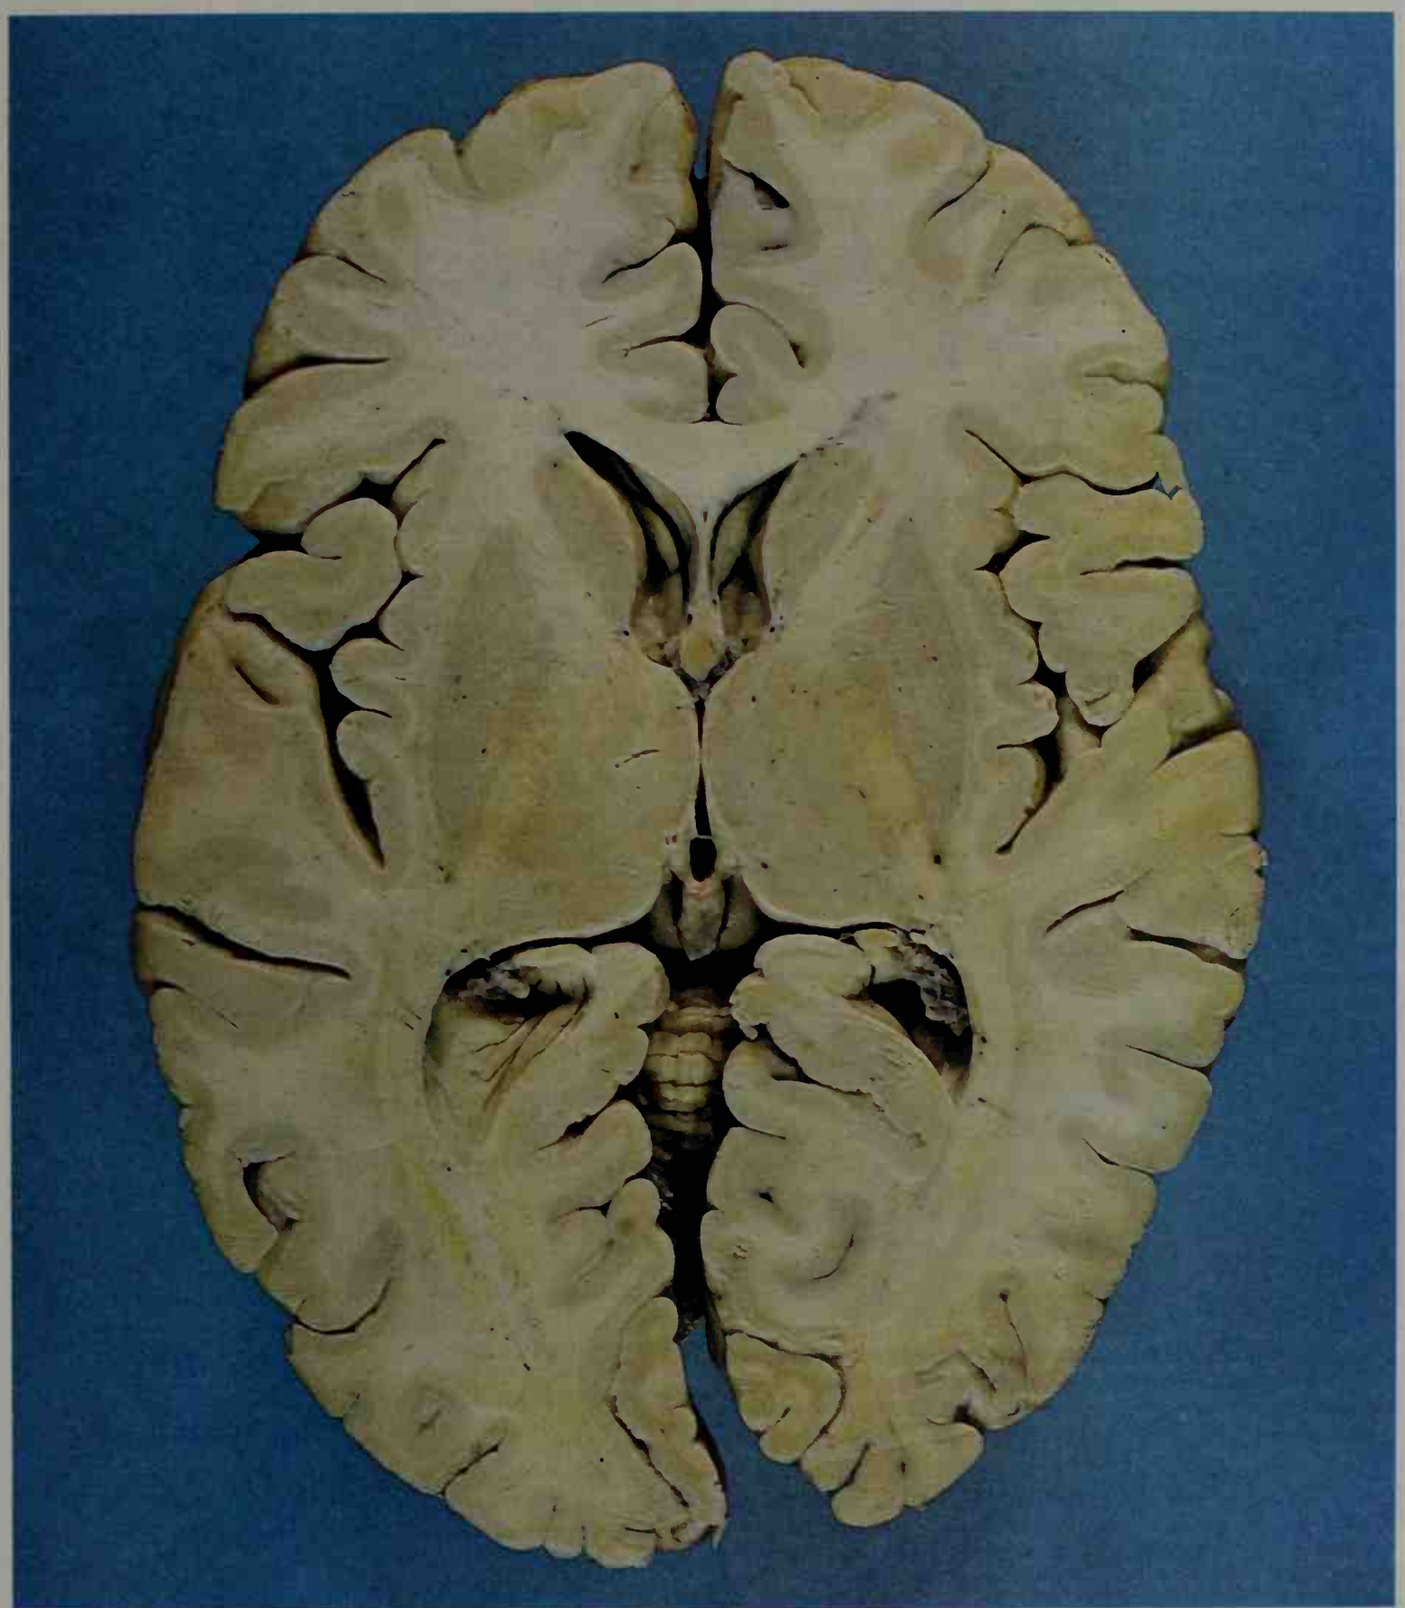
7.151 Superior aspect of a horizontal section through the right cerebral hemisphere.

in different forms and combinations, these various disease states usually present: (1) *disturbances of muscle 'tone'* or resistance to stretch; sometimes this is reduced, but more commonly some form of *rigidity* is present; (2) diminution or *loss of automatic associated movements* such as arm-swinging during walking, facial expression, etc.; (3) the presence of *unwanted movements* which are uncontrollable and purposeless; these may be *choreiform*, *athetoid*, or *ballistic* (p. 964), or they may take the form of a *tremor* resulting from the fairly rapid alternating contraction of opposing muscle groups. The tremor is usually 'static', that is, present when the limb is otherwise at rest, but occasionally an *intention tremor* is present as in some forms of cerebellar dysfunction (p. 929). Attempts to link the various combinations of symptoms and signs with disease in specific locations have met with limited success. Similarly, experiments with animals have often been uninformative.

Ablation of the putamen, the caudate nucleus, or the globus pallidus, often causes little obvious change in motor behaviour, provided the lesions do not affect surrounding structures. Complete ablation of the globus pallidus on both sides in the monkey, however, results in a general poverty of movement and a reduction in manipulative skills.

Rapid stimulation of the caudate nucleus in unanaesthetized animals sometimes elicits movements of the head and limbs, and some evidences of a somatotopic pattern in the nucleus have been adduced. Low-frequency stimulation, or chemical stimulation, at different points in the corpus striatum, however, usually results in an inhibition of motor responses. It may induce long periods of immobility, an inhibition of cortically induced movements, or 'arrest reactions' in the unanaesthetized animal. Confirmation of this has been obtained by electrophysiological 'unit' recording from the motor cortex and the ventrolateral thalamus—inhibition of unit activity followed stimulation of the caudate nucleus. Other experiments have demonstrated the inhibition of responses which had been established by learning processes, following caudate nucleus stimulation.

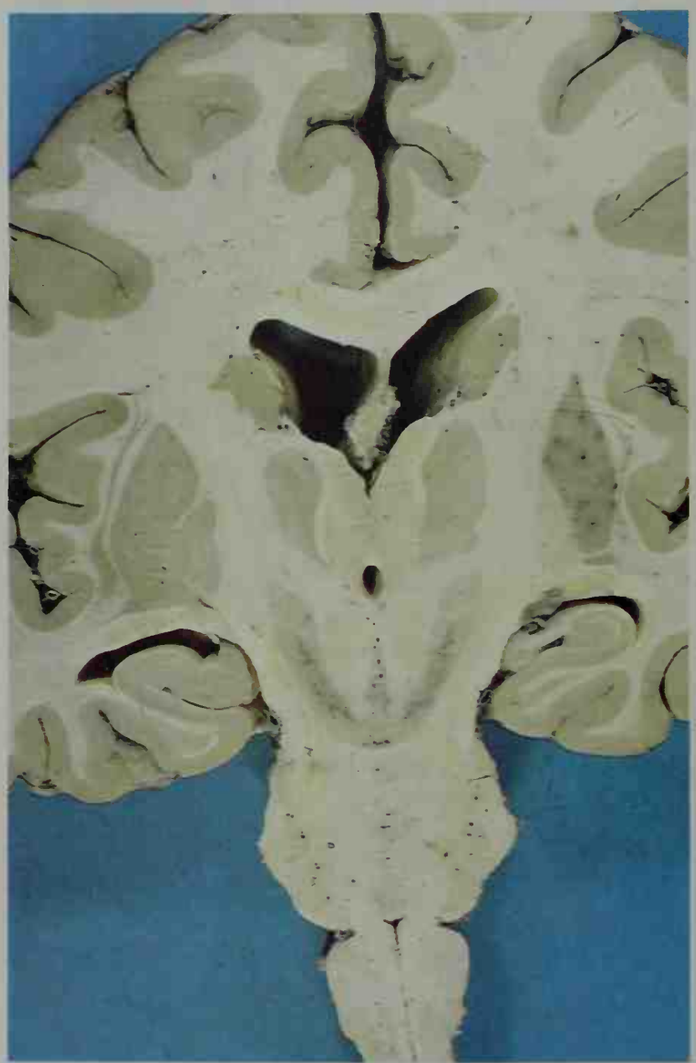
Neurosurgical ablation of the globus pallidus or ventrolateral thalamus has been used, often with considerable success, to diminish contralateral rigidity and tremor in human disease. Thalamic ablations seem more effective in the relief of tremor (including cerebellar tremor) whilst pallidal lesions have a greater effect in reducing rigidity. In addition to their therapeutic value, such manœuvres provide a source of material for histopathological and neuropharmacologial study and also allow electrophysiological recording to be carried out. Most interesting in this regard has been the identification of neurons in the ventrolateral thalamus in cases of Parkinsonian tremor, which show a repetitive, rhythmical discharge of impulses, the frequency of which corresponds to that of the tremor (Guiot *et al.* 1962; Guiot *et al.* 1964; Jasper 1966; Bates 1969). Similar findings have been induced experimentally by placing brainstem lesions in the monkey. Intensive experimental analysis involving anatomical, physiological, behavioural and pharmacological methods is now in progress attempting to define the causal mechanism of the rhythmic neuronal discharges. Much interest has been aroused by the demonstration of an *inhibitory dopaminergic nigrostriate pathway* which is probably involved in a proportion of cases of Parkinsonian tremor (Calne 1970). Of the various possible mechanisms proposed, it is currently considered most likely that normal striatal function depends upon a balance between the inhibitory afferent pathway just mentioned, and excitatory afferent pathways which are cholinergic. Reduced activity in the inhibitory pathway leads to an excessive excitatory output from the pallidum, which in turn leads to oscillating bursts of activity in ventrolateral thalamic neurons. Finally, the latter through their cortical radiations are thought to generate rhythmical activity in the various corticofugal descending pathways to the lower motor centres. On this view, dopamine is a normal neurotransmitter in the striatum; there is a considerable body of evidence to show that dopamine levels in the striatum are reduced in many cases of Parkinsonism, and this is paralleled by the encouraging clinical responses to replacement therapy in a substantial proportion of patients who have been given L-dopa, a precursor of dopamine.



Despite this dramatic progress in the pharmacological and clinical sphere, however, beyond the long-held view that the corpus striatum is intimately involved in motor control, and the displacement of emphasis from descending pathways to a control of the cerebral cortex by this region of the brain, its precise role in normal behaviour remains conjectural. (For an excellent 'non-clinical view of the structure and function of the basal nuclei' and an extensive bibliography consult the stimulating paper by Webster 1975.)

The claustrum is a thin sheet of grey matter coextensive with the insula and the putamen of the lentiform nucleus, from which it is separated by the fibres of the external capsule. It is thickest below and in front, where it becomes continuous with the anterior perforated substance, the amygdala, and prepiriform cortex. It has been regarded by some authorities as belonging to the corpus striatum and by others as a detached portion of the insular cortex. However, more detailed studies suggest that it probably consists of at least two structurally and functionally distinct zones. These have been termed the '*insular*' *claustrum* and the '*temporal*' or '*prepiriform*' *claustrum* respectively. In experimental animals the insular part of the claustrum has been shown to possess reciprocal, topically organized *corticoclaustral* and *claustrocortical* connexions with many regions of the neocortex. Its detailed connexions and functional significance are unknown in the human brain.

The external capsule is a thin layer of white matter which is interposed between the lateral aspect of the lentiform nucleus and the claustrum. The fibres of the external capsule are derived from the frontoparietal operculum of the insula and, after passing across the lateral surface of the lentiform nucleus, they turn medially below the nucleus and the ansa lenticularis. Their subthalamic connexions are uncertain. Some of the fibres of the anterior commissure are believed to traverse the external capsule.



The Choroid Plexus of the Lateral Ventricle

Projecting into the lateral ventricle on its medial aspect is a highly vascularized fringe composed of pia mater and of the ependymal lining of the cavity (7.157, 158). This is the choroid plexus of the lateral ventricle, which is itself only part of a larger structure, the *tela choroidea*, to be described below. The pial basis of the choroid plexus is invaginated during development (p. 169), over a linear region of the medial wall of the hemisphere where no nervous tissue develops. The pia therefore comes into direct contact with the epithelial lining of the ventricle, the *ependyma*, and the two tissues are fused in the structure of the choroid plexus, which otherwise consists chiefly of small blood vessels, capillaries and nerve fibres. The plexus extends anteriorly to the interventricular foramen, where it is continuous across the third ventricle with the choroid plexus of the opposite lateral ventricle. From this point it passes posteriorly above and in contact with the thalamus (7.144) to curve round its posterior end into the inferior cornu of the ventricle, reaching as far as the pes hippocampi (7.147). When the choroid plexus is torn away from the hemisphere, the line of its

7.152 A horizontal section through the brain including the frontal and occipital poles of the cerebral hemispheres. Features appearing in this section are discussed at many points throughout the text. For appropriate labelling compare with 7.151. (Dissection by Dr. E. L. Rees, Dept. of Anatomy, Guy's Hospital Medical School.)

invagination appears as a narrow cleft, the *choroid fissure*. Through the main part or body of the ventricle the fissure is limited superiorly by the fornix and inferiorly by the thalamus (7.157); in the inferior cornu it is between the stria terminalis above and the fimbria (7.158). The choroid fissure is the first groove to appear on the surface of the cerebrum (p. 170). In coronal sections of the brain at eight weeks of embryonic development it can already be seen that the choroid fissure is in direct contact with the ependymal roof of the body of the lateral ventricle, and that vascular pia mater becomes folded into the fissure. At this stage, before the development of commissures and expansion of the lamina terminalis, only one layer of pia mater extends over the roof of the third ventricle (2.86A). When the corpus callosum expands posteriorly it does so above the level of the choroid fissure, carrying with it a layer of pia on its inferior surface. This overlies the original single pial layer, fusing with it to form the main part of the tela choroidea, lateral extensions of which, also double layered, form the two choroid plexuses in the lateral ventricles. Posteriorly the two layers separate, the inferior (original) layer following the roof of the third ventricle to reach the pineal gland and the tectum, the superior cleaving to the corpus callosum and passing round the splenium to the superior surface of the former (8.195).
